of the aqueducts after their emergence. The arches of the Claudia and Anio Novus gradually increase in height from Capannelle to Roma Vecchia, until beyond it they reach their greatest elevation in this section, estimated by Lanciani at 27.41 metres.* In this stretch they are extremely well preserved and have not required restoration to any considerable extent. The lower stone channel of the Claudia is surmounted by the concrete specus of the Anio Novus, faced with brick and *opus reticulatum*—an obvious afterthought, the detrimental effects of which we have already seen.

Further on, as we come nearer to the city, considerable reinforcements have become necessary. In many places the original stonework of the piers has been removed for building material, and Lanciani quotes the records of the sale of, e.g., two or four peperino pillars by the Hospital of Sancta Sanctorum at the Lateran, to whom the ground belonged. But, as he also points out, sometimes the brickwork was removed and the stonework left; or, again, the brick facing is sometimes hammered away from the concrete.

The question as to the amount of water carried by the aqueducts depends upon the value given to the *quinaria*, the official unit of measure, explained by Frontinus, who, as *curator aquarum* under Trajan, wrote a treatise upon the aqueducts. The most probable value* has recently been determined as 0.48 litre per second or 41.5 cubic metres in twenty-four hours; and we thus get the following table:

	Quinariae (Frontinus).	Litres per second.	Cubic metres per diem.
Anio Novus	4738	2274	196,627
Claudia	4607	2211	191,190
Marcia	4690	2251	194,365
Anio Vetus	4398	2111	182,517

There were no large clearing or settling tanks within the city, only comparatively small reservoirs (*castella*) from which distribution was made by lead pipes; and this is the case with the modern aqueducts also, so abundant is the supply.

The Romans, as we have seen, having at their disposal comparatively little theoretical knowledge of mechanics, they yet succeeded in achieving marvellous results, largely from their practical ability. They must have solved such problems as the transportation of an obelisk by the multiplicity of simple elements of traction employed and by the ingenuity displayed in their arrangement. When it is a question of sea transport, we cannot but admire the courage of those who succeeded in bringing such huge masses of stone through the Mediterranean from Egypt to Italy without the aid of steam—an even greater enterprise than dragging them along the land without the appliances that we now have at command. The study of practical engineering among the Romans shows us that in this, as in other spheres, they added very considerably to the sum of human achievement, and thus contributed in no small measure to make the condition of the human race what it is.

The Science Museum, South Kensington.

WORK has just been commenced on the eastern portion of the new Science Museum buildings in South Kensington, and by the spring of 1927 a handsome façade (Fig. 2) should have replaced the

plastered brickwork which has stood on the west side of Exhibition Road since the War.

Behind this east face, however, much has already been done, and a series of galleries on each of the four floors have been completed during the past three years to replace the Western Galleries on the north side of Imperial Institute Road, which were transferred to the Imperial War Museum in 1922. With the completion of the eastern front, which includes four galleries facing Exhibition Road, the first portion of the new Science Museum buildings will have been provided, following the recommendations of Sir Hugh Bell's Committee of 1911.

This Committee recommended¹ that the existing buildings, which had been originally erected for the refreshment rooms of the Exhibition of 1862, should be replaced by three main blocks with connecting galleries, to be erected on the existing site and to extend ultimately from Exhibition Road to Queen's Gate between the Natural History Museum and the Imperial College of Science. The eastern block, which is now nearing completion, will provide 100,000 sq. ft. of exhibition space, and so much of the connecting galleries as are in use, though not completely finished,

G.C. = Galleries connecting Science & Geological Museums.

FIG. 1.—Plan of museum buildings, South Kensington.

¹ H.M. Stationery Office, Cd. 5625 and 6221, 1911, 1912.

brings the total up to 135,000 sq. ft., or about one-third more than was available in 1912; but since then it has been necessary to allot more than 20,000 sq. ft. to the aeronautical collection and to that which illustrates wireless telegraphy and telephony. Up to the present, therefore, the exhibition space which will shortly be available is only about half of what the Committee of 1911 considered to be immediately necessary, so that the construction of another block, to provide about 110,000 sq. ft., is already an urgent need, and this would bring the available accommodation about up to the Committee's recommendation; the old buildings which it would replace are constructed with wooden floors, staircases, etc., so that the risk of fire in them is great, and should a conflagration occur, practically nothing of the important naval and shipping collections which they now contain could be saved.

The provision of the third block, which will face Queen's Gate, would, in the opinion of the Committee,

lines of a storehouse of all that relates to advance in science and technical industry, would require accommodation far in excess of that which is likely to be available. The policy, therefore,² which has been adopted is to show for each group such a critically selected series of objects as will illustrate all important stages in the development of a group, and to exhibit also a number of examples to represent the current practice of to-day. But even this is difficult with the existing accommodation, and several groups are still inadequately represented.

In the series which illustrate historical development, examples of early mechanical and scientific apparatus which have been designed, constructed, or used by pioneers in various branches of science and technology are not only of great historical interest, but are also most stimulating to those who visit the Museum and study its collections. Among the more recent acquisitions several are of this kind, for example, the

FIG. 2.—The Science Museum, South Kensington, when completed.

be needed later for the development of the collections or in consequence of an extension of the scope of the Museum, but not for several years.

For the present, the galleries in the eastern block which have been completed are being utilised to accommodate the collections which were exhibited in the galleries now occupied by the Imperial War Museum, that is, those illustrating physical science, mining and metallurgy, and some which have been long in store for lack of exhibition space; others have been moved there to allow more space for the aeronautical collection which is being developed rapidly. But in every case only a selection from each collection can be exhibited, since the space which is or shortly will be available is insufficient to do more than this.

The scope of the Science Museum as formulated by the Committee of 1911 is "to afford illustration and exposition of the various branches of Science within its field, and of their applications in the arts and industries," which is a very wide definition, as it includes the illustration of current practice as well as the preservation of objects of historical interest; so wide indeed is it that to develop the Museum on the

contents of James Watt's workshop, Henry Maudslay's screw-cutting lathe of 1810, Hughes' microphones of 1878, Prof. Fleming's thermionic valves (1889-1904), and early wireless apparatus lent by the Marconi Co. These and many others furnish starting-points of special interest from which history of the groups to which they belong can be studied.

In various parts of Great Britain there must be many other objects of a similar character which might be with advantage presented or lent to the Museum for exhibition, if only to guard against the risk of them passing into the hands of those who may be ignorant of their historical importance and may therefore dispose of them, when they are usually lost sight of. The historical value of what has already been lost to the history of science in this way is incalculable.

The present arrangement of the collections is only temporary, being determined by existing conditions, and by the need for exhibiting the science collections which have been for the most part stored during the past three years. When another block of the new

² Report on the Science Museum for the year 1923 H.M. Stationery Office, 1924.

buildings becomes available, more satisfactory arrangements can be made, and collections which can now only be shown in part will be more adequately represented.

The ground floor contains the more important objects illustrating prime movers, and locomotive

his machines, tools, etc., as they were at his death in 1819; its position within sight of three of the engines designed by him and built at Birmingham towards the end of the eighteenth century is especially appropriate.

The rest of the ground floor, the west gallery which is to connect the eastern with the centre block, contains part of the collection illustrating aeronautics. Here are models of the early machines of Henson and Stringfellow, Wright's aeroplane of 1908—the gliders of Lilienthal, Chanute, and Weiss, Maxim's flying machine and other objects illustrating the pioneer period of aviation. A collection of some fifty aeroplane models shows the strikingly rapid development of the heavier-than-air machine during the War, culminating in the Vickers-Vimy Rolls-Royce plane which was flown across the Atlantic by Sir John Alcock and Sir Arthur Brown in 1919. A large collection of aero-engines, many of them sectioned, is also shown here. The aeronautical collection has now extended into two adjoining rooms of the old buildings, where the structure of aircraft is illustrated; Roe's interesting triplane of 1907 is also here. Aeronautical instruments of all kinds are shown in the wall cases.

The aeronautical collection includes that of the Imperial War Museum, which has been lent by the trustees of that institution, and the combined collections form an exhibit of air transport which is more complete

FIG. 3.—North hall, ground floor, Science Museum, South Kensington. Locomotive Collection.

engineering. Six early pumping and rotative engines of great historical interest are placed on either side of the main hall, the atmospheric engine from Pentrich Colliery (1791), the Old Bess pumping engine by Boulton and Watt (1777), and Heslop's beam engine (1795) on the left, with Boulton and Watt's rotative engines of 1788 and 1797, together with a rotative beam engine of about 1820 on the right. Models of the principal types of stationary engines occupy the wall cases, while others of windmills, water power installations, etc., are in the south gallery. Such internal combustion engines as are not shown in connexion with aeronautics or motor transport are also exhibited here. On the north side of the floor, the four early locomotives, the *Puffing Billy*, the *Agenoria*, the *Rocket*, and the *Sans Pareil*, are arranged down the centre of the north hall, with models of many other types of locomotives on either side (see Fig. 3). This gallery was originally designed for special exhibitions in which various groups would be shown more fully than could be done in the normal collections, but this use of it has to be postponed until the locomotives can be accommodated elsewhere. At the end of this hall is the reproduction of James Watt's attic workshop at Heathfield, Birmingham, showing all

FIG. 4.—Centre gallery, first floor, Science Museum, South Kensington.

and important than any other in existence; the full-size planes and some other of the larger exhibits have for the time being to be placed in the basement, where they are available to visitors, but it is hoped that later on the collection may be shown as a whole.

The first-floor galleries will before long be connected

by a bridge with the new Geological Museum which is about to be built alongside the Science Museum to receive the collections which are now in Jermyn Street, and the Office of the Geological Survey. In these galleries, therefore, so much of the collections illustrating mining, ore-dressing, and metallurgy are being arranged as can be shown there (Fig. 4). The north gallery on this floor will contain the valuable collection of textile machinery which has been in store for several years. Tools and machine tools are shown in the western cross gallery, where the development of certain selected tools, such as the axe, drill, hammer, etc., from the times of the earliest civilisations to the present day, form interesting and instructive exhibits. In the gallery which connects this floor with the old buildings, the collections of electrical engineering and of telegraphy, telephony, and radio communication are being arranged.

The upper floors of the eastern block are being utilised for the exhibition of the collections of scientific apparatus, which were formerly in the galleries on the north side of Imperial Institute Road. Of these the following are being arranged on the second floor: mathematical, electrical, thermal, and acoustical instruments, while the north gallery will contain the geophysical collections of meteorology, seismology, gravity instruments, and terrestrial magnetism. In the western gallery, which will later on connect this floor with the centre block, will be the collection of pumps, and also that which illustrates engineering construction, and certain aspects of municipal engineering which are

now being developed. On the third floor the collections of astronomical and optical instruments will be shown, as well as those illustrating geodesy, surveying, cartography, geography, and oceanography, so far as the space allows. The western gallery of this floor has been allotted to chemistry and industrial chemistry, and these collections are being actively developed.

The naval and marine collections will still remain in the old buildings (the southern galleries). Many additions have recently been made to these, especially in the section of boats and small craft. Mechanical road transport will shortly be arranged in the western hall near to the Imperial Institute Road entrance.

The great superiority of the new galleries in their arrangements, the lighting, and generally in the facilities for exhibiting the collections to the best advantage, will be apparent to every visitor. The wall cases do not extend to floor level but stop at a height of 2 ft. 6 in. from it and are carried up to a height of 7 ft. By this means the whole of the contents are comfortably within the visitor's view, and the ineffective display of objects at ground level is avoided (Fig. 4). Channels in the floors carry electricity, compressed air, and gas to all the galleries for use in the demonstration models, and the number of these which are shown in motion or which can be operated by the visitor is being largely increased. Seating accommodation for visitors has not been overlooked, and the need of students in this respect who may wish to examine objects in detail, and to make notes, has been met by placing portable stools in each gallery.

Obituary.

SIR FRANCIS DARWIN, F.R.S.

A SON who follows a famous father is apt generally to find himself in somewhat of the position of a sequel to a very popular romance, and that Francis Darwin stands prominently forth in the light of his own achievements is enough to show that in him we possessed a man of great distinction. Whilst he will probably remain best known as the author of his father's *Life*, much of his work in other lines has borne fruit. But to those who had the privilege of his friendship, he will always be a living memory on account of his very human personality, his great kindness of heart and ready sympathy, and his extraordinary personal modesty. The writer well remembers his astonishment, when first attending Darwin's lectures, at his frequent confessions of ignorance (shared, of course, even if not admitted, by all other physiologists) upon this or that point that was under consideration. This, though to-day a more common frame of mind, was less customary at that time, when the teacher usually strove to make a more or less completely rounded presentation of his subject, avoiding the unknown or the little understood so far as was conveniently possible.

Educated at Clapham Grammar School and at Trinity College, Cambridge, where he obtained a first class in the Natural Sciences Tripos, Darwin afterwards went to Würzburg to study under Sachs, as did so many of our most capable men at that time. He afterwards graduated in medicine, but never practised.

Francis Darwin's earliest published paper appeared in 1872, during the time of his medical study at St.

George's Hospital. It was a conjoint paper with the prosector at the Zoological Society's Garden, describing the anatomy of an ostrich which died of copper poisoning through the ingestion of "two pennies and fifteen halfpence." Then followed in 1876 the publication of his M.B. thesis on the causation of vascular dilatation in acute inflammation, which records experiments carried out under Dr. E. Klein at the Brown Institute in London.

During the next few years Darwin worked at Down, where for eight years he acted as his father's secretary, and assisted him in much of his work. More especially was this the case in Charles Darwin's researches into the movements of plants, the well-known book upon this subject appearing in 1880 under the joint names of Charles and Francis Darwin. Two years later the latter was elected a fellow of the Royal Society, and when his father died in the following year he removed to Cambridge, where, except for occasional absences in London and elsewhere during recent years, he resided during the remainder of his life, at first in one of the houses of the well-known "Darwinery" on the Huntingdon Road, and afterwards at 10 Madingley Road.

University lecturer in botany from 1884 until 1888, and reader from 1888 until 1904, Francis Darwin had much to do with the complete reorganisation of the Botany School that then went on, especially when from 1892 until 1895 he was deputy for Prof. Babington. He devoted the stipend to the improvement of the teaching in various departments of the subject, while he himself

gave his time to teaching and research in vegetable physiology. The results of his experience in this direction appear in the well-known manual of "Practical Physiology of Plants" by himself and the late E. H. Acton, published in 1904; and he also brought out a stimulating work upon the "Elements of Botany," designed for the medical course in elementary biology. Though not what would be called an eloquent lecturer, Darwin always aroused great interest in the subjects that he taught, and by his great kindness of heart, by his clear understanding of the difficulties of a student, and by the minute and painstaking care that he devoted to their explanation, he won the affectionate esteem of many generations of undergraduates.

During this period Darwin published his first paper on the transpiration of plants, and so entered the field which was to include his major experimental work. In this paper, with R. D. Phillips (1885), he introduced his own particular form of the potometer for measuring the rate of uptake of water by a cut shoot so expeditiously that several readings might be taken within a minute. In 1893 there followed an attractive piece of work upon the growth of large gourd fruits, recorded by a weighing mechanism designed by his brother Horace Darwin. This demonstrated the extent to which the fruit, on the plant, might actually lose weight when the leaves associated with it were transpiring water actively. In 1897 he described a quite new instrument—the horn hygroscope—for investigating the rate of transpiration from living leaves. This ingenious device made use of the strong curvature of a shaving of horn when one side is exposed to more humid air than the other. It can be applied to leaves on the plant with the minimum of disturbance; and Darwin's big paper of 1898, entitled "Observations on Stomata," contains an extensive study of the effect of external conditions on the rate of transpiration made with this hygroscope.

In 1911, in association with Miss D. F. M. Pertz, Darwin described yet another simple instrument for studying transpiration. His porometer measures, not the water vapour given off from the leaf, but the openness of the stomata, since it determines the rate at which air can be drawn through the pores of the stomata under a standard suction. It can be attached to leaves upon the plant; and it has been widely used by subsequent investigators.

The other field of physiology in which Darwin specialised may be considered as an extension of his early studies at Down on the movements of plants. He published a certain amount of experimental work in support of the localisation of sensitiveness to the factors producing curvature of growing organs, and he was a staunch exponent of the statolith theory of "geo-perception."

Darwin's greatest service to science, perhaps, was the "Life and Letters of Charles Darwin," a biography which may rank with the best that have ever been written. It gives the clearest possible picture of Charles Darwin as a man and as an enthusiastic student of science, tracing in a masterly way the gradual development of his views upon evolution and upon other subjects, while at the same time keeping the actual author of the work in the background, and leaving his character to be traced only from the general style, and the occasional references in letters. A con-

tinuation, or expansion, of this work was later published as "More Letters of Charles Darwin" by Francis Darwin and A. C. Seward.

President of the British Association at Dublin in 1908, Darwin devoted his address to the subjects of his own researches, especially bringing forward his since little accepted hypothesis of unconscious memory or habit in the development of plants and their movements. He received honorary degrees from his own University and also from St. Andrews, Dublin, Liverpool, Sheffield, Brussels, Upsala, and Prag. He served twice upon the Council of the Royal Society, and was its foreign secretary from 1903 until 1907, and vice-president 1907-8. He was knighted in 1913. A keen musician, and a kindly host with a strong sense of humour, Darwin was regarded with affectionate respect by great numbers of people.

MR. F. J. BRODIE.

MR. F. J. BRODIE, who entered the Meteorological Office in April 1869 and retired in December 1919, after fully fifty years' service, died on August 29 in his seventy-third year. He was principal forecaster for many years, and was essentially a forecaster of the old type, basing his predictions strictly on past experience, with a thorough grip of weather changes and their controlling features, whereas the present-day forecasters work on a somewhat more strictly scientific basis.

Mr. Brodie was for many years an active fellow of the Royal Meteorological Society, and he contributed numerous papers to the Quarterly Journal of the Society, dealing chiefly with fogs and gales; "Prevalence of Fog in London, 1871-1890," and "Prevalence of Gales over the British Isles, 1871-1900," being of especial importance. He was a prolific worker and writer, communicating regularly to *Symons's Meteorological Magazine*, now the *Meteorological Magazine* issued by the Air Ministry. He was the principal forecaster throughout the War, the period involving much responsibility, and the especial duties required were at times ill supplied with necessary meteorological data, and under such conditions Mr. Brodie's long training and experience were of the utmost value. He continued his official position until two years after the age limit. Mr. Brodie's health failed considerably during the last two or three years of his life. He was greatly respected by his colleagues, and many who were associated with him in the early days of the Meteorological Office, as well as those working with him in more recent years, can testify to his amiability of character and his willingness at all times to help forward the development and better understanding of meteorology.

WE regret to announce the following deaths:

Prof. A. A. Friedmann, Director of the Central Geophysical Observatory of Russia, on September 16, aged thirty-seven years.

Prof. Andrew Gray, F.R.S., emeritus professor of natural philosophy in the University of Glasgow, on October 10, aged seventy-eight years.

Dr. C. F. Sonntag, prosecutor to the Zoological Society of London, on October 10, aged thirty-seven years.

Current Topics and Events.

THE City of Gloucester proposes to commemorate the achievements of Sir Charles Wheatstone, the practical founder of telegraphy, by placing a bronze memorial tablet on one of its public buildings. This will be unveiled by Sir Charles Sherrington, president of the Royal Society, on October 19, which is the fiftieth anniversary of Wheatstone's death. To electricians, Wheatstone will long be remembered as the perfecter of the "Wheatstone bridge" which they use in their everyday work. In 1867 he described the self-exciting, shunt wound dynamo. They remember him also as the pioneer of the electric telegraph. So far back as 1837, in conjunction with Sir William Cooke, he made the electrical transmission of messages an assured success. In 1844 he conducted some of the earliest experiments in submarine telegraphy. To physicists Wheatstone is well known by the use he made of a rotating mirror to detect whether an electric discharge was oscillatory or not. He made valuable researches in sound, particularly in connexion with Chladni's figures and for his experiments on the prismatic decomposition of the electric light. In 1837 he made the important discovery that sparks between metals gave distinctive spectra. Wheatstone had a marvellous gift for interpreting documents printed in cipher. He deciphered with apparently little difficulty an important document sent him by the Trustees of the British Museum. He invented the Wheatstone's cryptograph, which is one of the most successful devices for rapidly coding and decoding secret messages. The ordinary English concertina was invented and patented by him in 1829. He was a professor at King's College, London, for many years and bequeathed to it all his scientific library and apparatus. This bequest was added to by his family and also by the Physical Society of London. An article on his connexion with the growth of telegraphy was published in *NATURE*, vol. II, p. 510 *et seq.* It is interesting to remember that Oliver Heaviside, whose death we had recently to deplore, was his nephew.

DR. ALEŠ HRDLÍČKA in the course of his lecture on "Early Man" before the Royal Anthropological Institute (see *NATURE*, October 10, p. 557) expressed a fear that the important work on the fossil apes of the Siwalik Hills might not be continued. In a statement published in the *Times* of October 7, Dr. Pilgrim, director of the Geological Survey of India, stated that although the Geological Survey in a country like India must be subservient to economic requirements rather than to those of pure science, there is at present an exceptional opportunity for combining the two, owing to the discovery of oil in the fossiliferous deposits of the Punjab. This statement will reassure those in Great Britain who are interested in the advancement of science, as they have regarded recent developments in India with some apprehension, lest changing conditions may lead to a neglect of those branches of research in which immediate advantage is not always apparent. The danger of the neglect of opportunity which Dr. Hrdlička feared in India

is also very real elsewhere. He referred to the material, possibly of priceless value to science, which is being lost beyond recovery in Java on the site of the discovery of *Pithecanthropus erectus*. According to information which has been received from Australia, the situation there also has some disquieting elements. It is stated that under recent regulations all skeletal remains of aborigines which may be discovered there have to be deposited in local museums. It is therefore impossible for specimens to be sent out of Australia for study by anthropologists elsewhere. This, though serious enough, might be regarded as a not entirely unreasonable requirement on the part of the Australian authorities if there were some assurance that these remains would be carefully preserved and stored, their provenance recorded, and that after careful study the data to be obtained from them were published and made accessible to other workers. Apparently, however, this is not the case. It is surely incumbent upon scientific workers in Australia to see that provision is made for this to be done. It should certainly be taken into account when an appointment is made to the recently founded chair of anthropology.

SOME interesting particulars have reached us of an exhibit which has been arranged in the new house at the Royal Botanic Gardens, Kew, for the display of plants of special interest. One portion of the exhibit shows various examples of phyllodes and phylloclades illustrated by different species of Acacias, which, instead of the normal leaves, have the leaf petiole flattened and leaf-like. The leaves proper are usually only seen in seedling plants, the green leaf-like organs of the mature plants being entirely flattened petioles. This condition of affairs is also exhibited by *Oxalis bupleuroides*, and in this case the three normal leaflets may be seen at the tips of the phyllodes. In some other plants the leaf-like organs are flattened shoots, and these are illustrated by the common Butcher's Broom, *Ruscus aculeatus*, and by *Semele androgyna*. These phylloclades or flattened branches are also shown by species of *Asparagus*, *Carmichaelia* and *Phyllocladus*. Other plants displayed in this house show examples of "parallel development" in plants belonging to unrelated natural families. Those which have assumed an Ericoid habit with leaves of a heath-like character are shown by a heath, by *Fabiana*, one of the Solanaceæ, by *Gamolepis*, one of the Compositæ, and by *Calythrix*, a member of the Myrtaceæ. Near these are placed some specimens with a cypress-like character of foliage illustrated by a *Crassula* and a New Zealand *Veronica*. The various Cactoid types of growth are shown by species of *Pelargonium*, *Vitis*, and *Rhipsalis*, one of the true Cactaceæ, while larger specimens are illustrated by one of the South African *Euphorbias* and one of the candelabra-like Cacti from Central America. The Cactoid habit is also shown by a *Senecio*, one of the Compositæ, and by an *Asclepiad*, *Stapeha hirsuta*. The spherical type of plant structure is exhibited by a South African

Euphorbia, *Euphorbia obesa*, and by representatives of South American Cacti.

IN his address to the French Association for the Advancement of Science at Grenoble in July, the president, M. Emile Borel, dealt with the problem of the organisation of scientific research in France. Every one now recognises that the social progress of a nation depends on its use of the laws which facilitate the production of the means of living. A smaller band sees that the greatest material advances have been founded on discoveries made by research workers in fields which at the time seemed of little or no practical interest, and the problem of how to keep alive this type of research when democracy can only appreciate results which are immediate and material is a serious one. M. Borel considers it cannot be solved by allowing the academies and other institutions to determine the researches which are to be encouraged by the nation, or by providing national support for all research workers, but by placing in the hands of the academies, universities, institutions like the Association for the Advancement of Science, and of distinguished men of science, funds for the encouragement of young men who are willing to engage in research and are worthy of support. Some of these men would prove worthless, but M. Borel would apply to them the old axiom of law that "it is better to acquit ten guilty than to condemn one innocent." The address is reproduced in the issue of the *Revue Scientifique* for August 22.

IN accordance with resolutions passed at a preliminary representative meeting, held at the suggestion of the Optical Society on July 21, arrangements to hold an Optical Convention in 1926 are now being made by the executive committee appointed for that purpose. Mr. F. Twyman has been elected chairman of the committee. The Convention, which will be entirely British in character, will be held in London about the middle of April next. Its activities will be directed towards providing a coherent presentation of the very notable advances which have been made in British optics during and since the War. Lectures, discussions, demonstrations and exhibits will be arranged, and it is intended that these shall be of such a nature as to appeal to professional men, to those engaged in industries, and to the general public. A record of the proceedings of the Convention will be published, in which will be included an account of the papers read and the discussions held, together with a description of the instruments exhibited. Although no general appeal for financial support has yet been issued, promises have already been made, by several members of the optical industry and by the Optical Society, to contribute to the Guarantee Fund sums which amount, in all, to more than 1000*l*. This may be taken as an indication of the interest that is being taken in the proposal, and suggests that adequate financial support for the Convention will be forthcoming.

AN interesting feature of the September issue of the *Aeronautical Journal* is a paper by R. A. Frazer submitted for the R. 38 Memorial Prize Competition and

awarded the prize. It is entitled "The Rigid Airship in Relation to Full-Scale Experiment" and deals not merely with the experimental methods that have been evolved specifically to cope with scientific experimentation on such a large scale, but also with many interesting historical details relating to early struggles to arouse interest in this form of investigation. The driving force, it would appear, behind much of this work in its initial stages was J. R. Pannell, one of the members of the staff of the National Physical Laboratory at Teddington, who lost his life in the R. 38 disaster over the River Humber. Among the equipment salvaged from the wreck were three note-books comprising all the entries made by the N.P.L. representatives, and a film registering the pressures over the upper rudder practically up to the moment of the disaster. From the material which came to hand in this way it was found possible to reconstruct the principal stages and episodes of this dramatic flight. The experimental observations proved sufficiently complete to admit of reduction, and these data, which cost so many valuable lives, are now on permanent record in a paper published by R. A. Frazer and H. M. Bateman, one of the survivors of the disaster.

IT is a question how far the public in general is aware of the excellent work which is being done by the London County Council in stimulating the interest of its teachers in those scientific and artistic subjects which fall outside the scope of the ordinary curriculum, but are of incalculable value as a broadening influence on their intellectual outlook. Among the courses of lectures which have been arranged from time to time, the anthropological and biological courses given at the Horniman Museum, Forest Hill, which is maintained by the Council, have been particularly useful. This museum has been arranged especially with a view to the instructional value of its exhibits, and an excellent series of handbooks has been compiled by the curator, Dr. H. S. Harrison. These are written on thoroughly sound and scientific lines, but at the same time are not too technical to be of assistance to those whose scientific knowledge has not reached a very advanced stage. The latest issue in this series deals with the cases in the museum illustrating simple means of travel and transport by land and water (Horniman Museum, Forest Hill, S.E., No. 14, 1925, price 6*d*.). As the museum is liberally supplied with models, Dr. Harrison has been able to cover the subject adequately from the simple application of man or woman power by means of the headband or pack to the various types of wheeled transport, and from the skin canoe to the sailing ship.

CAPT. ECKERSLEY recently broadcast the main results arrived at by the International Radio Conference which has just been held at Geneva. The results of the tests made in September proved conclusively that Europe has too many broadcasting stations. This is mainly due to the narrow limit of the wave band (300 to 500 metres) that has been allotted by the European governments for broadcasting purposes. As government, maritime and commercial radio services must be considered, it is

unlikely that longer wave-lengths will ever be permitted. The majority of the experts therefore were in favour of reducing the number of broadcasting stations. To accomplish this, every nation must be prepared to sacrifice some of its stations. A few well-designed high-power stations will probably give better results than many low-power stations. If this were done the crystal set users would get a better service. It can be so arranged that these high-power stations cannot interfere with one another. An objection might be raised that certain towns would lose their broadcasting status and that the programmes they receive would have little local colour. This difficulty might be overcome by retaining the local studios in those towns and allowing them to give regular programmes by means of land lines to whatever station had charge of their district. The new scheme, which begins on November 1, will only come into operation gradually. It was absolutely necessary to attempt to mitigate the troubles caused by interference which would have caused a chaotic state of affairs during the coming winter. Details of the scheme will be announced as they are finally arranged by the permanent staff at Geneva. New stations outside the scheme will be given wave-lengths below 200. The new Dublin station, which will begin operations this year, was fortunate to be allotted a wave-length in the regular broadcasting wave-band.

A CIRCULAR issued by the Bureau of Standards, Washington (No. 276), contains a useful survey of progress in the design of motor headlights. Tests conducted by various committees have led to the conclusion that for modern driving it must be possible to see any substantial object on the road 200 feet away. This involves a powerful beam and inevitably some degree of dazzle to approaching persons. The most hopeful solution lies in the scientific control of the beam, and various optical devices for limiting it below a horizontal plane 30 to 40 inches above the roadway are described. In addition it is desirable to spread the beam laterally so as to show up the limits of the roadway. Various dimming devices, involving diminution of the light, have not proved very satisfactory. Methods of controlling the beam are more hopeful, e.g. devices for tilting the headlight or reflector so as to direct the beam downwards when approaching another car. The same result is obtained in some modern headlights by the use of either of two filaments within the same bulb, one out of focus. In the final portion of the circular, requirements for headlights are summarised, and the method of testing in the Bureau of Standards laboratory is described. These tests are based mainly on specifying candle-power in various directions with the view of ensuring a sufficient beam for driving, and at the same time limiting emission of light in undesirable directions.

A SUMMARY of the past season's work at Knossos is given by Sir Arthur Evans in the *Times* of October 9. In the course of completing the reconstitution of the west wing of the Palace, a series of discoveries of exceptional interest throw a new light on the entrance

system from the west and at the same time link up its processional scheme of decoration with the religious functions of the Palace Sanctuary. According to the earliest planning, belonging to the great building preceding and partly incorporated in the Palace we know, the entrance had run in directly from the west instead of from the south as in the later building. This West Porch was itself preceded by an earlier structure giving into a corridor, of which the side walls have been traced. In a void where the old foundations had been grubbed up were found stucco fragments which had been torn from the wall. These fragments showed a decoration of painted groups of seated female figures engaged at their toilet. It has been suggested that the decoration of the later corridor, which replaced this earlier passage after the greater part of the Middle Palace had been destroyed by earthquake, represented not only processional votaries bringing in gifts to the goddess, but also acolytes carrying out relics from the inner sanctuary for public exhibition in the presence of the "Priest-King." This has received unexpected support from a discovery in the South Propylæum which has brought to light a subterranean depository choked with debris and pottery of the last Middle Minoan period. Abundant remains of painted stucco show that its interior had been decorated in a deep Venetian red ground with ochre bands grained with ruddy brown to imitate woodwork. This Sacristy within the Propylæum may have been the sanctuary from which the sacred vessels were taken out to be borne in procession. Remains of brilliantly polished stone plaques with marble-like surface indicate the splendour of the Early Palace entrance which it was attempted to reproduce in the Later Palace in stucco.

IN 1875 the Bradford Naturalists' Society, now the Bradford Natural History and Microscopical Association, and also the Bradford Scientific Association were formed in Bradford. With varying fortunes both societies have continued active in the cause of natural history and of science, and on September 25 and 26 they joined in the celebration of their jubilee. The Lord Mayor honoured the two societies by a civic reception at the Cartwright Hall on September 25, and on September 26 a most successful exhibit and demonstration of the scientific work of the members was held at the Technical College in Bradford. Under the title of "Fifty Years of Local Science" an interesting account of the work of the two societies has been published under the joint editorship of H. J. M. Maltby and W. P. Winter, which includes brief notes of many stalwart Yorkshire workers in the cause of natural history, notably the late William West, whose influence upon natural history, radiating from his classes at the Technical College at Bradford, will long remain a living force in the development of clubs of Yorkshire field naturalists.

WE much regret to learn that Prof. H. Maxwell-Lefroy, professor of entomology, Imperial College of Science and Technology, South Kensington, was rendered unconscious by fumes while experimenting with insecticides in his laboratory on October 10 and was taken to hospital in a serious condition. In

answer to an inquiry at the moment of going to press, it was stated that he was still unconscious and his condition remained grave.

MEMBERS of the staff of Rothamsted Experimental Station, Harpenden, Herts., are available for lectures during the winter to farmers' unions, chambers of agriculture, agricultural societies and similar bodies. No charges are made, but associations are expected to defray the lecturer's expenses. The subjects for lectures are included under such general titles as manuring, soil micro-organisms, weeds, chemistry of manuring and crop production, soil physics, insecticides and fungicides, insect pests, bees, and plant diseases. Communications regarding the lectures should be addressed to the secretary of the Station.

THE annual exhibition of electrical, optical, and other physical apparatus arranged by the Physical Society of London and the Optical Society is to be held on January 5-7, at the Imperial College of Science and Technology, South Kensington. In addition to the usual display by instrument makers, the exhibition this year will include new features in the shape of illustrations of recent physical research and of improvements in laboratory practice, examples of effective lecture experiments and repetitions of historical experiments in physics. These exhibits will be kept distinct from the trade exhibits, and a section of the catalogue will be devoted to them. Offers of such exhibits should be sent to the secretary of the Physical Society at the Imperial College of Science not later than November 16. The new development will afford an opportunity for the interchange of ideas between research workers and teachers, and will also be of service in bringing the

latter into touch with recent advances in physical science. The repetition of historical experiments will be of interest not only to teachers but also to the general public, who will be admitted to the exhibition on January 7. This is another novel feature, admission to the exhibition in previous years having been confined almost entirely to scientific workers.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: An assistant lecturer in agriculture at the Farm Institute, Spars-holt, near Winchester—The Director of Education, The Castle, Winchester (October 26). A demonstrator in inorganic chemistry in the University of Leeds—The Registrar (October 26). A lecturer in the department of chemistry of the University of Cape Town—The Secretary to the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (October 27). A professor of botany in the Rhodes University College, Grahamstown—The Secretary to the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (November 4). Assistant-Secretary to the Royal Society of Arts—The Secretary, John Street, Adelphi, W.C.2 (November 7). An editorial assistant under the British Non-Ferrous Metals Research Association, for abstracting and reviewing British and foreign scientific and technical publications and for editing and interpreting research reports—The Secretary, B.N.F.M.R.A., 71 Temple Row, Birmingham. Two male junior assistants in the research department, Woolwich, for computing work in connexion with ballistic observations—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Our Astronomical Column.

ANOTHER FAINT NOVA IN AQUILA?—Prof Max Wolf recently detected a star of magnitude 8.7 in Aquila, which was absent both from the Bonn Durchmusterung and from numerous photographs taken in recent years at Königstuhl, which show stars down to magnitude 12 or 13. It has been in the neighbourhood of mag. 8.7 for about three weeks, and was observed on Oct. 3 by Mr. B. M. Peek at Bournemouth and on Oct. 5 by Mr. G. Merton at Blackheath. Its place for 1925.0 is R.A. $19^h 27^m 24.7^s$, S. Decl. $6^\circ 35' 10''$. It is either a Nova or a remarkable variable, and in either case deserves careful observation. The object souths at about 6 P.M., so it will be possible to follow it for at least two months before it gets too near the sun for observation.

BRIGHT METEORS.—Mr. W. F. Denning writes that, on the evening of October 6, meteors were rather abundant though fog prevailed and the gibbous moon was up during the latter part of the observation. Meteors are often plentiful in the first week of October, several minor showers of moderate richness being of annual recurrence at this period. A few bright meteors were among those recorded on October 6 at Bristol, namely, one at $19^h 39^m$ G.M.T., equal to Jupiter, passing upwards just under Cassiopeia from a radiant at $14^\circ + 31^\circ$ or $12^\circ + 7^\circ$, another at $21^h 0^m$ G.M.T. falling in the S.E. sky rather slowly from $18^\circ + 14^\circ$ to $33^\circ - 10^\circ$. This was brighter than Venus and probably directed from a radiant in Cygnus, Cepheus, or Draco. A third at $21^h 56^m$, about

equal to Jupiter, shooting from near α Ursæ Minoris to between α and β Ursæ Majoris. If one or more of these objects were noticed at other places, it would be interesting to hear of any details of their apparent paths which would enable their actual courses to be computed.

ORBIT COMPUTING.—There is at present a dearth of readily accessible books in English that give full details of the rather difficult but fascinating problem of orbit computing. Students of celestial dynamics will therefore welcome the paper on this subject by Mr. G. Merton (Monthly Notices of Royal Astronomical Society, June 1925). The method described is based on that of Gauss, but full use is made of various improvements introduced since his time, including some by Mr. Merton himself. Special attention is given to rapid convergence, a point in which many of the older methods are defective, and to the avoiding of all unnecessary repetition after the first approximation to the geocentric distance is obtained. In particular, the parallax is eliminated in a less clumsy manner than that of Gauss's *locus fictus*. There are two fully worked out numerical examples, elliptical orbits being illustrated by the case of Baade's planet 1924 TD (lately named Ganymede) and parabolic ones by Orkisz's comet 1925 II. Some tables are appended to the paper, which avoid the necessity of consulting any other work, except a table of logarithms and the Nautical Almanac for the sun's co-ordinates.

Research Items.

CARVED STONES IN ASSAM—In vol. 20, New Series, No. 5 of the Journal and Proceedings of the Asiatic Society of Bengal, Dr. J. H. Hutton gives some further notes on two groups of carved menhirs in Assam, one at Dimapur in the Dhansiri Valley and another, which is scarcely known, at Kasomari-pathar near Jamuguri in the Dayang Valley. Adjacent to the latter are remains, previously undescribed, consisting of a couple of carved stones and a broad upright slab surrounded by the remains of a brick wall. One of the stones is carved into a hollow like a basin. Outside its rim is a trough ending in a spout. The second, an oblong stone, is carved into a wedge-shaped trough. The upright slab, at the foot of which a hollow has been excavated, is broken at the top at a point originally pierced by two round holes. As the basin must have been connected with a libation ceremony, it is possible that an offering was poured through the two holes as is done by the Angami to-day in the *hsu* ceremony at which wooden phallic symbols, corresponding to the monoliths at Dimapur, are erected. The Kasomari monoliths presumably are also phallic, or connected with fertility, as is shown by two pairs of domes on one stone which undoubtedly represent breasts.

ABORIGINAL ROCK PAINTINGS AND CARVINGS IN AUSTRALIA—In the course of an account of the aborigines of the Northern Flinders Ranges, Southern Australia, in Vol. 3, No. 1 of the Records of the South Australian Museum, Messrs. Herbert M. Hale and Norman B. Tindale describe some interesting rock paintings in a former native camping ground at Malkaia, six miles south-east from Mount Serle, and a series of rock carvings at Owicandana on a number of outcrops of sedimentary rock. The former, of which the designs sometimes recall those of the carvings, are on a cliff overhanging a shelf and forming a shelter, of which the walls are blackened with smoke from the occupants' fires. The paintings are in pipeclay, charcoal, and red and yellow ochre. The designs consist of perpendicular bars with branches, or crossing bars, a bird track, a meandering pattern possibly representing a snake, a figure which Basedow elsewhere identified as a pubic tassel, a boomerang, etc. The rock carvings are similar to those which have been described by Basedow in other localities in South Australia. They are covered with a hard dark rust-coloured patina and some have been smoothed by age. The present natives are unacquainted with their purpose or meaning. In the main they consist of "corroboree circles," incomplete circles, a few emu and other tracks, and some unidentified designs. Some, the circles for example, are formed by a number of closely connected indentations, possibly made with a stone chisel; others of inferior technique and possibly made with a cold chisel, look like comparatively recent, sporadic attempts to copy ancestral work.

FUNDAMENTAL WORK UPON THE COTTON HAIR—It is very striking to note that the development of fundamental research in the newly formed Research Association dealing with commercial fibres, be they wool, flax, or cotton, leads the investigators back to study their problems in terms of their fundamental biologic unit. This is again exemplified in the study of the mercerisation of the cotton hair without tension by Mary Alexandra Calvert and Frederick Summers, which has recently been published from the British Cotton Industry Research Association (Journal of the Textile Institute, vol. 16, pp. T233 to T268, August 1925). These investigators have shown how regular is the change of width of the single hair during

swelling upon mercerisation, in a number of typical cottons, and how fully this change can be accounted for in terms of the change from collapsed dry hair to a hair with swollen elliptical section, contracted in length and with lumen nearly filled by the swollen wall. Further, they show that no additional change in width can be produced by increasing the concentration of sodium hydroxide beyond about 16 per cent., and that the maximum width then obtained is identical with the width of the original hair as it existed in the fruit boll, contraction occurring as the boll opens and the hair dries. They show in addition that the reason for this limit to increase in girth must be sought in the cuticle, which fails to extend beyond its original dimensions in spite of the pressure of the swelling cellulose within. When the width of this mercerised hair afterwards shrinks, without change in the shape of the cross-section, as the hair is washed in water and then dried, this inextensible cuticle smoothly follows the contraction, and the authors have some very interesting suggestions as to the minute structure of the cuticle in the light of its behaviour. These suggestions are accompanied by some very good microphotographs. In fact, this study in a field of applied science is a botanical contribution of absorbing interest.

AN AUTHENTIC BUD VARIATION IN POTATO—So recently as 1918 so experienced a plant breeder as Mr. A. Sutton expressed the view that "there is no ground for believing nature ever has given rise to any new and distinct variety of potato by bud-variation." The point at issue is of first-rate importance, both scientifically and from the practical point of view, and it is therefore very interesting to have Mr. R. N. Salaman's confirmation, as the result of extensive breeding experiments, of Mr. McKelvie's original view that he had found an authentic bud sport turning up in the case of the Arran Victory potato. Thus sponsored, this bud sport, or somatic mutation, deserves the most serious consideration. Actually a series of such sports has been under observation, the obvious point attracting attention to them being the suppression of patches of the purple coloration in the skin, leading ultimately to a form with white tubers with occasional patches of colour, or, in the extreme form, tubers with a pure white skin. Most of the forms thus arising produce plants with vegetative form and foliage indistinguishable from Arran Victory, but one remarkable mutant has definitely a different growth form and different shaped leaflets, a point noticed by McKelvie and completely confirmed by Salaman. This same mutant also shows the tuber form altering in a large majority of its produce from the typical round tuber of Arran Victory towards a typical "kidney." Mr. Salaman has carried out crossing experiments with these bud mutations, with the result that the loss of pigment in the tuber appears to be accompanied *pari passu* with a reduction in the number of ovules capable of giving rise to coloured tubers. Thus it appears that a change arising in a vegetative shoot and propagated in the first place vegetatively, a change presumably in the genes controlling colour formation in the tuber but, in one mutant form at least, associated with other far-reaching changes in the constitution of the plant, has been associated with changes in the genetic constitution of the germ cells. Mr. R. N. Salaman describes his breeding experiments in the *Journal of Genetics* (vol. 15, No. 3, July 1925), his final conclusion being that "A somatic mutation which is characterised by the loss of a specific character such as pigmentation of the tuber skin, may evince this loss in other directions.

both in its own body and, through its germ cells, in its offspring."

MOVEMENT OF SAND CAYS.—A short report on the movement of sand cays on the Great Barrier Reef under the influence of atmospheric conditions is contributed to the *Queensland Geographical Journal*, vol. 39, by Lieut. T. Taylor, and forms one of the Great Barrier Reef committee's reports. Beaver Cay, on a small coral reef about 20 miles from Dunk Island, was used as a triangulation station in 1921. In 1922 the position was found to have moved. The position of the new mark was fixed, and after an interval of two months, during which high winds prevailed, was redetermined. Again it was found that the cay had moved. In short, there seems to be no doubt that this cay, as well as another three miles distant, moved approximately 100 yards in less than two years. The paper is accompanied by a chart of the reef and cays.

THE COMPTON EFFECT.—When γ -radiation falls on matter it is "scattered," that is, sent off in directions which make angles θ with its direction on incidence, and the scattered radiation is "softer," that is, more readily absorbed, than the incident. Two years ago Compton came to the conclusion that the scattering was accompanied by an increase of wave-length of the radiation which for a range from 0.7 to 0.025 Ångström units was equal to $0.048 \sin^2(\theta/2)$. He also gave an expression for the intensity of the scattered radiation in the direction θ which involved the term $1 + \cos^2 \theta$, basing his work on the quantum theory. In the issue of the *Physikalische Zeitschrift* for July 21, Dr. G. Wentzel discusses the experimental results obtained up to the present time and the alternative theories which have been proposed to explain them, and comes to the conclusion that the Compton theory is most in harmony with the facts.

CONTACT ELECTRIFICATION OF SNOW.—A series of experiments on this subject and some measurements are described by Dr. A. Stager in the *Annalen der Physik* for August. When hoar frost is blown away from an ice surface by dust-free air, it is negatively charged, one gram carrying on the average -180 electrostatic units, and in exceptional cases -1000 units. An experiment at the Hahnenmoos Pass in the Bernese Oberland, with icicles about 20 cm. long and 1 cm. thick suspended by silk threads attached to the two ends, showed that when they were hung in the drifting snow near the ground, and then brought into contact with a Lutz electrometer, deflexions of more than 56 volts were generally obtained, the charge being negative, when they were hung in the finer drifting snow one or two metres above the ground, the charge was generally positive and smaller than before. It was found that an iron wire, 9 metres long and 0.3 mm. thick, could be raised to a potential of several thousand volts by driving snow, and could give a continuous current for several seconds with about 3 watts power. The method used by the author in measuring the space charge during snowfalls is described, together with experiments with solid carbon dioxide and with different powders, in some of which luminous effects are obtained similar to those which have been observed in clouds of street dust. The experiments are used to explain winter thunderstorms, and the connexion of sleet and hail with ordinary thunderstorms where the ice effect, in addition to that due to liquid water, contributes to the production of electric charges.

RESISTANCE TO CORROSION OF ELECTROPLATED CHROMIUM.—Mr. F. A. Ollard read a paper on this subject before Section B (Chemistry) of the British Association, at the recent meeting at Southampton.

Two series of tests were described, one made in the laboratory and the other in service. The laboratory tests were made on test pieces cut from a strip of mild steel, which were then plated with cadmium, nickel, copper and chromium and combinations of these metals in various orders. The test pieces were then subjected to an exposure test, boiler test, salt spray test, and heat test, and the results noted. The most satisfactory results were shown by the test pieces which had been plated first with nickel and then with a thin layer of chromium. Test pieces plated first with cadmium and then with chromium showed a tendency for the chromium to flake off, and all test pieces containing cadmium failed badly under the influence of heat. The nickel-plated specimens usually showed a certain amount of surface corrosion, while the specimens in which the chromium was plated directly on to the steel usually failed owing to the coating being somewhat porous. Contrary to expectations, the chromium stood fairly well in the salt spray. The second series of tests were made by placing chromium-plated articles in service. Spoons, forks, and knives were treated by this process and used in various places under very heavy conditions, and these remained bright and untarnished without any cleaning. Also, some small parts on motor-cars, etc., had been plated and are standing very well, although sufficient time has not yet elapsed to give any definite results. A pin in a die-casting mould has also been treated and appears to withstand the action of the molten metal very satisfactorily. It is hoped to do a considerable amount of further work on this subject, and among the experiments to be tried are the effects of sea water and the variation of reflective power with ageing.

TUNGSTEN IN CONSTRUCTIONAL STEELS.—R.D. Report, No. 65, from the Research Department, Woolwich, gives an account of an investigation carried out by Mr. J. A. Jones on "The Influence of Tungsten on the Properties of Medium Carbon Steels containing Nickel and Chromium." The carbon varied from 0.3 to 0.4 per cent, nickel from 2.5 to 5.9 per cent, chromium from 0.6 to 1.1 per cent, and tungsten from 0.7 to 2.4 per cent. The thermal critical ranges, microstructure, and mechanical properties of a number of these alloys have been examined. The principal results are that in steels of otherwise identical composition increasing tungsten raises very slightly the temperature of A_{c1} . The rise amounts to about 8° C. for the addition of 1 per cent. of tungsten. This element behaves like other alloying elements in increasing the efficiency on hardening at the slower rates of cooling such as are involved in the heat treatment of large masses. Its effect in this direction is most pronounced when added to nickel steels containing about 6 per cent. of nickel. Addition of tungsten also reduces the fall of hardening produced by tempering. The carbon-tungsten steels containing up to 1.7 per cent. of tungsten, and the 3.5 per cent. nickel-tungsten steels containing less than 1.5 per cent. of tungsten, with a carbon content of 0.3 per cent., did not give sufficiently good mechanical properties to be considered as high tensile constructional steels. Remarkably good properties are, however, given by the 6 per cent. nickel steel containing 0.3 per cent. of carbon and 0.6 per cent. of tungsten. The steel giving the most promise of useful application was a steel with 6 per cent. of nickel and from 0.6 to 1.0 per cent. of tungsten. The author's final conclusion is that while tungsten, in common with other alloying elements, beneficially affects the properties of constructional steels, there is nothing so distinctive in its influence as to warrant any special recommendations in its favour.

The Evolution and Colonisation of Tidal Lands.

THE joint discussion on "The Evolution and Colonisation of Tidal Lands" between the Sections of Botany and Geography during the British Association meeting at Southampton was opened by Prof. F. W. Oliver, who spoke of the raw materials that go to the making of tidal lands, namely, shingle, sand, and fine silt, and of the transport of these by tide, currents, and wind. Plants can only become established on tidal lands during periods of quiescence. Vegetation thereon arises almost entirely from sea-borne seeds, the sea also bringing drift which in time enriches the ground with humus. Plants as they become established collect and hold silt and blown sand, and are, therefore, in effect creative. In the case of sand dunes, the conditions were traced which lead to permanence. The parts played by *Agropyrum junceum* and *Psamma arenaria* in the building of dunes were discussed, it being pointed out that the latter was liable to be killed when invaded by abnormally high tides for some hours. Gales of 60-70 miles an hour stimulated the formation of dunes owing to the consolidation of the sand by wind force. Salt marshes differ markedly in type according to the nature of the ground, being either sandy or slushy or consisting of firm mud. Their proper development requires the concurrence of a number of plants at each successive phase. Reference was made to the almost unique capacity of *Spartina Townsendii* to occupy the softest muds and to spread rapidly on them. Its efficiency in such ground is comparable to that of marram grass in sand and *Suaeda fruticosa* in shingle.

The possibilities of artificial control of the shore line by appropriate planting and conservation of plants were alluded to, and the possibility of consequent injury to navigation pointed out. Extensive mud flats are the natural "hinterland" of a system of tidal creeks or channels, and if the level of these muds be unduly raised by the silting action of halophytes, by so much is the volume of tidal water that can enter a harbour reduced. In the absence of sufficient water to scour out the channels at later stages in the ebb, they are always liable to become shallow and ultimately choked.

Prof. J. W. Gregory laid stress on the fact that although deposition by rivers and currents in the formation of tidal lands was of vast importance, coast erosion was also accompanied largely by the deposition of the matter thus set free. This deposition took place rapidly in sheltered positions. Sedimentation was much more rapid and complete in salt water than in fresh. Thus the transport of the products of erosion was restricted, and sedimentation in protected places along the coast was easy. Three processes are involved in the deposition of such tidal lands; first, the formation of a sand bar; second, the formation of a spit of longshore drift; and third, the deposition of plains in quieter waters behind the bar or spit. The development of these features on the British coasts was illustrated by reference to the records, from Roman times onwards, of the

mouth of the Humber and other rivers. Mention was also made of the occurrence of similar phenomena on the coasts of Australia and Burma. In conclusion it was pointed out that the conditions controlling tidal-land formation at the present time were probably similar to those under which the great coal fields of the world had originated.

Prof. R. H. Yapp dealt particularly with the colonisation of the mud flats in the Dovey estuary in Wales. The vegetation succession *Salicornia* → *Glyceria* → *Armeria* → *Festuca* was described. In the early stages vertical accretion of silt is rapid, but the rate decreases as age advances. Stress was laid on the efficiency of the dominant plants as silt-binders. Sun-cracks, even during prolonged drought, rarely appear on such surfaces covered with vegetation, except in the earlier phases of colonisation when roots are few and binding less complete. Erosion resulting in the undercutting of the margins of the marsh and of the numerous drainage "pans" was described step by step. The rate of retrogression due to such erosion is slow compared with the rate of the various constructive forces leading to the increase of tidal lands.

Dr. Vaughan Cornish pointed out that little attention had been given to the importance of the ebb and flow tides in the formation of tidal lands. This was mainly due to the difficulty of observation. He described the interplay of ebb and flow tides in the passage of detritus, and held that the beach is stroked intermittently in one direction only, that of the flood tide. In this connexion it is important for local authorities and coastal engineers to examine carefully the movements of detritus at the turn of the tides.

Lord Montagu of Beaulieu spoke of his contact with the work of Prof. Oliver, and of his firm belief that only by the co-operation of local authorities with trained botanists could the problems of coast protection be dealt with adequately. His own experiments on reclamation were referred to with the object of dispelling the belief that easy and quick returns from grass crops could be secured by enclosing and draining salt marshes. He stated that *Spartina* sometimes acted indirectly as a denuding force, owing to the current being concentrated into narrower channels through the growth of the grass. This led to the falling in of the banks in consequence of undermining.

Dr. E. J. Salisbury described chiefly the ecological changes occurring in sand dunes with increasing age. There is a gradual diminution of calcium carbonate as the dune gets older, owing to the accumulation of carbon dioxide through the action of micro-organisms leading to a rise in the hydrogen-ion concentration. This is correlated with changes in the types of plants found on the dunes at different ages. Whereas the pioneer plants of the dunes are "lime-loving," several chalk down plants being commonly found, the character of the vegetation gradually changes until the old dunes are covered with plants characteristic of acid soils, such as heather.

Natural Mental Tests.

NATURAL mental tests are defined, in a pamphlet recently received, by Mr. Arthur MacDonal, of Washington, as "studies of man which have for their object an estimate of him with reference to his reputation, education, and culture, and also with regard to the things he has done, the results he has accomplished . . . in short, his mental products."

Thus a study of the occurrence in a group or community of men of genius or talent, those who are noted for literary, scientific, or any other educational achievement, forms a test of the mentality of that group. Such a series of natural tests is of considerable anthropological significance. By means of them we compare the effects of various conditions and

environments upon the mental status of the average man, who is the representative of the community. Mr. MacDonald has brought together the data from a number of studies of man's mentality which, though not designed for that purpose, form such a series.

Mental ability has been found to resemble the physical properties of man in range and distribution; it conforms to the normal curve of distribution. Thus among a representative group, the proportion of successful men is about the same as that of morons and individuals of low-grade intelligence; and the proportion of men of great talent and genius the same as that of idiots and imbeciles. The range of intelligence above the normal ordinary man is as great as the range below.

In general, men of outstanding ability obtain a great reputation among their contemporaries; so that we are enabled to compare the varying occurrences of men of genius and of talent by means of their reputations. The number of such occurrences varies chronologically, with nationality and geographical situation, with social origin and parentage, and with degree of education. Finally, there are various types of genius and talent which occur in fairly constant proportions among different communities.

Not much reliance can perhaps be placed upon data dealing with the number of eminent men who have lived in the various centuries and decades of our history; for the spread of publicity and the improved means of communication are likely to give an advantage to more recent periods of time. It is interesting to note, however, that while men of talent increase in number up to recent years in Great Britain and in the United States of America, the largest number in France lived in the seventeenth century.

When we turn to a comparison of the number of great men of science in various countries, however, we do not find any advantage resting with the English-

speaking races. Ever since 1750 Switzerland has had the largest number of associates of foreign Royal Societies; Holland has sunk from second place to tenth, Germany has risen from low down to third, and France is high throughout. England is about sixth, and the United States about tenth throughout. In Great Britain itself, the Nordic races have a great advantage as regards men of genius. England and Scotland much out-top Ireland and Wales—a fact which is fairly generally recognised.

Coming to the influence of social origin and environment, we find that it is the great middle class, the commercial and professional group, the "neither poor nor wealthy," which produces the bulk of talent and genius both literary and scientific. In France and in the United States also, it is the urban rather than the rural districts which have the advantage in this respect. This is probably connected with the superiority of educational opportunity in the former, for naturally we find more talent among educated than uneducated persons; 80 per cent. of a group of distinguished American men of letters had received at least a high-school education, while 98 per cent. of a group of talented French men of letters were well educated.

Dividing men of genius into men of letters, sciences, arts, and action, we find that in all countries the greatest number of men of genius are men of letters, especially in France and Germany. Men of action come next in all countries except Germany, where there are more men of arts and sciences with genius. In most countries the arts have the advantage of the sciences.

These conclusions probably need the support of more statistical evidence to become firmly established, and to show clearly their bearing upon one another. They nevertheless form the introduction to a number of interesting problems connected with variation of mentality in man.

M. D. VERNON.

Bergens Museum.

ON April 25 Bergens Museum celebrated its centenary by a festival to which representatives of Norwegian, Danish, Finnish, Icelandic, and Swedish institutions were invited, and by the publication of a handsome volume, which permits the friends of the museum in other countries to share the interest and to offer congratulations to their colleagues of Bergen. In 1900 a complete history down to that date was published by Dr. J. Brunchorst. The present work records the remarkable expansion during the succeeding quarter of a century, and the fruition of ideas that germinated in the bygone decades.

Bergens Museum has never been content to remain a mere storehouse and exhibition. It has been a centre of scientific research and of the publication of the results to all classes. The museum itself has so grown that it has occupied three successive buildings. To the last of these, two wings were added about 1900, and an entirely new building for the history of culture now approaches completion. The museum also has a separate laboratory and a modern biological station, and is about to erect a building for its geophysical institute. It possesses a seismological station, a bio-chemical laboratory, and a botanical laboratory.

The two serial publications of the museum—the yearbook for researches and *Naturen* for popularisation—are widely known. Among many separate publications, "An Account of the Crustacea of Norway" by Dr. G. O. Sars stands pre-eminent. To the printed word is added the spoken. Not only are there popular lectures, but there have also arisen regular schools in zoology, botany, and geology, with

the right of examining their students for public posts.

Thus we arrive at the goal of the museum's activities, its incorporation—which cannot much longer be delayed—as the University of Bergen. Already its staff of 25 men of science includes 8 recognised professors. The ideas that had been gaining ground since 1892 were set on a broader basis in 1915. Plans were prepared and funds solicited. The intention was first to establish faculties of natural science and of medicine based on the museum and such medical institutions as exist in Bergen. Unfortunately the hard times have rendered it impossible to have these two faculties at work in the centenary year; but the course of future development is marked out and will undoubtedly be followed so soon as the economic situation permits. Many a university has founded a museum of high rank; but we do not remember a museum that, beginning as a private institution in a single school-room, has so determinedly used its energies for the highest and widest ends of learning as to blossom into a university for which a prosperous future is assured.

In its earlier years men of the highest scientific distinction were connected with Bergens Museum, such as D. C. Danielssen, Herman Friele, Fridtjof Nansen, G. Gustafson, A. Appellof, and Jørgen Brunchorst. A welcome feature of the present volume are the portraits and brief biographies of those who have served the institution during the present century. Into the hands of the present staff the future of Bergens Museum and Bergens University may be entrusted with confidence.

F. A. B.

The Tensile Properties of Single Iron Crystals.

AT the autumn meeting of the Iron and Steel Institute held in Birmingham on September 9-11, Prof. C. A. Edwards and Mr. L. B. Pfeil presented a continuation of their work on the subject of the tensile properties of single iron crystals. Eighteen months ago, they succeeded in preparing some large iron crystals by the method of straining and heating introduced by Carpenter and Elam. The

FIG. 1.

large crystals described in the present paper were prepared by this method, although some small modifications have been introduced which allow them to be made with greater certainty. This method consists, briefly, in so treating the original mild steel sheets as to obtain a grain size of 120 per square mm. Suitable strips were decarburised at 875°C . for 48 hours, heated to 1000°C . for 12 hours, and finally slowly cooled. In this way a number of strips $8\text{ in.} \times 1\frac{1}{2}\text{ in.} \times \frac{1}{8}\text{ in.}$ were obtained, each strip consisting of one large crystal in the central part. In all cases it was necessary to remove the surface film of fine crystals by carefully filing before the existence of the large crystals could be detected by light etching. Test-pieces were cut from these with the aid of a manganese templet. This ensured that they were all of the same size and minimised the risk of bending of the metal, which is very soft. The test-pieces were $2.5\text{ in.} \times 0.75\text{ in.} \times 0.110\text{ in.}$

The stress elongation curves obtained show that up to about two tons per square inch the strain was proportional to the stress, and further that there was no well-defined yield point. In this respect, therefore, single crystals of iron behaved quite differently from the ordinary microcrystalline metal, which has a well-defined yield point and approximated much more nearly to a non-ferrous metal such as copper. Later on in the paper the authors give a diagram showing the gradual development of a yield point in this iron as the size of the crystals is diminished and crystal boundaries come more and more into play. It may, therefore, be concluded that this very characteristic property of microcrystalline iron is due in some way to the influence of the crystal boundaries. The limits of proportionality of ten crystals were determined and were found to vary from 1.72 to 2.52 tons per square inch, with a mean figure of 2.19. It is possible, however, that these values are too high, since the filing of the specimens will in all probability have caused some work hardening of the metal. The limit of proportionality of microcrystalline iron is about eight tons per square inch, so that the values for single crystals are little more than a quarter of this and may possibly be even less.

Tensile strength determinations were carried out on 25 crystals. Eighteen of these give figures in the neighbourhood of 10 tons per square inch. The corresponding figure for microcrystalline iron is about 20 tons, so that the tenacity of the single crystal in more than two-thirds of the test-pieces is only about half that of the metal in the ordinary form. In the remaining 7 single crystal test-pieces, however, the values varied from 11 to, in one case, 15.38. In this case, therefore, the tenacity of the single crystal was fully three-quarters that of the microcrystalline metal. This figure, however, is well below the highest figure for single crystals of aluminium obtained by Carpenter and Elam, namely, 90 per cent. of the tenacity of the microcrystalline metal. It is interesting to notice that, on the whole, the single crystals possessing the highest tenacity were also the most ductile. Figures varying from 30 to 53 per cent. were obtained. Corresponding to these differences of tenacity and ductility, the crystals distorted in different ways during the tests. The majority of test-pieces broke similarly to type II. of the aluminium crystals described by Carpenter and Elam; that is, the crystals retained their width but diminished in thickness. At the fracture they drew down to a knife edge and parted in a straight line nearly at right angles to the axis of the test-piece. Crystals which gave a higher tenacity and ductility both narrowed and thinned and showed a marked tendency for the cross section to change from a rectangle to a parallelogram (Carpenter and Elam, type IV.). At the point of fracture they necked and broke without drawing to a knife edge. Just before parting a large slip occurred on a plane making an angle of 45° with the length of the strip and with a "dip" of 45° . The crystal which broke at 15.38 tons per square inch gave a fracture different from the two types mentioned. It narrowed, thinned, and also necked.

Prof. Edwards and Mr. Pfeil have not as yet been able to determine the orientation of these crystals.

FIG. 2.

It is tolerably certain that the differences in tenacity, ductility, and method of distortion correspond to differences of original orientation of the crystals and of the method of distortion. The authors state definitely that the orientations of twelve crystals examined by them were not identical, basing this opinion on an examination under oblique illumination, and they speculate as to how it is that equal tensile strength values can be associated with variations in

orientation. It is important to point out, however, that they do not yet know whether an iron crystal during a tension test slips upon a dodecahedral plane or cube plane, or indeed upon either of these. This work has still to be done.

A beginning, however, has been made by Miss Elam, who contributed a note at the same meeting entitled "The Orientation of Crystals Produced by Heating Strained Iron." In their previous paper, Prof. Edwards and Mr. Pfeil had stated that square etching pits were frequently obtained with a diagonal in the direction of straining, and concluded from this and other observations that the crystals were similarly oriented. Miss Elam has examined several of their single crystals by X-ray methods, and the crystal axes relative to the axis of the strip of ten crystals have been determined. Some of them have been done by her and the remainder by Mr. R. W. Aston at the Cavendish Laboratory, Cambridge. The accompanying diagram (Fig. 1) represents part of the stereographic projection of the crystal axes with the positions of all the axes of the test-pieces, and hence the direction of straining, marked by a point. The relation of each point to the three principal crystal axes, *i.e.* the apices of the spherical triangle marked (100), (110), and (111), indicates the orientation of the crystal. This diagram shows that the points are scattered throughout the triangle and that the orientation of the crystals is consequently very varied.

Only two crystals showed cubic etching pits, and in both of these the surface of the strip was parallel to a cubic (100) plane in the crystal. These pits were quickly developed by etching in dilute nitric acid, whereas the other crystals appeared unattacked. When first formed the pits were rather indefinite-shaped pyramids, but on prolonged etching they became square. Crystals of other orientations showed pitting only on prolonged etching, and although the form varied from crystal to crystal, the pits had no regular shapes. Fig. 2 shows two crystals. The lower one is deeply pitted and has a cube face nearly in the plane of section. The upper one is not pitted and is attacked to a less extent although more uniformly. X-ray examination showed that the plane of the section was approximately a (112) plane. Miss Elam's experiments show, therefore, that the single crystals produced by Messrs. Edwards and Pfeil have not necessarily the same orientation, and that it should be possible to pick out those in which a (100) plane lies in or near the plane of section.

H. C. H. C.

University and Educational Intelligence.

ABERDEEN.—Kilgour research scholarships have been awarded to Miss E. H. M. Geddes (botany), and to Miss I. Dean and Mr. A. H. H. Fraser (zoology).

The University Court has appointed the following assistants: botany, Mr. N. J. G. Smith and Dr. R. Crookall; materia medica, Mr. T. J. C. Macdonald; pathology, Mr. J. Gray; zoology, Nita I. Rennet.

BIRMINGHAM.—At a meeting of the Council of the University on October 7, the following appointments were made: Dr. W. C. Osman Hill to be demonstrator of anatomy; Miss H. I. Pfister to be lecturer in physiology; and Mr. J. F. D. Shrewsbury to be lecturer in bacteriology.

The foundations of the new buildings for the biological departments having been completed, work

has been begun on the superstructure. The new building for the oil-mining departments is nearing completion.

CAMBRIDGE.—Dr. A. C. Seward, master of Downing College and professor of botany, has entered on his second year of office as vice-chancellor.

The Cambridge University Commissioners are considering their draft of the new statutes; it is expected that it will be published before the term divides and that the final document will go to the Privy Council before the end of 1925; its provisions will not come into operation until the beginning of the academic year 1926-27.

For the moment local interest is focussed on the new restrictions of the motoring activities of persons *in statu pupillari*. Mr. D. Portway, of St. Catherine's College, has been nominated as special pro-rector to deal with the enforcement of the new regulations. There are some members of the Senate who view any new restrictions as contrary to the "Spirit of Progress," but the discussions and voting last term showed quite clearly that a large majority felt that restriction of some kind was imperative and would be wholesome.

H.I.H. the Prince Regent of Japan, who visited the University and took an honorary degree in 1921, has presented the library with four cabinets containing the 666 volumes of the Gunsho Ruiju and a framed portrait of their blind author.

It is announced that there will be an election to an Isaac Newton Studentship (for research in astronomy or physical optics) early in the present term.

THE third annual report of the Imperial College of Tropical Agriculture, for the year ended December 31, 1924, has just been issued, and is a very satisfactory and interesting document. At the close of the year there were eighteen diploma students and fourteen post-graduates working at the College. As there were only six post-graduates on the register at the beginning of the year, the increase of this type of student is very satisfactory. The College is still hampered by lack of adequate funds for the completion and equipment of its new buildings and laboratories, and for the building of a hostel, which is so desirable an addition to the College for the proper accommodation of the students. As a result of the appeal for 100,000*l.* made by the late Lord Milner, 21,083*l.* were contributed during the past year, and this sum has been slightly augmented since the report was published. The report records the laying of the foundation stone of the new building of the College on January 14, 1924, at which several members of the Governing Body were present, including Sir Arthur Shipley, the chairman. Reference is also made to the death of Mr. Claude Tinné Berthon, honorary consulting engineer to the College, who not only designed and superintended the erection of the Instructional Sugar Factory, but was also largely responsible for securing gifts of machinery and plant from the British Sugar Machinery Manufacturers and allied firms to the value of upwards of 20,000*l.* towards its equipment. The year under review was also marked by the retirement of Sir Francis Watts, the first principal of the College, who had been Imperial Commissioner of Agriculture for the West Indies for twenty-four years. Sir Francis, in recognition of his services, was appointed, on his retirement, to the honorary position of Principal Emeritus of the College. The report also records the appointment of Dr. Hugh Martin Leake, formerly principal of the Agricultural College, Cawnpore, to be principal of the College in succession to Sir Francis Watts.

Societies and Academies.

CAMBRIDGE.

Philosophical Society, July 20.—Sir J. J. Thomson: The structure of light.—A. S. Eddington: Internal constitution of the stars.—H. Nagaoka: The transmutation of mercury into gold.—W. Burnside: On groups of linear substitutions which contain irreducible meta-cyclical subgroups.—S. Pollard: On Hausdorff's proof of the extended Riesz-Fischer theorem.—M. H. A. Newman: On the theorem of Pappus.—C. G. Darwin: Notes on optical constants.—R. de L. Kronig: The theory of the influence of magnetic fields on the stopping power of gases for α -particles.—J. T. Saunders: The trichocysts of paramacrum.—V. Nath: Spermatogenesis of *Lithobius forficatus*.—H. Munro Fox: The effect of light on the vertical movement of aquatic organisms.—E. C. Francis: (1) On differentiation with respect to a function. (2) The Lebesgue-Stieltjes integral.—D. H. Black: The β -ray spectrum of the natural L -radiation from radium B.

PARIS.

Academy of Sciences, August 24.—C. Sauvageau: The presence of free iodine in *Polysiphonia Doubletii*. A definite proof is given that iodine in the free state is present in this plant.—L. Escande: Similitude extended to high velocities. Supplementary researches on the similitude of viscous fluids.—R. de Malleman: The calculation of the rotatory power of a tetrahedral molecule. It is concluded that the existence of rotatory power, in an asymmetric molecule, is not incompatible with optical isotropy of the atoms.—Agafonoff and Mlle. Malicet: Some considerations on the lower loess of the neighbourhood of Paris.—J. Cabannes and J. Dufay: Measurement of the height of the ozone layer in the atmosphere. The assumption is made that the ozone layer is so high that the sunlight is first filtered by the ozone and then diffused by the lower layers of the atmosphere. The heights deduced are about 50 kilometres.—Bordas, François-Dainville, and Roussel: The elimination of benzoic acid and the benzoates in the body economy. In six out of seven cases, the complete elimination of benzoic acid took three days, and it is concluded that the continuous administration of benzoates, as when used as a food preservative, might, owing to accumulation in the body, give rise to serious troubles.—Paillot: The *grasserie* of the silkworm. This disease causes the most serious losses in the silkworm industry, and has been more prevalent in 1925 than in the preceding years. There is no certain cure for the disease, but some precautions are detailed which reduce the chances of infection.

August 31.—André Blondel: A modification of Lord Rayleigh's photometric method, rendering possible the use of a diffusing comparison surface in photometry.—Michel Akimoff: Confluent hypergeometric functions.—Nicola Obrechhoff: The summation of Fourier's series of analytical functions.—Kolossof: General solutions.—Carl A. Garabedian: Solution of the problem of the thick rectangular plate having two opposite sides supported and two sides free, and carrying a load uniformly distributed or concentrated at its centre.—Hoegelen: Circular arcs of uniform thickness. Application to arched barrages.—D. Foucher and E. Rougetet: Contribution to the study of the mistral. The acceleration. An experimental study in the Rhone Valley shows that the velocity of the wind is the resultant of two velocities, one determined by the barometric gradient, the other caused by local conditions (orographic velocity).—Jules Amar: The mode of walking known as "*sur la pointe des pieds*." The mode of walking

described by the author (with MM. d'Arsonval and Gautiez) has been misunderstood: details of the correct method are given.—Fernand Wyss: The biochemical estimation of insulin. A method of testing the strength of insulin *in vitro* is given, based on the retardation of the oxidation of resorcinol by hydrogen peroxide in the presence of insulin.

CAPE TOWN.

Royal Society of South Africa, August 19.—S. H. Haughton: On some new mollusca from tertiary beds in the west of the Cape Province. The following new mollusca are described from a deposit at Doornbaai on the Van Rhyndorp coast, south of the Olifants River mouth: *Mytilus tomlini*, sp. nov. *Donax (Iphigenia) rogersi* sp. nov. and *Chamelea Krigeri* sp. nov. The beds from which the shells were obtained average about 10 feet in thickness and form the upper portion of marine cliffs, which attain a height of 50 to 60 feet above sea-level.—R. S. Adamson: On the anatomy of some shrubby Iridaceæ. In the S.W. Cape region there are five species of the Iridaceæ which form woody stems with secondary growth. The main features of the structure of these plants were described. While the general type of secondary growth is the same as that occurring in other Monocotyledons with secondary thickening, there are many differences in detail. The secondary tissues are much more compact and in some of the plants show a definite arrangement into concentric growth zones.—V. A. Wager: The breeding habits and life-histories of some of the Transvaal Amphibia. In this paper the author describes the life-histories and habits of two species of Transvaal batrachia, *Chiromantis xerampelina* and *Rappia marmorata*; both are tree-living, the terminal phalanges being provided with adhesive discs. In the first-named species the eggs are laid in the form of a large white glutinous mass on branches overhanging water. The tadpoles drop from the egg-mass into the water where they complete their metamorphosis. The fore-limbs, before breaking through the operculum, are already provided with phalangeal discs. The tadpole does not increase in size during metamorphosis, and when the tail disappears the young frog leaves the water for an arboreal existence. In *Rappia marmorata* the eggs are laid in a jelly-like mass under water. A peculiarity of the tadpole is the absence of horny jaws, comb-teeth, or papillæ of the mouth, which bears a superficial resemblance to that of the tadpole of *Xenopus laevis*, but from which it can be readily distinguished by the absence of the two tentacles at the sides of the mouth. From this it is concluded that the tadpole feeds on micro-organisms in water drawn through the unusually large spiracle, and this is borne out by an examination of the intestinal contents, which includes amongst other organisms Euglena, Volvox, and a few minute annulates.—B. F. J. Schonland: Cathode ray scattering. Preliminary measurements of the scattering of fast cathode rays through 90° have been made under conditions which ensure "single" scattering. Values for the nuclear charges of gold and aluminium are derived from these results which lie within 12 per cent. (the experimental error) of the true values. They support the addition of the relativity correction to the orbit of a β -particle, this correction having the high value of 2.40 in the present case.—C. W. Kops: Marriage and mortality rates of the population of the Union of South Africa according to the conjugal condition of the population. The paper is a preliminary investigation into the marriage rates among widowed persons and never-married persons, and the death rates among widowed, never-married, and married persons.

NO. 2921, VOL. 116]

The Aeronautical Research Committee.¹

THE report of the Aeronautical Research Committee marks another milestone in the organisation of research in one of the comparatively newer fields. A study of this report, and the list of publications during the year, emphasises the progress that can be achieved by steady systematic team work.

Since the early days of aviation when the first bold pioneer steps were taken, there is scarcely a single outstanding achievement to the credit of any individual worker comparable with those that have occurred in other fields of scientific inquiry, and yet the progress that has been made is little short of wonderful. The modern aeroplane has acquired characteristics of speed and agility, stability and control, load-carrying capacity and strength of structure, a beauty of outline and a cleanness of design, that marks it out almost as belonging to a different species from its prehistoric ancestor of only twenty years ago. It is no criticism of the band of aeronautical enthusiasts to say that much of this result has been achieved in the main by the direct adaptation of well-recognised scientific knowledge and methods to a definite concrete end. An examination of the work of the Aeronautical Research Committee shows, in fact, that the main impetus has been received not so much from any specific first-class discovery of a purely aeronautical nature, but from the large number of points of contact the subject possesses with other branches of science.

Broadly speaking, the matter dealt with by the Committee on the technical side groups itself under the triple interlocking headings of 'aerodynamics, power, and materials, each of which embodies a network of specialised inquiry. Decentralisation is effected by six sub-committees, namely, aerodynamics, engine, materials and chemistry, accidents investigation, air transport, and structures. The separate branches of the work in each sub-committee are then dealt with in an appropriate panel of that sub-committee. The aerodynamics sub-committee, for example, has separate panels dealing with design, stability and control, airscrews, and sea-planes, while the materials and chemistry sub-committee branches out into panels on elasticity and fatigue, light alloys, fabrics and dopes.

A glance at this scheme of subdivision indicates the extensive range of subjects that bear directly on the specifically aeronautical field, and contribute towards its development. It is evident that the design and organisation of this scheme has been achieved only as a result of careful thought and mature experience. In itself it is an experiment in the organisation of research that is well worth study, while its success is borne out

¹ Report of the Aeronautical Research Committee for the Year 1924-1925. Pp. 44. (London: H.M. Stationery Office, 1925.) 1s. 6d. net

by the imposing list of concrete advances that are recorded in each annual report.

Among the numerous important papers that have been published by the Committee during the present year, an interesting feature is the rapid progress that is at last being made in the prediction of aerofoil performance. Until the development of the Prandtl vortex-theory, an impasse on the theoretical side of this subject had for all practical purposes been reached, and progress in aerofoil design was only to be sought by steady systematic, if arduous, wind channel tests. The development of the Prandtl vortex theory, unsatisfactory as it is in certain respects from an abstract theoretical point of view, has opened the way to classification of aerofoils and allied parts and prediction of performance to a remarkable degree of accuracy. The most recent investigations seem to suggest that even the aerodynamically complicated airscrew will yield up its properties to this remarkable theory.

One of the more important aeronautical problems of recent years is that associated with controllability, especially at low speeds or during stalling. As a result of investigations by the stability and control panel, the characteristics required in an aeroplane to make it controllable when stalled are now understood, and it has been demonstrated that these characteristics can be introduced by means of practical modifications in the organs of control. It appears that conventional aeroplanes are defective in two respects: they have insufficient rudder power, and the ailerons, when applied, effect a turning of the aeroplane and in so doing neutralise their direct effect on roll. It has been found by analysis, and verified by experiment, that either an increase of rudder power or the use of an aileron which does not turn the aeroplane would provide the pilot with sufficient power to regain an even keel from any position and so obviate the fatal spinning dive. The most successful device so far developed seems to be a combination of a Handley Page slot on the leading edge in conjunction with a balanced aileron of the Bristol-Frise type. This advance towards the elimination of one of the most potent causes of accidents is extremely encouraging.

In the actual constitution of the Aeronautical Research Committee, a change has this year been introduced which is likely to have a profound effect on the nature of the researches which are inaugurated. Future membership of the Committee is to be confined solely to members appointed in virtue of their scientific standing rather than as representatives of definite interests, such as, for example, the Society of British Aircraft Constructors. This change goes hand in hand with a modification in the nature of the duties of the Committee, which in future is to advise the Secretary

of State for Air on scientific matters relating to aeronautics rather than on scientific and technical problems relating merely to the construction and navigation of aircraft. In view of the fact that one of the functions of the Committee is to supervise the aeronautical research at the National Physical Laboratory, it will be obvious how far-reaching this change may be in determining the nature and trend of that research.

The work of the Committee is not confined to that conducted at the recognised research stations. Grants amounting to 1500*l.* have been made to enable individual workers to pursue a number of special investigations—experimental research on redundant structures, wind tunnel and theoretical research on skin friction and on the problem of control at low speeds. A sum of 1000*l.* will be available for a similar purpose during 1925–26. From the point of view of widening the field of interested researchers in aeronautical science, no better method could be adopted. It would be interesting to know, however, what machinery there is, if any, for ensuring that such detached workers maintain sufficiently effective contact with the main body of work in progress in aeronautical inquiries adjacent to their own, as the interval between completion of an investigation and publication by H.M. Stationery Office of the numerous R. and M. Reports is often considerable.

Without the financial backing of the Air Ministry, it is evident that the greater part of this extremely valuable scientific work would never have been undertaken at this stage. In the days of its inception, the activities of the Aeronautical Research Committee were naturally dominated largely by military considerations. At the close of the War, when the need for an impetus to commercial aviation became apparent, the nature of these considerations underwent a gradual transformation. The latest orientation of the Committee, where it has practically thrown off the necessity for concentration on problems either of immediate military or of commercial utility, while still retaining intimate contact with both these spheres, is a great achievement for the scientific outlook. It was, moreover, inevitable.

Solar Sophistry.

Le Soleil: ses phénomènes les plus importants, leur littérature et leur explication. Par A. Brester, Jz. Préparé à la publication par les soins du Dr. T. van Lohuizen. Pp. iv+315. (La Haye: W. P. van Stockum et fils, 1924.) n.p.

DR. BRESTER died on June 25, 1919, and this great monograph with pages 9½ by 11¾ inches, is published after his death by his wife and daughter, and is edited by Dr. T. van Lohuizen. It would, therefore, be unseemly to criticise any defects in the

printing or accessories of the book. But since the author continually elaborated one fundamental theory, during the thirty years that he devoted to the making of the book, if this theory was wrong initially, he had time enough to go very far wrong indeed.

The theory is one that no solar observer could entertain for a moment, for it is this: that the sun is in a state of absolute calm; that there is a complete absence of all radial convective movements; that the different vapours in the photosphere and chromosphere are in a stratification that is invariable and undisturbed by currents; that the prominences are not eruptions—*ever*, they are entirely tranquil in spite of their seeming movements, whether these be outwards from the sun radially or in the line of sight; that the spots differ in no wise in temperature from the photosphere in which they appear. But it was Dr. Brester's pride that "this theory has been elaborated, not by some astronomer who has made observations all his life, but by an amateur theorist, who has never made any observations at all." For, he says, astronomers have chosen a method (by observation) for getting their knowledge of the constitution of the sun,

"which is still too imperfect to allow them to elaborate a solar theory. And, besides, since astronomers are eminently patient scholars, finding an entire satisfaction in the production of observations, letting themselves be delayed or even turned aside willingly by their noble ambition to discover new facts, they occupy themselves rather with the 'How' than with the 'Why' of the phenomena, and, in short, they work above all for posterity. But the amateur theorist is in more of a hurry. He has only a very mild interest in posterity . . . and not being in the conditions in which he can make observations, he can give all his time and energy to the more interesting task of interpreting other people's observations, and it is thus . . . that *this* theory has been able to be built up"

In this year, 1925, six years only after Dr. Brester completed the writing of this book, posterity, in the form of a solar observer, can judge of Dr. Brester's method of interpreting astronomical observation, and can come to a fair conclusion as to whether his "hurried Why" is legitimately based on the astronomers' "patient How." Such is the purpose of the following criticisms.

In the very beginning, in his introduction, the author falls foul of "Kirchhoff's law" and "Doppler's principle." He seems to think that physicists apply this principle blindly, and he complains that Kirchhoff's law has become "an excessively dangerous guide" since "it can only have reference to calorific rays," and "the luminosity of a gas does not necessarily depend upon temperature, but more often upon a *luminescence* which is independent of temperature and results directly from chemical or electrical phenomena

in the luminous gas," and yet "the great majority of astronomers have never taken this sufficiently seriously." So he both uses and abuses the Doppler principle when giving^a an account of how the solar rotation is evidenced in the region of the reversing layer by the displacement of lines at the east and west limbs. These displacements are small and often very discordant, so he mentions four reasons that are usually accepted as explaining this, but urges most strongly a fifth of his own: "It seems due also to a *tenacious prejudice* that all the rays of the reversing layer ought to give the same rotation, and if they do not in fact do so, their mean will correspond to the real rotation."

Therefore, in accordance with this fifth reason, the author feels justified in dismissing observations of great weight, and accepting observations which the astronomers who made them deemed of little weight (as being few in number or made under bad conditions), because the former did not, and the latter did agree with what his theory set forth as to what the solar rotation should be. So he puts on one side the work done by Hastings, Young or Langley, and asserts that the measurement of spectral displacements only became of importance when Crew, in 1888, found from 10 chromospheric rays a slight polar acceleration instead of the polar retardation found by Carrington from sun-spots. But Brester complains that though Crew's measures were obviously insufficient and his conclusion carried no weight with solar astronomers, yet "this conclusion responded so well to my ideas, that I at once made it a principal foundation of my theory."

That is indeed the author's test of observation; on the plea of *tenacious prejudice* on the part of astronomers, a bad observation is admitted if it agrees with his ideas, a good observation incontinently rejected if it does not. In such a fashion he judges Dunér, Halm, and especially Adams. The latter's work published in 1907 Brester dismisses as of no account; that published in 1908, he declares, "gave a definitive solution to the problem," for the displacement of the H_α ray proved "that the rotation of the hydrogen atmosphere is precisely, as I had already described it in 1892, that is to say uniformly without polar retardation." In 1906-1907, also, Adams used 20 lines the displacement of which east and west were measured at 12 different latitudes, and, to Brester's indignation, he took the mean of these 20 lines in order to determine the variation of rotation with latitude, because their mean showed a polar retardation similar to that shown for the iron lines by Dunér. Still worse, Adams re-measured them in 1908, and in the case of the iron line 4291, which had previously given an *acceleration* of $0^{\circ} \cdot 54$ for latitudes 60° - 80° , he now found a *retardation* of $1^{\circ} \cdot 11$,

Yet, Dr. Brester says, Adams considers the 1908 observations as "probably better" than those of 1907. Indeed, the author shows so little appreciation of the conditions of measurement that he does not perceive that so close to the solar poles, the accidental errors are so large in measurement that any such differences are negligible.

Such criticism as Dr. Brester makes of Adams's spectroscopic work may perhaps be dismissed, as due to invincible obscurantism. Not so his habit of selecting only the observations which suit his theory, and ignoring in that connexion any that do not accord with it, even though these latter may be the special feature of the paper the authority of which he quotes. For example, in his section on the tranquillity of the reversing layer, he cites in proof of this a paper by Prof. Newall in the *Monthly Notices of the Royal Astronomical Society* for January 1907, that "*during the summer of 1906, which was a time of great solar activity, Newall and Hubrecht observed minutely the solar spectrum especially to try to discover any sign of movement; but they found not the smallest indication*" [the italics are Dr. Brester's]; "and it is therefore evident that the reversing layer, even during the period of spot maximum, is never traversed by such terrible radial currents as the partisans of the hypothesis of solar eruptions have always supposed." But the very point of this paper of Prof. Newall's was to emphasise that the year 1906 was abnormal in being quiet, since at the corresponding period of solar activity eleven years previously in 1895, the radial movements were very violent, as is usual at sunspot maximum.

Again and again, if we consult the authorities that Dr. Brester quotes, we find that he adopts this line of treatment: he suppresses all evidence that goes against his theory, and wrenches from its context anything that might, if isolated, appear to confirm it. One other example may suffice. On p. 143 he cites a note in the *Journal of the British Astronomical Association* for November 1916 by Prof. Eddington on "The Radiative Equilibrium of the Stars" to show "that it is wrong what every astronomer thought until quite recently, that convective currents are necessary to convey the heat from the centre to the surface." This is but a minor point in Prof. Eddington's work (though he does not affirm that convective currents play no part anywhere on the sun), but his main theme was that radiation-pressure plays a fundamental part in maintaining the radiative equilibrium of the sun and stars. Of this main theme, Dr. Brester makes no mention at all until p. 158, when he says we know of two forces which can have the effect of opposing gravity (where this is not great) at the sun's surface: (1) the pressure of radiation, and (2) the pressure of electrons continually projected from the whole solar

surface. It is the second, his *electro-luminescent* theory, to which he continually returns during the remainder of the volume, and by this he explains the prominences, quiescent or eruptive, and the corona. The first he ignores except by a single phrase, "an impossible effect of radiation-pressure," on p. 233.

Dr. Brester read much: his *Index Bibliographique* occupies nearly fifty pages; but the above are samples of how he treats his authorities. In his reasoning on evidence, he is not even consistent with himself. He defines a facula as a blister, and a spot as the bursting of this blister; to explain the east over west predominance of sunspots, he assumes that all faculae burst on their preceding side (p. 188); to explain the fact that magnetic storms occur as a rule after the spots with which they are connected have passed the central meridian, he assumes that all faculae burst on their following side (p. 210).

After all, astronomers are right in working for posterity, since it is by the verdict of posterity that any theory stands or falls.

Rapid Air Surveys.

Aerial Surveying by Rapid Methods. By Prof. Bennett Melvill Jones and Major J. C. Griffiths. Pp. xvi+159+26 plates. (Cambridge: At the University Press, 1925.) 16s. net.

IN the course of the operations during the War in Palestine, it was found that a very practicable method of making maps was to take a series of air-photographs in long, straight strips, forming a framework of triangles, or other figures; the detail inside these strips of photographs being filled in by photographs taken in parallel flights, so close together that the photographs overlapped. In this system, instead of having three or four points on each photograph, of which the relative positions were accurately fixed, it was possible to work from points fixed at very wide intervals; instead of having four fixed points a square mile, let us say, it was possible to construct a very fairly accurate map with three or four fixed points in a hundred square miles, or even less. It was on this system that the map of Palestine was built up on the scale of 1:40,000.

The experience gained by Capt. Hamshaw Thomas, in making this flying map of Palestine, seemed to be applicable to civil uses, and the problem was taken up at Cambridge by Prof. Melvill Jones and the late Major J. C. Griffiths. The piloting was throughout in the hands of Flight-Lieutenant F. H. Coleman, Flying-Officer C. E. H. Allan, and Flight-Lieutenant D. L. Blackford. Those carrying out the experiments were always in close touch with Capt. Thomas. The investigations

were commenced in the autumn of 1920, and by the spring of 1923 enough had been done to justify the publication of the results and conclusions. Prof. Melvill Jones and Major Griffiths collaborated in the preparation of the book under review, but, alas! in October 1923, Major Griffiths was accidentally killed whilst flying at Coventry, and it has remained for Prof. Melvill Jones to complete the book alone.

The essence of the method described is the flying in straight courses, at a uniform height above ground, with wings level. Pioneer investigations of this kind must have a beginning, and the choice of the fairly flat country near Cambridge as a site for the experiments was a very wise one. It was certainly not desirable to complicate the problems involved by experimenting in a mountainous region. For it was not only desired to ascertain what accuracy could be reached, but also to examine into the character of the errors involved in the process, and to determine what kind of training was necessary—for the success of the method chiefly depends upon the pilot.

In the flying, one of the chief necessities is to cover the ground with photographs without any gaps, and the best way to effect this is to take the photographs during a series of parallel, straight flights. The book describes very clearly the difficulties that are met with in trying to accomplish this; not the least being the effect of horizontal acceleration in altering the pilot's estimation of the vertical. Then we have the necessity of flying over selected lines, the effect of the roll of the aeroplane, and so on. The method actually used was that the pilot "should bring his aeroplane accurately over a given point at the start of the photographic flight and, henceforward, proceed in the required direction by compass . . . without reference to the ground." It is abundantly clear that only specially trained men are likely to be successful.

As to the making of the map, the photographs are uncorrected, and are fitted together by an ingenious system which is fully described. The height of the aeroplane was usually about 10,000 feet above the ground; if local differences in level do not greatly exceed one-twentieth of the height of the aeroplane—say 500 feet in this case—the map is not seriously affected. Photographs were taken for these experiments over the Bedford level, and the tilt, azimuth, and height were determined, in order to study the elements of error. A series of most interesting diagrams is given, showing in eleven cases the actual plan of the track, the variations in azimuth of the aeroplane, its fore-and-aft and lateral tilts, and its variations in height. The net result is that it is possible to fly an aeroplane so that the tilt shall seldom exceed 2° , whilst the height seldom varies more than 100 feet from the mean value. The

lens usually employed in the camera had a focal length of 6 inches, so that the scale of the photographs was about 1 : 20,000. Attached to the book is the resulting "mosaic" of 225 square miles on the reduced scale of 1.53 inches to 1 mile. As to the errors of the mosaic, a ten-mile square mosaic, of flattish country, should not show positional errors, when "fitted" to an accurate map, of more than a hundred yards.

A long chapter deals with navigational mapping and the joining up of mosaics. There are also excellent chapters on equipment and training, and useful mathematical appendices. It is an indispensable book for those interested in the subject of air survey.

C. F. C.

The Aborigines of Central and North Australia.

The Australian Aboriginal. By Dr. Herbert Basedow. Pp. xx+422+56 plates. (Adelaide: F. W. Preece and Sons, 1925.) 30s.

DR. H. BASEDOW has had exceptional opportunities for studying the mode of life and the customs of the aborigines of Australia, since in the exercise of his duties as State Geologist, and later as Chief Medical Officer and Chief Protector of the Aborigines for the Commonwealth Government in the Northern Territory, he has travelled widely and come into intimate contact with the natives. He has published a few papers on the anthropology of the Australians, and now presents us with a more comprehensive account of his observations on the natives, mainly of those of the Northern Territory. For reasons which he states in the preface, he has not consulted the previous literature, and thus he goes over ground which has been well covered by Spencer and Gillen in "Native Tribes of Central Australia" and "Across Australia," and by Spencer in "Native Tribes of Northern Territory." The reader therefore has to compare these four volumes in order to see where they agree and where differences occur, and in the latter case he will have to make up his own mind which is the better version.

The volume affords an excellent general survey of the ordinary life of the native, and where necessary the differences between various tribes are pointed out. The racial characteristics are dealt with fairly fully, but no measurements are given. The chapter on the "Likely Origin of the Australian Aboriginal" is by no means so satisfactory. The accounts of various mutilations and other subjects which would appeal to a medical observer are of value. The section dealing with social organisation is weak and of no interest to a student, and that on language is not much better;

the author does not appear to be acquainted with the work of Pater W. Schmidt.

There are some valuable suggestions in the chapter on religious ideas. Although phallic emblems have been found in various parts of Australia, the author claims that he was the first to observe ceremonies connected therewith. He says:

"One often reads, and I was under the same impression myself until I became better acquainted with the tribes, that the Australian natives do not connect the knowledge of conception with any intercourse which might have taken place between the sexes. This I find is not altogether correct, although usually the younger people are kept in complete ignorance of the subject. No doubt strangers are treated similarly when they put any pertinent questions to the old men on matters of sex. The old men believe in the duality of human creation, the spiritual and the material; sexuality is regarded as the stimulus of corporeal reproduction, but the spirit quantity is derived through mystic and abstract influences controlled by a 'totem'-spirit or Knaninja" (pp. 284-5).

Carveth Read says: "So far as ignorance exists, it is due to repression by opposing doctrines and desires" (Journ. Roy. Anthropol. Inst., 1918), and the psycho-analytic view has recently been stated by Roheim in "Australian Totemism." The author gives some information about the manufacture of stone implements.

The best chapter in the work is that on aboriginal art, in which the author gives numerous illustrations and elucidates the meanings of the designs; it will be seen by comparing these with the explanations given by Sir Baldwin Spencer that the same design may have several interpretations. The book is well illustrated, and it will have a lasting value as a record of the investigations of an independent observer. A. C. H.

The Mystery of Rhythm.

What is Rhythm? An Essay. By Prof. E. A. Sonnenschein. Accompanied by an Appendix on Experimental Syllable-Measurement, in which Stephen Jones and Eileen Macleod have co-operated. Pp. viii + 228. (Oxford: Basil Blackwell, 1925.) 10s 6d net.

PROF. SONNENSCHIEIN has made a substantial contribution to the subject of rhythm. There are very few persons who could have written this book, which shows a scholarly familiarity with the verse of many languages, with music, with phonetics, and with psychology.

In Chap. i. Prof. Sonnenschein leads up to a definition of rhythm by way of a discussion of the definitions offered by his forerunners—a discussion which brings home to the reader how necessary it is in all branches of exact knowledge to define our terms, if we are to

avoid confusion of thought. Not a few controversies have arisen through a want of clearness, or from ambiguity in the essential terms used in the debate itself. Prof. Sonnenschein's definition is a development and, as we think, an improvement of that of the Greeks; it reads:

"Rhythm is that property of a sequence of events in time which produces on the mind of the observer the impression of proportion between the durations of the several events or groups of events of which the sequence is composed."

This is comprehensive; and it stands the "pragmatic test" when applied to various manifestations of rhythm dealt with in the subsequent chapters—rhythm in music, in isosyllabic verse, in Greek, Latin, French, and English verse. In all these fields Prof. Sonnenschein shows a wealth of learning and a minute acquaintance with previous research which commands the respect of the reader.

In his treatment of English verse the author strikes out on original lines, but a pleasing feature of his writing is its urbanity of tone.

The "war of the prosodists" has become a by-word: Prof. Sonnenschein, however, in differing from Dr. W. Thomson, Prof. Saintsbury, and the Poet Laureate, does so with moderation and courtesy. The most original and distinctive feature of his theory of English verse is that it is based on experimental observations, for he has measured the actual durations of the vowel sounds and of the consonantal sounds in hundredths of a second by means of the well-known physiological recording instrument, the kymograph. In this research Prof. Sonnenschein has been helped by the Superintendent of the Phonetics Laboratory at University College, London.

The results are summarised in Chap. viii.—"Syllable Measurement in English"—where we find simple and intelligible rules of quantity in English syllables based on the distinction between the relatively short and the relatively long, and analogous to the rules of quantity with which every schoolboy ought to be familiar in his Greek and Latin. Phoneticians and prosodists alike will have to study these experimental results, since they place the whole matter on an objective and statistical basis.

A shorter if less exact definition given is—"Rhythm is a recurrence of similar phenomena at regular intervals of time." This excellent "working" definition rules out of court the so-called "irregular" rhythms, which are, strictly speaking, contradictions in terms.

We venture to think that this treatise would have been made still more interesting and "popular" in the best sense of the word if, in an introductory chapter, the author had alluded to some of the rhythms in

Nature—the rhythms of the heavenly bodies, and the rhythms of the earthly. Rhythm rules in the interstellar spaces, rhythm throbs through living beings. A study of these cosmic and vital rhythms, respectively, teaches us that the absolute time-interval between the “events” is not of the essence of rhythmicity; for there is as true a rhythm in the return of a comet or the repetition of an eclipse, which involves years, as there is in the rhythm of the beating heart where, between successive systoles, there are only a few fractions of a second.

There is much to interest the psychologist in Prof. Sonnenschein's treatise, while the physiologist can learn something in it about the physics of speech. It would not be true to say that this book is easy to read, no work involving so much detail about a not very familiar subject could possibly be easy to read: but it is an enduring monument to the patience, the scholarship, and the fine appreciation of music and poetry on the part of the former professor of Greek and Latin in the University of Birmingham

D FRASER HARRIS.

Our Bookshelf

(1) *Fishes* By David Starr Jordan. Revised edition. Pp xv+773+18 plates (New York and London: D. Appleton and Co., 1925.) 30s net.

(2) *The Fishes of the British Isles, both Fresh Water and Salt* By Dr J Travis Jenkins (Wayside and Woodland Series.) Pp vii+376+143 plates. (London and New York: Frederick Warne and Co., Ltd., 1925.) 12s 6d. net.

(1) D. JORDAN's book on fishes, in two volumes, issued in 1904, was reviewed in NATURE soon after it appeared (vol 72, p. 625, October 26, 1905). The present work, in one volume, does not call for an extended notice, as it differs from the former one only in the omission of certain chapters or sections of chapters. Of the thirty-five chapters in the first volume of the 1904 edition, eighteen have been left out entirely, and parts of four others; but nearly the whole of the second volume is retained. The book has evidently been reprinted from standing type and to describe it as a revised edition is misleading. There is one new paragraph (p. 184) inserted because the fitting together of parts of two chapters of the original book left a space that had to be filled; this paragraph refers to the recent discovery of a rudimentary sixth gill-arch in *Heterodontus*, and includes the statement that “the presence of five species in the *Squalidae* perhaps indicates affinity with *Heterodontus*”, here “five species” should obviously be “fin-spines”.

(2) There is no modern work on British fishes, and Dr. Jenkins has attempted to supply this need by producing what is described as a handy pocket volume, dealing with the characteristics and habits of British fishes, both fresh-water and salt. The book is illustrated by so many as 143 plates, nearly half of which are coloured; most of the coloured representations of

marine fish are reproduced from Smitt's “Scandinavian Fishes,” and most of those of the fresh-water species from Grote, Vogt and Hofer's “Fresh-water Fishes of Central Europe.” A number of the uncoloured figures are taken from Day's “Fishes of Great Britain and Ireland”; some of these are good and some rather poor, for although all the plates in this work were inscribed as drawn by Day, he employed two lithographers, one of whom was far superior to the other.

With the aid of the illustrations, and of the short diagnoses given by the author, the owner of Dr Jenkins's book should be able to identify any fish he is likely to catch in British waters; having done so, he will find a certain amount of information about it, which may or may not include what he wants to know, as the treatment of the different species is rather unequal. In general it is the important food-fishes, such as the herring, cod, and plaice, that are most fully dealt with, and it is in his account of these that the author is most convincing.

The classification is nearly that of Gunther's Catalogue, it is a little surprising to find a modern work on fishes beginning with the perch and ending with the *Chimæridæ*—these, we are told, “connect the cartilaginous fishes (Sharks and Rays) with the Ganoids (Sturgeons).” Even in the arrangement of the species there is often no regard to relationships: for example, the coal-fish and pollack are separated by the whiting, and the skate and the long-nosed skate by the bottlenosed ray. This is, in our opinion, the most serious defect of the book.

C. T. R.

Reports of the Progress of Applied Chemistry Issued by the Society of Chemical Industry Vol 9, 1924. Pp 700. (London: Society of Chemical Industry, 1925.) 7s. 6d., to non-members, 12s. 6d.

THE ninth volume of these reports follows closely on the lines of preceding issues; it contains eighty more pages than the report for 1923, a report on the non-ferrous metals is not included, but that on photographic materials and processes makes a welcome reappearance. The occurrence of such slight changes suggests that, on occasion, nothing is lost by making a report cover a longer period than one year. Space is saved, and the writer has a better chance to delineate the wood as well as the trees. Although the mass of material dealt with in each report is always great, the actual progress achieved is by no means always proportionate. In reading these reports, one is struck by the prodigious activity of those who are working to harness chemistry to industrial uses—in the present report, well over 3000 names appear in the name-index—and for this reason it is obviously impossible to give more than a cursory survey of most of the subjects treated. If the present increase in output continues, the annual volume will soon become unwieldy, and something in the nature of a quinquennial revaluation and digest will be called for, but the work of condensation would not be easy, as writers of the calibre of Hazlitt (who condensed seven volumes of Tucker's “Light of Nature Pursued” into one) are not common in the chemical profession. On the whole, it would appear better to issue such summaries in the form of monographs—a practice which has found favour in Germany.

No serious student of chemical technology can fail

to be interested in one or more of these excellent reports, the diversity in length of which varies far more than their merits. The report on plant and machinery is usually the least meritorious, mainly because sketches and diagrams are always omitted. This year the reporter has succeeded in infusing some life into the subject, although in doing so he has had to go a little outside his proper ambit. Among the subjects of up-to-date and general interest treated in the other reports are: low-temperature carbonisation, nitrogen-fixation (discussed by four writers), insecticides (a new and valuable feature), vitamins, preservatives in food-stuffs, and cinematography. Misspelt words are rather more numerous than one would expect in a work of this standing (e.g. "contributions" in lieu of "contributors" on the page facing the Contents, "molton," p. 57, "ashphalt," p. 99, "napthalene," p. 108); the use or non-use of hyphens is somewhat erratic (e.g. "cheap zinc blende acid," p. 180); and future issues might well include a list of the full titles of the journals referred to in the text, as some of them are little known and difficult to obtain.

Thamyris: or, Is there a Future for Poetry? By R. C. Trevelyan. (To-day and To-morrow Series.) Pp. v + 89. (London: Kegan Paul and Co., Ltd.; New York: E. P. Dutton and Co., n.d.) 2s. 6d.

MR. TREVELYAN has written a careful and penetrating study of the present position of poetry, and of its possible—he is too hesitant to justify the word probable—development in the future. Superficially, the prospect is not hopeful. The dissociation of poetry from music and intonation, and the fact that poetry uttered to-day is spoken, not sung, coupled with the further fact that it is usually not uttered at all but silently read, cannot but have the effect of impairing the force of its emotional and purely sensuous appeal. The growth of the scientific habit of mind, expressing itself in prose as its appropriate medium, and the competition of the cinemas and broadcasting, are further influences tending to the supersession of poetry as the normal method of emotional communication between man and man.

At the same time, Mr. Trevelyan contends, poetry fulfils a function, which, so long as the heart of man remains fundamentally unchanged, will lead him still to find the satisfaction of certain ideal and imaginative needs in poetry, whatever may happen to his head. As opposed to prose, which depends for its significance primarily upon the intellectual content of the matter communicated, the value of poetry resides in the beauty of the medium itself, so that if poetry were proscribed by Act of Parliament, we should find ourselves trying to make shift with a clumsy substitute for it in the form of rhythmical prose.

The danger to poetry, which, driven off the popular stage by music, hurry, and the cinema, is forced to make its appeal to the cultured and leisured few, is that it should become precious and obscure, seeking in far-fetched allusiveness and merely verbal nicety to compensate for its divorce from the flowing stream of popular life. This danger, already manifest to-day, is likely to grow in the future, unless poets can find a new source of inspiration in the changing needs and interests of the time and the new aspects of the world revealed by modern science.

Industrial Poisons in the United States. By Prof. Alice Hamilton. Pp. x + 590. (New York: The Macmillan Co., 1925.) 21s. net.

DR. HAMILTON writes with the authority which comes from great experience of diseases arising from the manufacture and use of poisonous substances, and it is satisfactory to learn from her that, on the whole, the incidence of such diseases is diminishing.

More than one-third of the book is devoted to lead poisoning; a good account is given of the industrial processes in which this hazard is experienced, the toxic symptoms are fully discussed, and the numerous controversial points are stated fairly and reasonably. The other inorganic poisons are dealt with similarly, and it is interesting to note that most of the modern industries have brought in their train new problems of this kind. Thus the alloys required for special steels have introduced manganese and vanadium poisoning, and the Mond nickel process has led to poisoning cases with nickel carbonyl.

Both in Great Britain and the United States the development of the fine chemical industry has brought the industrial physician into contact with new problems due to the toxicity of raw materials and intermediates used in producing dyes and explosives, and if the chemist is to help him in solving these, it is important that they should understand each other. Dr. Hamilton, unlike many of her medical colleagues, is reasonably familiar with chemical processes; rarely does she fail to use the tribal language of the chemist accurately, and she always translates factory slang into English. Even the academic chemist can, therefore, read this work with pleasure and profit, and if he is inclined to assist in biological and pathological investigations, he will find many problems suggested to him in its pages.

The author refers so constantly to European, and especially to British literature on this subject, that the book might well have been called "Industrial Poisons" without the geographical limitation implied in its present title. The one exceptional substance is "wood spirit," which is probably an industrial poison only in the United States, and that for peculiar and well-understood reasons.

T. A. H.

Ionisation et résonance des gaz et des vapeurs. Par Dr. Léon Bloch. (Recueil des Conférences-Rapports de documentation sur la Physique. Vol. 11, 2^e Série. Édité par la Société *Journal de Physique*.) Pp. 223. (Paris: Les Presses universitaires de France, 1925.) 25 francs.

IN few subjects is the difficulty of interpretation of the experimental evidence greater than in that which deals with the resonance and ionisation potentials of gases. It is, however, of such importance to the theory of atomic structure that a clear and critical survey of its present stage of development is to be welcomed. Such an account is to be found in the volume under notice. Prof. Bloch is well aware of the many pitfalls which beset the path of the experimenter and of the danger of too much speculation on too slender an experimental basis. He insists, again and again, on the fact that, without spectroscopic confirmation, the interpretation of the electrical measurements must always be somewhat uncertain.

The early chapters deal with the experimental

technique and the measurements of monatomic gases and vapours. It is here that the greatest success has been achieved in the association of critical potentials with the single line, double line, arc and spark spectra. Of particular interest is the evidence for the existence of atoms in metastable states. The possibility of a change from one state to another slightly less stable is likely to prove one of the most helpful ideas in the interpretation of both critical potentials and spectra. The diatomic gases present a much more difficult problem, as these molecules may dissociate or be disturbed in so many different ways.

The final chapters deal with the photoelectric effect and the statistical equilibrium between atoms, electrons, and radiation. The author points out the ever-increasing importance of the Wilson track photographs in this field. This volume, which forms the eleventh of the series of monographs issued under the auspices of La Société *Journal de Physique*, fully maintains the high standard set by its predecessors.

Forme della terra. Trattato di geologia morfologica (Geomorfologia). By Prof. Gaetano Rovereto. Vol. 1: *Basi e generalità.* Pp. xv + 641 + 16 tavole. Vol. 2: *Tipi regionali.* Pp. viii + 645 + 1188 + 22 tavole. (Milano: Ulrico Hoepli, 1924-25.) 150 lire.

PROF. ROVERETO, of the University of Genoa, has prepared an elaborate and beautifully illustrated textbook of geo-morphology which should be of wide service to geologists and geographers, owing to its authoritative account of the physical geology of Italy, its copious bibliographies thereon, and its clear explanation of Italian geological terminology. It also includes a wide selection of references to the cosmopolitan literature on the subject. As might be expected from the previous contributions of the author, the volume draws many illustrations from South America, and the section on mountain structure, which is illustrated by an instructive map of the tectonic divisions of Italy, is of especial interest.

The first volume deals with the general principles and processes of physical geology, and the second describes the chief regional types due to them, including coast lands, volcanic regions, glaciated areas, karsts and deserts, plains and mountains. The classifications adopted are in many cases more artificial and elaborate than those used by British geographers, but the book should be the standard authority in Italy, and elsewhere a convenient work of reference to recent work on the exceptionally interesting geography of the Italian peninsula.

The Vegetation of Burma from an Ecological Standpoint. By Prof. L. Dudley Stamp. (University of Rangoon Research Monographs, No. 1.) Pp. vi + 65 + 28 plates. (Calcutta: Thacker, Spink and Co., 1925.) 7 rupees.

THIS is one of the first presentations of a study of the vegetation of a British tropical dependency, based on present-day ecological methods. The author, in collaboration with Mr. Leslie Lord, has already given a more detailed study entitled "Part of the Riverine Tract of Burma." The present work shows this area in relation to the rest of the country and provides a general review of the distribution of the vegetation

and its controlling factors. Of these, the chief are elevation, climate, and geology and soil. A brief discussion is given of the effect of each of these, after which the author enumerates, with brief descriptions, the main types of vegetation and their natural relationships. These types are classed under mountain vegetation with six types and lowland vegetation with twenty-five types. Four seral medial stages are also noted. The inter-relationships of the types are graphically indicated in tabular form, where it is clearly seen that with a very high rainfall soil has little effect, but with a rainfall of 40 inches and less its influence is paramount. The discussion on geology and soils is in more detail, and the general relationship of geology and ecology is discussed and summarised in the concluding chapter. The book is accompanied by several maps reproduced as text figures, and is profusely illustrated with photographs of the various types of vegetation discussed.

An Introduction to Economic Geography. By Wellington D. Jones and Derwent S. Whittlessey. Vol. 1: *Natural Environment as related to Economic Life.* Pp. xxxvii + 375 + 225 plates + 7 maps. (Chicago: University of Chicago Press; London: Cambridge University Press, 1925.) 5 dollars.

IN spite of its large size, this book covers only a small part of economic geography. It claims to deal in outline with the several factors of the natural environment as they affect human life. A second volume is to treat of the chief economic activities in relation to natural environment. The plan of the book is novel. In the first part a number of exercises are set which the student is to work out by reference to the "textual materials" in the second part and the illustrations and maps in the third part. Atlases, topographic maps of the United States, and outline maps are also to be used. The textual materials are short paragraphs and extracts from authoritative works dealing with different aspects of the subject. The exercises are well planned, and the paragraphs in Part 2 are accurate and fairly representative, and the book may be regarded as a useful introduction to the subject. Examples are mainly drawn from America. Illustrations and maps are clear and well chosen, and a full index is provided.

Block Diagrams and other Graphic Methods used in Geology and Geography. By Prof. A. K. Lobeck. Pp. xi + 206. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1924.) 22s. 6d. net.

THE value of block diagrams in geographical and geological instruction cannot be questioned, but many teachers find these difficult to draw, especially on the blackboard, at short notice. Prof. Lobeck has written a volume that should prove most helpful and deserves to be widely known. By the help of several hundred diagrams and sketch maps, he explains the value of perspective and the construction of diagrams from maps and illustrations. Examples of various land forms are given, and it would be a dull teacher who fails to gain something advantageous from a study of the pages. Later chapters deal with isometric diagrams, sketching from photographs, and crystal drawing. Each step in the development of the art has a number of instructive practice exercises.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

An Early Reference to Mendel's Work.

THE rediscovery of Mendel's classic "Versuche über Pflanzen-Hybriden" must undoubtedly be attributed to the references made to it by Focke in his "Pflanzenmischlinge" (Berlin, 1881). As Dr. Iltis points out in his recent life of Mendel, the fresh movement towards crossing experiments at the end of last century inevitably sent workers to the "Pflanzenmischlinge," where, unless they were either hasty or careless, they could scarcely fail to come across one or more of the half-dozen references to Mendel's name. But how came Focke to light upon a paper which was so securely buried? Apparently Dr. Iltis propounded this question to Focke himself, who replied that he had come across it in the literature of 1870, but could not then say where. ("Auf Mendels Arbeit bin ich durch die Literatur der 70er Jahre aufmerksam geworden, kann aber nicht sagen, wo ich sie erwähnt gefunden habe"—Iltis' "Life of Mendel," p. 204).

I wish to suggest that the reference which escaped Focke's memory is to be found in H. Hoffmann's "Untersuchungen zur Bestimmung des Werthes von Species und Varietät," Giessen, 1869. On p. 136 of this work Hoffmann refers to Mendel's "sechsjährige Beobachtungen," though for him the point of most interest appears to have been the evidence that Pisum is generally self-fertilised. Mendel's results are dismissed in the brief sentence "Hybride besitzen die Neigung, in den folgenden Generationen in die Stammarten zurückzuschlagen." Prof. Hoffmann was evidently looking for something else.

It is worthy of note that he makes no mention of Mendel's experiments with Phaseolus, though a considerable part of his essay is taken up with his own experiments in growing and crossing different forms of this genus. These experiments of Hoffmann are discussed by Darwin in his "Cross- and Self-Fertilization" (2nd edition, 5th impression, p. 151), so that Darwin must have had in his hands a brochure which contained a reference to Mendel's work only four years after its publication. Valence Theories and the Magnetic Properties of Complex Salts.

NATURE of September 5, containing the letter of one of us and the courteous criticisms of Dr. Jackson, reached the library of the Institute at the very time that we were engaged in a task suggested in Dr. Jackson's note. When writing on July 23, we were of the belief that it would be impossible to explain magnetic anomalies in complex salts until detailed information should become available regarding the orientations of the orbital planes. It was the explanation given by Oseen¹ of Ingersoll's non-magnetic nickel which suggested to us that the problem might be simpler. It suggested that we need only to consider the number of electrons in certain levels associated with the central metal atom, and that we may, for the present purpose, disregard the matter of orientation.

¹ Zeit. f. Phys., 1925, 32, 940.

The Kossel and Lewis-Langmuir valence theories are a guide in determining the number of electrons which the central atom of the complex may obtain from or give to the groups or radicals in the compound. They have been used with success by several investigators to account for the behaviour of complex salts as electrolytes. We have made most use of a paper by Sidgwick,² but the reader should consult also the papers of Lowry,³ Spiers,⁴ and Brockman.⁵ The ideas of electron sharing, or rather the sharing of orbits, and of electron transfer are explained and illustrated with examples by Sidgwick. Here we shall merely list the number of electrons given to or taken from the central atom by the groups or radicals.

Each NH_3 , OH_2 , C_2O_4 and $\text{OC}(\text{NH}_2)_2$ adds 2 electrons, 1 by sharing and 1 by transfer.

The $\text{en} = \text{NH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ and $\text{pn} = \text{NH}_2\text{CH}_2\text{CH}(\text{NH}_2)\text{CH}_3$ groups add 4 electrons each.

Each univalent radical CN , NO_2 , Cl , SCN , etc., within the complex adds 1 electron by sharing. The same radicals outside of the complex remove 1 electron by transfer. Similarly, the divalent SO_3 and SO_4 each remove 2.

K and Na add one by transfer.

Finally, it can be deduced from the "octet" theory that CO contributes 2 electrons by sharing, and that NO , when it enters the complex, contributes 3, 1 by transfer and 2 by sharing.

We shall now apply this scheme of addition and removal to many of the salts which have been studied magnetically, considering first the diamagnetic salts of iron. The iron, with 26 electrons, in the salts $\text{K}_4\text{Fe}(\text{CN})_6$, $\text{Na}_3\text{Fe}(\text{CN})_5\text{NH}_3$, $\text{Na}_4\text{Fe}(\text{CN})_5\text{NO}_2$, $\text{Na}_2\text{Fe}(\text{CN})_5\text{NO}$, and $\text{Fe}(\text{CO})_5$ acquires 10 more, making 36 in all, and thus corresponds to the diamagnetic, rare gas krypton. The formula for another diamagnetic salt $\text{Na}_5\text{Fe}(\text{CN})_5\text{SO}_3$ does not seem to be correct from our present point of view. From this view-point, also, $\text{Na}_3\text{Fe}(\text{CN})_5\text{OH}_2$ should be diamagnetic. As mentioned in the previous letter we have had trouble with this salt, and some samples have been nearly neutral towards the magnet.

Next, consider the 64 cobalt compounds measured by Rosenbohm.⁶ All but two are diamagnetic. The two exceptions are so slightly paramagnetic that the magneton number may be taken to be zero. Disregarding 8 of these cobalt compounds which are, as Rosenbohm remarks, of doubtful composition, we find, in all cases, that the cobalt atom acquires 9 electrons and attains the krypton configuration of 36.

The same investigator measured three salts of ruthenium and two of rhodium. In these the metal atom takes on the configuration of xenon, atomic number 54, since ruthenium obtains 10 electrons and rhodium 9 from the attached groups and atoms. He found the salts of iridium and of quadrivalent platinum to be diamagnetic. Considerations such as the foregoing show that iridium, atomic number 77, and platinum, atomic number 78, acquire 9 and 8 electrons, respectively; thus achieving the configuration of neon with 86 electrons. Two of Rosenbohm's four platinum salts in which the metal appears to be divalent, indicate that 6 electrons are added, giving the configuration of polonium with 84 electrons. We do not care to venture an opinion as to the possibility of the polonium configuration; nor are we informed as to its magnetic properties.

It is interesting to note that $\text{Ni}(\text{CO})_4$, which, according to Oxley, is diamagnetic, and $\text{K}_3\text{Co}(\text{CN})_6$,

⁴ Chem. and Ind., 1923, 42, 534.

⁵ Chem. and Ind., 1924, 43, 756.

⁶ Zeit. f. phys. Chem., 1919, 93, 693.

which we found to be diamagnetic, both lead to the configuration of krypton. In concluding this discussion of the diamagnetic salts, it may be mentioned that the nearly diamagnetic substances KMnO_4 and $\text{K}_2\text{Cr}_2\text{O}_7$ yield the configuration of argon if each oxygen removes 2 electrons and each potassium adds 1.

A slightly different treatment is required in the case of salts giving magneton numbers which are not zero and are different, very often, from the numbers obtained with the simple salts. Let us assume the existence of stable configurations other than those of the rare gases and let us see how the magneton numbers we may expect agree with the experimental values. Consider the ferric compounds, $\text{K}_3\text{Fe}(\text{CN})_6$, $\text{Na}_2\text{Fe}(\text{CN})_5\text{NH}_3$, $\text{Na}_3\text{Fe}(\text{CN})_5\text{NO}_2$ and $\text{Na}_2\text{Fe}(\text{CN})_5\text{OH}_2$. In these salts the iron atom acquires 9 electrons. Taking liberties in the distribution of electrons among the levels, we may assign 5 of the 9 to the N level, thus making it complete with 8, and then we shall assign the remaining 4 to the M level, giving us 17 in all in that level. This is exactly as required by the Bohr scheme in divalent copper, and divalent copper shows 9 to 10 magnetons in its simple salts. This is in fair agreement with the magneton numbers we have assigned to most complex ferric salts, considering the uncertainties in our numbers and the still rather large uncertainties about the divalent copper ion.

Rosenbohm made observations on many chromium complex salts and found in general 19 magnetons. The central atom acquires 9 electrons. Assigning 5 to complete the N level of trivalent chromium, we have 4 left to add to the 11 already in the M level. This corresponds to the M level of divalent cobalt. Experimentally, the divalent cobalt ion in simple salts gives 24-25 magnetons, but it is apparently anomalous and we should expect 19, as indicated in Fig. 2 of Sommerfeld's paper, in which this anomaly is noted.

Seven of the nine nickel salts measured by Rosenbohm gave about 16 magnetons. The nickel atom obtains 10 electrons, which, added to its own 28, give the 38 corresponding to strontium. We have no magnetic data for strontium, but it is fair to infer that it is analogous to neutral calcium, which has been assigned 2 Bohr magnetons or 14.1 Weiss magnetons by Sommerfeld.

The copper salts of Rosenbohm gave 9 magnetons, and, according to the scheme proposed in this letter, the central atom gains 6 electrons. It will correspond to bromine of atomic number 35. Taking, again, the liberty of first filling up the N level with 8 electrons, we find 17 in the M level, as we do in simple divalent copper ion with its 9 magnetons.

It seems, then, that the chromium, nickel, and copper atoms can be just as "abnormal" in their complex salts as are those of iron, cobalt, and the others we have considered. The fact that we find in complex salts of chromium, nickel, and copper the same magneton numbers as in the simple salts, is due to the peculiarities or, perhaps better, to the orderliness of atomic structure and of the periodic system.

It is evident, if the assumptions which have been made can be maintained, that we have not only a solution of the problem of magnetic anomalies in complex salts, but also quantitative support for certain current theories of chemical valence.

Carnot's Cycle and the Efficiency of Heat Engines.

IN a paper on Carnot's Cycle and the Efficiency of Heat Engines, reported in *NATURE*, August 29, Dr. J. S. Haldane comes to the astonishing conclusion that "the Carnot cycle is radically inefficient" and gives a cycle of operations which has convinced him that the maximum efficiency of a heat engine is 50 per cent. Prof. A. W. Porter has already dealt with this claim in its more general aspects (*NATURE*, October 3), but it may be of interest to calculate directly the efficiency of Haldane's cycle and compare it with that of a Carnot cycle working between the same temperature limits.

Dr. Haldane takes a cylinder containing water and some aqueous vapour at the pressure corresponding to its temperature T_1 and carries out a cycle of operations consisting of three stages. (1) The temperature is raised to T_2 while the volume is kept constant. (2) The system is allowed to expand

FIG. 1.

adiabatically until the pressure has fallen to the original pressure p_1 . (3) It is brought into its original state by means only vaguely specified.

The nature of this cycle of operations will be gathered from Fig. 1.

With such a liquid-vapour system, a number of different cases are possible depending on the relative proportions of liquid and vapour, and on the temperature difference. We shall take a case (ABCD) in which complications in the calculation are reduced to a minimum.

We have then the following heat and work terms in the various stages.

(1) AB. Heat absorbed $\int_{T_1}^{T_2} C_p dT$. No work done.

(2) BC. Adiabatic expansion. Work done A . No heat absorbed.

(3) CD. Combination of infinitesimal isothermal and adiabatic stages. Heat absorbed $q = \int C_p^* dT$. Work done $-p_1 \Delta v$.

(4) DA. Isothermal condensation of vapour. Work done $-p_1 \Delta v$. Heat absorbed $-L$. (L = latent heat of vaporisation of liquid at T_1 .)

Equating the sum of the heat and work terms for the whole cycle to zero, we have :

$$\int_{T_1}^{T_2} C_v dT - L + q - (A - p_1 \Delta'v - p_1 \Delta''v) = 0.$$

The "efficiency" of the cycle in Dr. Haldane's reckoning, *i.e.* the ratio of the work obtained in the whole cycle to the heat absorbed in stage (1), is

$$E = \frac{A - p_1 \Delta'v - p_1 \Delta''v}{\int_{T_1}^{T_2} C_v dT} = 1 - \frac{L}{\int_{T_1}^{T_2} C_v dT} + \frac{q}{\int_{T_1}^{T_2} C_v dT}.$$

Neglecting the third term, we have, to a first approximation,

$$E = 1 - \frac{L}{C_v(T_2 - T_1)}.$$

For water L is of the order of 540 calories per gram, C_v about 1 cal., therefore a temperature difference of about 1000° would be required for 50 per cent efficiency. The efficiency of a Carnot cycle working between the same temperature difference, for a cold

body temperature of 300° K, would be $\frac{1300 - 300}{1300} = 77$

per cent. Dr. Haldane's cycle is therefore, in this case, considerably less efficient than Carnot's.

Hermaphroditism in the Portuguese Oyster.

THE Portuguese oyster, *Ostrea (Gryphæa) angulata*, has been studied by many investigators, among others M. Bouchon-Brandley (1882), J. A. Ryder (1882), and J. L. Dantan (1912, 1914, 1918), but no one has ever recorded the occurrence of hermaphroditism in this species. It was believed that the sexes in this species were strictly separate, although other forms of *Ostrea*, such as *O. edulis*, *O. lurida*, and *O. denselamellosa*, are always hermaphroditic.

While studying oysters at the Plymouth Marine Biological Laboratory, I observed two hermaphrodite individuals in a batch of 75 Portuguese oysters, which were sent from Whitstable Oysterage, where they had been relaid and cultured. All the oysters were well-grown, large specimens and were kept alive in the outside tank of the laboratory for some time.

The dates of examination and the distribution of the sexes were as follows :

Date.	♂♂	♀♀	♂♀	
May 29 (1 day after arrival)	2	9	0	
" 30	1	5	0	
June 3	2	3	0	
" 12	2	9	0	
" 14 (examined by Prof. Awati)	1	9	0	
" 15 (examined by Prof. Awati)	1	4	0	
July 3	1	2	1	
" 16	4	18	1	
Total	14	59	2	Σ = 75
Ratio per cent. . .	18.6	78.6	2.6	

The sex-ratio differs from that observed by Dantan (43.6 per cent. ♂♂, 56.37 per cent. ♀♀) who examined a larger number of individuals. Of course, in the present case the numbers examined are not sufficient to warrant any conclusions being drawn, but the figures are worth noting.

The hermaphrodite specimens were examined

whilst fresh under the microscope, and no differences were found in the nature of the eggs and sperm as compared with those taken from normal specimens in which the sexes are separate. The eggs were of the ordinary size and shape, and the sperm exhibited active movement. Sections of the hermaphrodite gonad showed male and female elements in the same tubule. Only mature sperm were present, although eggs were found in all stages of development up to complete maturity; some of the latter were detached from the germinal layer and lay free in the sperm aggregates.

The diameters (μ) of a few of the eggs were found to be as follows: 73 × 86, 75 × 86, 79 × 79, 83 × 86, those of the nuclei being 23 × 26, 23 × 28, 24 × 28, and 25 × 28 respectively; so that the size of the egg is nearly the same as that of other dioecious oysters, and much smaller than that of all the true hermaphrodite forms mentioned above, in which the larger size of the egg is characteristic.

It is also noteworthy that the hermaphrodite specimens were found among animals which had been kept alive in the tank for more than a month, *i.e.* which had endured, so to speak, a prolonged period of starvation.

A parallel example would appear to be that of the American oyster, *O. virginica*, a species in which the sexes are distinct; however, one hermaphrodite specimen has been recorded (Kellog, 1892). It was obtained from a rearing-batch of oysters at the Woods Hole Marine Laboratory. In view of this, I am inclined to suggest that possibly there exists some relation between nutritive conditions - and hermaphroditism in those species of oysters in which the sexes are as a rule separate.

Apparently Anomalous Protection against Oxidation.

IN his address on "Catalysis and Oxidation," printed in NATURE for August 22, Prof. Henry E. Armstrong refers to surface peroxidation of metals as affording protection against further oxidation.

An interesting example of the interference of oxygen with oxidation came to my attention recently. In the course of a technical investigation of the blackening of copper, brass, and bronze in potassium persulphate solutions, it was noticed by my assistant, Mr J. Schmitt, that when the strip of metal was dropped into the solution it blackened readily and completely. If, however, it was slowly lowered into the solution, at rates up to 14 linear inches per minute, blackening either did not take place or was very patchy and imperfect, generally not more than a tarnish.

E. Groschuff, in a valuable article on the blackening of copper and copper alloys by alkaline persulphate solutions (*Deutsch-Mechan. Zeit.*, 1910, p. 135), notes disturbances coming from oxide layers "which on account of their impermeability prevent the action of the colouring bath," and cites in this connexion the experiments of E. Muller (*Zeit. f. Elektrochem.*, 13, 137 (1907)) on passive copper, but does not note that a disturbing tempering layer may form on freshly cleaned metal if lowered slowly into the alkaline persulphate bath. The interference is still more marked with copper alloys than with pure copper. The solution used for this process is an alkaline solution of potassium persulphate, *e.g.* 1 to 2 per cent.

$K_2S_2O_8$, with 2 to 3 per cent. KOH. The persulphate is hydrolysed, according to the equation

The excess alkali neutralises the acid salt and prevents the solution from becoming acid. Investigations on the velocity of decomposition of persulphate solutions (Green and Masson, J.C.S., 1910, 97, 2086; S. E. Sheppard, *Phot. Jour.*, 1921, 61, p. 454; G. I. Higson, J.C.S., 1921, 119, p. 2048) have shown that the reaction is monomolecular with regard to persulphate, so that equation (1) probably represents the course of the reaction, and atomic oxygen is liberated. The initial production of atomic oxygen is in agreement with the oxidation potential of persulphate solutions.

The simplest representation of the blackening of copper by persulphate would be

but this undoubtedly only represents the initial and final results. That a more complex process occurs appears to be indicated by the structure of the oxide layer. This is formed as a soft velvety pile, which is not removed by gentle rubbing, but consolidates to a smooth and semi-lustrous layer. A further refinement of the oxidation process is to suppose that cuprous oxide is first formed; it has already been pointed out that the lattice structure of cuprous oxide is nearer that of copper metal than is that of cupric oxide. Hence we may write

When the metal is slowly lowered into the persulphate solution, it is exposed for a longer time to the air: solution interface. This is the only difference in condition in the two cases. It appeared to me that concentration of molecular oxygen in this layer might be causing the interference. Protection of the surface, as by holding a glass rod against it, while passing the interface, was enough to remove the interference, the protected part blackening normally. Again, if a little antoxidising solution, as hydroquinone-sulphite of soda, were allowed to trickle over the metal just as it entered the persulphate solution, the blackening was of course at first delayed, but soon took place with full vigour. Finally, electrolytic generation of hydrogen at the interface also overcame the interference.

Molecular oxygen is of course accumulating at the interface from the discharge of $O + O \longrightarrow O_2$ produced by the hydrolysis of the persulphate. My tentative explanation of the oxygen interference was that cuprous peroxide is formed:

and that this paralyses the reaction, a passive layer being formed.

In line with Mouren's work, it may be possible that both cuprous and cupric peroxides are formed:

and that these decompose each other, with mutual reduction:

Be that as it may, the facts appear to demonstrate another case of the impedance of oxidation by oxygen.

The Adult Form of the "Harvest Bug."

THE adult form of the larval mite known as the "Harvest Bug" (*Leptus autumnalis* Shaw), which causes so much annoyance in many rural districts at this time of the year, has long been sought for. In the middle of August, Prof. F. V. Theobald and Mr. C. W. Goode, of Wye, sent me three chickens heavily infested with this larval mite. From these larvæ I have succeeded in rearing an adult mite closely allied to *Trombicula*, Berlese, and resembling that genus in having a deep constriction behind the anterior pairs of legs, but more elongated in form and with the setæ on the cephalothorax shorter and differently shaped. I propose the name *Trombicula* (*Neotrombicula*) *autumnalis* for this adult mite, *Neotrombicula* being a new subgeneric name. The name *Leptus* was created by Latreille for *Acarus phalangi* (= *Achorolophus ignotus* Oudemans), now referred to the family Erythraeidae, and should not be used for the "harvest bug," which belongs to the family Trombididae.

Gibbs' Phenomenon in Fourier's Integrals.

PROF. CARSLAW has raised, in *NATURE* of August 29, p. 312, a point which has been interesting me during the past few months. In addition to the case of Fourier's integral which he cites, I have noticed that Hankel's integral

$$f(x) = \int_0^\infty J_\nu(xu) u du \int_0^\infty J_\nu(tu) t f(t) dt,$$

and Titchmarsh's integral¹

$$f(x) = \int_0^\infty H_\nu(xu) u du \int_0^\infty Y_\nu(tu) t f(t) dt,$$

where $H_\nu(z)$ is Struve's function, possess Gibbs' phenomena at points of discontinuity.

This can be shown by a method similar to that given by Prof. Carslaw, using the asymptotic forms for the functions concerned where necessary.

I may add that in the case of Hankel's integral this throws considerable light on the similar problem in the case of Fourier-Bessel series.

The "Kennelly-Heaviside" Layer.

EVERY radio engineer is familiar with what is called the "Heaviside Layer" and its supposed functions. I find, however, that the hypothesis of an electrically conducting stratum in the upper air was clearly enunciated in an article by Prof. A. E. Kennelly, of Harvard University, published in the *Electrical World and Engineer* of New York on March 15, 1902. The official date of Heaviside's disclosure of his hypothesis is December 19, 1902. About the same date H. Poincaré, A. Blondel, and C. E. Guillaume made similar hypotheses. If names are to be attached to this hypothetical layer it should be called, in equity, the "Kennelly-Heaviside" layer, a name which is beginning to be used in America.

The Chemistry of Solids.¹

By Prof. CECIL H. DESCH, F.R.S.

IT is remarkable how little we know with any certainty about the chemical properties of solids, although the idea of a solid is so fundamental. At the present time we always begin the study of chemistry with the gases on account of the simplicity of their mathematical treatment, but it must be remembered that this simplicity is the result of long study and of many discoveries. To the unscientific mind the solid is simpler, because more tangible. When men have tried to understand gases, they have expressed themselves in terms of solids. The atom, however attenuated it may have become in recent years, was in the first instance essentially a solid sphere, and the elasticity of gases has been explained in terms of the collision of elastic solid particles in motion.

Our conception of liquids has been based in the same way on the idea of moving particles, themselves thought of in terms of the solid state. Yet, of solids themselves, whilst our knowledge of their physical and mechanical properties is very extensive, our chemical information is of the most meagre kind. It was an old doctrine that chemical reactions could only proceed in the gaseous or liquid states, so that chemical action on a solid was always preceded by the tearing off of atoms from the surface under the influence of electrical forces. That view can no longer be maintained. Chemical reactions can occur within or at the surface of a solid, but the experimental difficulties are sometimes such as to make the exact investigation of the subject a difficult matter.

In the modern conception of a solid, the atoms are characterised by a regular arrangement in space, that arrangement being repeated so as to build up a crystalline lattice. Crystals and aggregates of crystals are thus the only true solids, glasses being regarded as under-cooled liquids of high viscosity. The X-ray method developed by Laue and by W. H. and W. L. Bragg has made it possible to determine, not only the class of a crystal, but also the exact lattice possible to crystals belonging to that class. The connexion between the chemical properties and the crystalline structure still remains indeterminate, although it must be very intimate.

There are many reasons why the chemical study of solids should receive greater attention. In metallurgy, although metals and alloys may, and most frequently do, pass through a molten stage in the course of their manufacture, they may undergo many important changes of structure and constitution at temperatures far below that at which the last liquid portions have completely solidified, and these changes may be so far-reaching as to convert an alloy into one seemingly of an entirely different class, although the gross chemical composition has not altered. The petrologist, especially when dealing with igneous and metamorphic rocks, has to consider reactions which proceed in the midst of solids of high rigidity. Several industries, such as that of cement, are based on reactions of the same kind as those with which the petrologist has to

deal. Sintering is not always due to the presence of small quantities of molten material between the solid particles, and it is now certain that union of solid masses under pressure may occur without actual melting. This was shown by Spring forty years ago, but for long, although frequently quoted, his results received little consideration.

The most striking application of the principle is seen in the metallurgy of tungsten. This metal was formerly described as very hard and brittle, and it is not possible, by casting it and then annealing, to bring it to a ductile form. The method now adopted is to prepare it in the form of a pure powder, and then to bring it to a compact state by compressing, heating, and hammering while very hot, and finally drawing. As this process is continued, and as an originally thick rod becomes extended into a slender wire, the brittleness progressively disappears, and at last the tungsten is obtained in those beautiful filaments, drawn to extreme fineness, with which we are familiar in our electric light bulbs and wireless valves. A somewhat similar example is that of the adhesion of an electrolytically deposited metal to its support, which is sometimes so perfect as to approach the breaking strength of one of the metals, although interpenetration of crystals is not to be seen under the microscope.

There is another aspect of the chemistry of solids which will make an appeal to some who are not chemists, but amateur students of Nature. The great beauty of natural crystals has attracted the attention of poets and artists as well as men of science. Much of this beauty depends on the varying habit of one and the same crystal species. Even with such a common mineral as quartz, it is possible on entering a mineral collection to point to some of the crystals exposed, and to name their locality, when once the form has become familiar. The same is true of other minerals. Why should there be this variation, when the chemical composition of the distinct varieties may be identical, so far as analysis is able to give information?

Again, the crystalline system will not account for the differences in the building up of individuals to form aggregates. Rock salt and cuprite crystallise in cubes, and the space lattice has a very similar form in the two minerals; but when the salt forms multiple growths, the cubes arrange themselves in characteristic stepped pyramids, whilst the red oxide of copper may form the most beautiful hair-like threads, a tissue of scarlet silk, as Ruskin calls it. Neither mineral ever assumes a form which is characteristic of the other, the simple cube being once departed from. Why should this be? It is known that the presence of traces of foreign matter may cause differences of habit, the most famous example being that of the crystallisation of common salt in octahedra instead of cubes when a small quantity of urea is added to the solution, but the explanation of these facts is still imperfect.

The work of Johnsen and of Gross has shown that the appearance of a face on a crystal placed in a supersaturated solution is really determined by the velocity of growth in a direction normal to that face,

¹ From the presidential address delivered at Southampton on August 31 before Section B (Chemistry) of the British Association.

those faces being produced which have a minimum velocity of growth. Some light is thrown on the subject by a study of the growth of a crystal when solvent is completely excluded, the substance used being sublimed in a vacuum. This has been undertaken by Volmer, who finds that cadmium, zinc, and mercury crystals grow in this way in a high vacuum. When small nuclei are present, those grow which have the face with the smallest velocity of growth perpendicular to the stream of impinging molecules. The differences between different faces are large, so that under these conditions either flat tables or long prisms are usually formed, according to the direction of the original nucleus. The crystal grows by the addition of thin laminae, probably only one molecule thick, which spread over the surface. This is likely to be the process when the crystal is growing in a solution or in a molten mass, as well as in the vapour; and, in fact, when cadmium or tin is being deposited electrolytically at a cathode, or when lead iodide is being formed from a solution of a lead salt and an iodide, the growth of the crystal may be watched under the microscope, when a thin film begins to form at some point on a face, and extends over the face, maintaining a uniform thickness throughout. It is realised that in the presence of a foreign substance, either molecules or ions may attach themselves to such a surface by their residual affinity, and this will necessarily affect the addition of further layers of the original substance. In other words, the velocity of crystallisation in a direction normal to that face will be changed. As the residual affinity of different faces of a crystal must, from the ordinary conception of an atomic space lattice, be different, the habit of the crystal, that is, the relative development of different faces, will be altered by the presence of a foreign substance. It is on these lines that an explanation of differences of habit must be sought.

When a face of a crystal is brought into contact with an etching reagent, such as water for rock salt, hydrofluoric acid for quartz, or cupric ammonium chloride for iron, the surface is not dissolved away evenly, leaving it smooth, but characteristic etching pits are produced, the sides of the pits being evidently crystal faces. This shows that chemical action proceeds more readily along certain planes of a crystal than along others, a fact which we should expect from the general properties of the space lattice. It is not explained, however, why these etching pits should appear at first separate from one another, the intervening portions of the surface being unattacked. Minute particles of some impurity, causing local electrolytic differences, suggest themselves as a possible cause, but it is unlikely that they would be so evenly scattered in, for example, a quartz crystal as to produce the regular distribution which is often observed. Minute inequalities of level, which may be of a periodic character, are more probable, and this suggestion is strengthened by the observation that a polished face of rock salt dissolves evenly in water, whilst a natural cleavage face shows etching pits.

It is now possible, when pursuing the study of solids, to eliminate one of the disturbing factors, the inter-crystalline boundary, by making experiments with specimens composed of a single crystal. There are several ways of preparing single metallic crystals of such a size as to allow of the determination of their

physical and mechanical properties. Even so brittle a metal as zinc has an extraordinary ductility in single crystals. The mechanism of deformation has been examined in detail by means of X-rays. There is now a large body of evidence as to the directions of slip in a crystal during deformation, and this knowledge is essential to any understanding of the nature of cohesion, with which the chemical properties are no doubt closely connected.

We may now turn to the subject of chemical reactions which take place in the interior of a solid, either originating at the surface or from nuclei which make a spontaneous appearance in the course of cooling below the melting point. A chemical change which has begun at some point in or at the surface of a homogeneous crystalline mass cannot advance unless the atoms are able in some way to change their places. Gross movements, represented in gases and liquids by convection currents, are out of the question, but the slower process of diffusion, by which atoms or molecules can make their way through the solid, must be possible. Experiment shows that diffusion in solids, whilst naturally a slow process in comparison with diffusion in liquids, proceeds at quite measurable rates.

The classical example of such measurements, and for many years the only one, is the study of the diffusion of gold in solid lead, undertaken by Roberts-Austen in 1896. A much simpler example is that of silver and gold, two metals which resemble one another closely in chemical character and in atomic volume, so that diffusion causes less change of properties than in any pair of less closely similar metals. The experimental results prove, as might have been anticipated, that diffusion is a much slower process when there is so little difference in chemical character. When the two kinds of atoms are closely alike, the tendency to diffuse must be small, but it is certainly not zero. By making use of an ingenious device, Hevesy has been able to determine the coefficient of self-diffusion of liquid and solid lead. Two isotopes should not differ appreciably in their rates of diffusion, so that when the radioactive isotope thorium B is allowed to diffuse in ordinary lead, the experiment is equivalent to selecting a certain number of lead atoms and attaching labels to them by which they may be identified in the course of their journey. In this way he found that the diffusion in liquid lead near to the melting point was of the order of that of salt in water, but that in the solid state it was very small. Further experiments, using a thin foil, proved that at 2° below the melting point the rate was $1/10,000$ of that in molten lead.

When a liquid mixture of two substances which are miscible in the solid as well as in the molten condition, such as an alloy of copper and nickel or a fused mass of albite and anorthite, begins to solidify, the composition of the crystals has to adjust itself continuously in order to maintain equilibrium with the changing liquid phase, as was shown by Roozeboom in his classical work on solid solutions. Such an adjustment is only possible by means of diffusion, and when cooling is sufficiently slow, the adjustment does in fact keep pace with the change in the liquid, but with more rapid cooling the interior of each crystal differs in composition from its outer layers, there being a concentration

gradient from the centre to the boundary. This condition produces the "cored" crystals which are familiar to every metallurgist, and the "zoned" crystals of the mineralogist. In most alloys this want of homogeneity disappears after a sufficiently long period of heating at some temperature below that at which the first drops of liquid are formed, but alloys of bismuth and antimony fail to become uniform even after weeks of annealing, whilst the feldspars and similar minerals have never been persuaded to lose their zoned structure by any methods known in the laboratory.

Bruni has shown and Vegard has confirmed the observation by the X-ray method, that true interdiffusion occurs between potassium and sodium chlorides when mixed and heated in the solid state. Electrolytic transport is observed in the solid halides of silver and in mixtures of silver and copper sulphides, but the modern view of the structure of such substances represents them as built up of ions rather than of neutral atoms, and this must be taken into account in any interpretation of the facts. The apparent absence of diffusion in minerals which have once solidified, even when given geological periods of time, is a serious difficulty in the way of any general theory of diffusion. Such examples of the passage of alkali metals through quartz and other silicious minerals under the influence of a difference of electric potential are probably not examples of true diffusion at all, but merely of the passage of traces of impurities through a mass which is not completely impervious.

A new field of investigation has been opened up by Tammann in his attempts to determine the arrangement of the atoms in solid solutions by purely chemical means, by studying the action of chemical reagents on the solid. It is a familiar fact that the "parting" of silver and gold in assaying, which consists in dissolving out the silver from the alloy by means of nitric or sulphuric acid, is only possible when the silver forms more than 60 per cent. of the alloy. When gold is present in excess of this proportion, only a little silver is removed from the surface, and the action then comes to a standstill, the acid being unable to penetrate to the interior. Assuming the alloy to be completely crystalline, the atoms of silver and gold will occupy the points of the space lattice, and as the two metals have face-centred lattices of only slightly differing dimensions, the amount of distortion will be small. There are, however, different ways of arranging the two kinds of atoms. They may be distributed at random, or they may be so regularly arranged as to form two interpenetrating cubic lattices.

The two forms of distribution may be distinguished by means of the X-rays, but Tammann has also drawn conclusions on the point from the action of various reagents on the alloys. He finds that each reagent which attacks silver ceases to act on the alloys when the proportion of gold atoms in solution exceeds a certain limit, which is not the same for different reagents, but he states that it is always capable of being expressed as $1/8$, $2/8$, $3/8$, and so on, of the total number of atoms. The limits so found are not consistent with the distribution according to the laws of probability, but they may be accounted for by a regular distribution on the assumption that a certain number of inactive atoms is necessary to protect each atom of silver.

On the basis of these results, an ingenious theory of the action of reagents on solid solutions has been constructed, and although the accuracy of the experimentally determined limits is not high, and there are several exceptions to the rules, an interesting case has been made out.

If our knowledge of the chemical properties of the interior of a crystal be very incomplete, what are we to say of its surface? Of this we know still less. Even in a crystal of a pure metal there must be some difference in the structure at the immediate surface, on account of the unsymmetrical forces between the atoms in the outermost layer and its neighbours. For so far as the radius of sensible atomic forces extends, therefore, there must be a condition different from that which prevails at a depth below the surface. One consequence is that the surface has residual affinity, which shows itself in the ease with which foreign atoms or ions will attach themselves to it. That the forces acting are chemical is shown by the great effect on the extent of adsorption of the chemical character of the solid and of the adsorbed substance. Films, often one atom thick, attach themselves to the solid, and are only removed with the greatest difficulty. Their presence makes the investigation of the properties of a surface difficult, as the surface actually examined may be in reality quite different from that which is assumed to be present. In photochemical experiments with mercury it is usual to prepare a completely fresh surface of the liquid metal by causing it to flow continuously in a fountain, but this device cannot be applied to solids. Only rarely can experiments be made with perfectly defined solid surfaces. Films of metal prepared by sublimation or sputtering in a vacuum are probably the most under control, but other surfaces are commonly covered by invisible films.

Schumacher has recently shown that mercury wets glass and silica more and more readily as care is taken to remove films from them, and the property of not being wetted by mercury is probably not one of glass and silica, but of those substances coated with a film of gas. Metals most readily take up atoms of oxygen or other elements, forming persistent films, which play an important part in the phenomena of resistance to corrosion.

There is one way of preparing a fresh surface of a crystalline solid for examination, and that is by cleavage. A freshly cleaved plate of a mineral may be supposed to be clean at the moment of its formation, although it will rapidly take up foreign atoms from the surrounding gas. Tammann has made the interesting observation that a fresh surface of mica is more soluble in water than an older one. Washing with water immediately after cleaving extracts a quantity of alkali salts which is much above the normal solubility of mica, and later washings extract only the normal quantity. It is suggested that the separation of the flakes of mica exposes the alkaline part of the molecules, which would be more readily attacked by water than the silicious part. It will be interesting to see whether the X-ray examination of mica confirms this arrangement. Again, however, a word of warning as to the effect of possible impurities must be uttered. Natural minerals are not pure, and any uncombined alkaline salts present might well segregate along cleavage planes in the

process of crystallisation, and so give rise to the effect noticed above, but the figures recorded by Tamman are striking and suggestive.

In this hurried review of a large field it may seem that I have presented rather our ignorance than our knowledge, my intention having been to show how much remains to be done before we can understand the chemical relations of solids as we do those of liquids and gases. One department of research is, however, more advanced than might have been supposed from my brief references to it. That is the study of the internal changes in metallic alloys as revealed by the microscope and by thermal and electrical methods. Metallography has made wonderful progress since the days of Sorby, and it would repay students of physical chemistry to give some attention to its main results, even though they may not intend to make a special study of the subject. Nowhere are the benefits of the doctrine of phases of Willard Gibbs to be more clearly traced, whilst the recognition of every change of phase by microscopical examination, making use of a tech-

nique which has been brought to a high state of perfection, gives concrete reality to the study by direct verification of its conclusions.

To understand more thoroughly the mechanism of these changes in alloys and to extend its application to salts, minerals, and rocks, we need a fuller knowledge of the relation between crystal structure and chemical behaviour. Research on the mechanical side is discovering the direction of planes of slip in the atomic space lattice under stress, and it remains to determine the corresponding planes of greatest and least chemical activity towards a given reagent. Next follows the still unsolved query as to the nature of the inter-crystalline boundary, and the solution of these two problems will make it possible to define exactly the chemical character of a given aggregate of crystals. The results will be of extreme interest for the study of metallurgy, of mineralogy, and of petrology, besides filling a serious gap in chemistry, serious because of the extent to which solids compose the world around us, and of the part which they play in our daily life.

The Meaning of Wages.¹

By Miss LYNDIA GRIER.

IT is as little within my intention as it is within my power to put forward a theory of wages. My business is one of analysis, not of construction, of re-statement, not of creation. My purpose is twofold: first, to discuss certain aspects of wages, and then to review from those aspects certain payments made to or on behalf of employees.

Let us then consider three aspects of wages, each important in its way. First, there is the distributive or competitive aspect, from which wages are regarded as a factor determining where labour shall go, who shall command it, in what manner labour of certain types and given efficiency shall be employed. Competition between employers seeking the best workers is expressed in the wage they offer, and competition between workers seeking the best employer is expressed in the wage they accept. This competition tends to bring the wages of workers of equal efficiency to equality and to ensure that the wages of workers of unequal efficiency shall be unequal.

Taken alone, this idea of wages treats of the supply of labour as being fixed independently of the wage, and of the wage as powerful only in directing the available supply. It is therefore a short-period consideration, dealing with market price rather than normal value; as in all short-period considerations, stress is laid on the quantitative side, on the notion of value falling with an increase in the supply of labour and rising with a limitation of supply.

Secondly, there is the idea of wage payment which treats of work and wages as completely interdependent, since the product of each worker constitutes his payment. The product of each worker, represented by his wage, makes an effective demand for the produce of other workers. His addition to wealth is his claim upon it. Numbers are important only if with alteration in numbers there are consequent alterations in

productive power per head, or if the proportions between the different types of labour required be ill-adjusted.

Finally, we may take the aspect of wage payments which is concerned with their effect on work and on the supply of workers, the wage being regarded as something that maintains the worker.

These three aspects of wages are not antagonistic. It is clear from the outset that there is no contradiction between the first two, between that from which they are regarded as a distributive force and that from which they are regarded as the actual product of the wage-earner. The idea that the worker produces so much wealth and that his work is paid in proportion to the wealth he produces is, indeed, associated with the idea that the demand for and supply of such labour as he has to offer determines its value. Wages so determined are known as "fair" or "normal": fair in that they are equal to those of other workers of similar capacity, normal in that they are the wages that tend to be paid under conditions of free competition.

Each worker on this reckoning tends to get what his work is worth. It may be worth little. This admission does not apply only to bad workers. It certainly does apply to them, whether the badness of their work be due to bad character, bad health, or bad mental equipment. But the question is one not only of efficiency but also of the type of ability and of the number of other workers possessed of that particular type. Work which is not entirely unskilled may be ill-paid if the numbers competent to do it are great. This is, perhaps, especially the case with women's work.

For the most part, earnings are low in occupations that offer no special attractions and are filled by workers who, thanks to heredity, or sex, or environment, have little chance of entering others. The able man or woman has not only the fun of being clever, but also the advantage of high earnings through belonging to a grade in which the numbers are relatively small.

¹ From the presidential address delivered at Southampton on August 28 before Section F (Economic Science and Statistics) of the British Association.

It is, perhaps, unfortunate that wages which reflect the value of the work done should be known as fair wages. It has already been stated that they are known as fair because they are equal, if mobility is perfect and competition free, to those of other workers of equal capacity and doing work offering equal attractions. It is the equality that has led to the epithet "fair." But it is a not very convincing fairness to the man receiving a low wage whose work is worth little through no fault of his own. For when the demand price sufficient to absorb all the workers in a given grade is small or, in more technical language, when the marginal net productivity of such workers is low, when the workers in that grade are neither bad nor careless, other members of the community gain by cheap goods as the workers lose in low pay.

Plenty is generally an advantage to the community. We rejoice if land is plentiful in proportion to the population and rents are low. We should like capital to be plentiful and cheap, competing for employment at a low rate of interest. We are aware also that the owner of a limited supply of a commodity that becomes plentiful loses wealth as the consumer gains it. It is one of the anomalies of economic measurement that when a country becomes richer through an increased supply of certain goods, wealth as represented by those goods may be calculated as being less than before, because of the lowering of this exchange value.

The owner of anything other than labour may be compensated, or more than compensated, by the greater amount he possesses. Not so the worker. Each worker is lord only of his own labour. Recognition of this leads to limitation of output. There are, roughly, two ways in which men may increase their own wealth: by increasing or by decreasing production. Adult workers who have their youth and their training behind them have little power of doing the first, and fall back on the second. Through limiting output, erecting barriers against new-comers into their trades, they may successfully maintain or raise their own wages. From this point of view the objection of men to opening to women any new branch of industry is perfectly logical. If women be found capable of doing work formerly reserved for men, and are allowed to do it without let or hindrance, they will tend to have a depressing effect on the wage; not because of their sex, but because of their number. Their exclusion from many trades makes their entry to any single trade formidable; they are jealously excluded from one type of work because they are jealously excluded from others; thus they come to be considered natural blacklegs.

It is not profitable to pursue this subject further, however, without discussing the third aspect of wages, and considering not merely the wage that a man is worth but also the wage that he needs. Wages, in addition to directing labour and being a return of goods and services to labour in exchange for the goods and services it supplies, are expected to maintain the worker. The owner of labour alone among owners of any agent of production is supposed to live on the product of the thing he owns. The economic fact that to a great extent he does so has been exalted, like many other economic facts, into a moral obligation; and when the normal wage is low without any discernible fault on the part of those who earn it, the moral obliga-

tion is shifted and it is said that the wage ought to be large enough for the worker to live on.

It being assumed that the worker lives on his wage, we concern ourselves greatly with the question of how far wages do or can be made to respond to needs. We are challenged daily, by proposals for minimum wage rates, cost of living standards, family allowances, contributory insurance schemes, to consider the connexion between the normal wage and a wage adjusted to the needs of the worker. The question is a complicated one.

It is far easier to see the connexion between the wage and "training and sustaining" the worker's energy than between the wage and the cost of rearing the worker. If labour be not adequately sustained during the period for which the worker is engaged the product will suffer. Diminution in the number of workers available, or in efficiency, or both, follow swiftly on lack of sustenance. Further, the wage must bear some relation to the cost of training, since so long as there are occupations which demand no training, or less training than others, those needing most will lack recruits if the earnings they offer are not relatively high.

The cost of rearing the worker raises different questions. It is clear that the individual worker does not pay for his own childhood; no bill of the cost is presented to him when he begins to work. It is equally clear that the childhood of most wage-earners is paid for from wages; part, and a considerable part, of the wage of many workers is devoted to the maintenance of their children. It may be said crudely, therefore, that unless wages cover the cost of rearing workers, there will be no workers. It cannot, however, be asserted that because a worker pays certain expenses from his wages those expenses are the cause of his wage, or of any part of it.

There is a tendency to assume that, while the efficient sustenance of labour during working days and hours is a prime cost of industry to be covered by the wage, sustenance in non-working days and hours, in sickness, during unemployment, in old age, and the maintenance of wife and children not only during but also after a man's working life, is a kind of supplementary cost for which provision should be made in respect of work done. This presupposes a vast amount of calculation both on the side of the employer and the employee.

First let us take the employee, as being the party to any wage contract most likely to reckon such costs. Here, roughly, we find workers divided into the calculating and non-calculating classes, those who expect security and those who do not: an expectation which probably makes a far sharper class distinction than that made by riches and poverty.

Arrangements for contributory insurance schemes have long been common in the professions. Contributory insurance schemes for the provision of pensions have, with the exception of some of the less exalted branches of the Civil Service, in the past been made compulsory among those classes who before their introduction attempted to make similar provision voluntarily. The same classes have perhaps more than others calculated the number of children whom their earnings would maintain. The fertility statistics of the last census show that the professional classes, who are very largely the calculating classes, have a

lower fertility rate than any other occupied section of the community: 0.90 being the average number of children under sixteen for married men in the professional classes as compared with 1.27 among all married men. These classes who calculate the future are but a small section of the community.

For most earners the exigencies of present maintenance exclude considerations of future maintenance. With dependents the case is somewhat different; more and more every class of the community tends to consider the possibility of making good provision for its children, and more and more do the parents of every class recognise that they can provide for their own needs by limiting the size of their families.

The effect on earnings of calculations made by the worker, either for his own future and that of his dependents or for the present needs of his dependents, is not easy to trace. A stimulus to activity which in effect raises the wage-earner to a higher grade, increasing his productivity and general wealth, makes him worth a higher wage. A limitation of numbers is slow in its action on supply, and, since it cannot be assumed that each grade or occupation is entirely self-recruiting, no positive result can be ascribed to it, except in so far as it is thought that a general increase or decrease of population is likely to cause a general rise or fall in wages.

Let us now turn to the question of how far such calculations affect the employer, purely from the business point of view. Employers have not reckoned the whole of the worker's life or maintenance of his dependents as an overhead charge. They do not pay adult male employees at a high rate because they have families dependent on them or because they must make provision for the future, but because their productivity is relatively high and because they are strong and experienced workers. They do not gravely reckon the average family of an average worker: they reckon what the man's work is worth.

Nor do the needs of the worker provide him directly with additional bargaining power. It has generally been recognised in foreign trade that needs are a weakness and not a strength in bargaining. It is the same with the worker. So far as fighting strength goes, bachelors who are without dependents can fight more effectively than men with families. The mere acquisition of a new set of needs, unless it stimulates activities and so is part of a higher standard of life, adds to misery and not to wages. To a certain extent it is notorious that dependents do stimulate activity, married workers being generally steadier and more regular than unmarried ones. Their higher productivity raises their earnings. But it is to be feared that bargaining power is in no way enhanced by the number of dependents, and every one present will call to mind cases of men who dare run no risk of losing their job because of their wives and children.

In view of this, we may think it fortunate that the workers who get low wages so often have few needs. Young untrained workers whose productivity is low have no dependents. They have often, in fact, just ceased from being dependents themselves and become contributors to the family wage. If women are crowded into a somewhat small number of occupations with low rates of pay, it is some comfort to remember that they

have comparatively few dependents to suffer from those low rates.

If we agree that the normal wage in some cases rises above and in many falls below the wage required by the worker for his maintenance in the future as well as the present, and for the maintenance of his wife and family in both the present and future, what should be our attitude towards the many persons and bodies who are concerned with raising the wage rate, with charging provision for unemployment and the future on to wages, and with readjusting wage rates? It is clear that we cannot expect the approximation of normal wages to wages adequate for such maintenance to be the main preoccupation of social reformers or statesmen.

Measures concerned with wages may be put into three categories roughly coinciding with the three aspects of wages with which we began. First, there are those which are concerned with the mobility of labour, with seeing that labour is as swiftly as possible directed where it is most needed, by the dissemination of knowledge, by facilities for movement such as are offered by the employment exchanges, by vocational selection, by the efforts of trade unions to ensure that in every instance the rate received shall be at least the normal rate. Secondly, there are those which attempt to increase the productivity of the worker and raise him from one grade to another; such as measures of educational reform, improved social conditions, even, when wages are very low, minimum wage rates, which by improving the health of the worker increase his productive capacity. Thirdly, there are measures which attempt something further and try either to add to the normal wage rate or to "stretch" the rate so that it will pay for things that it did not previously pay for.

I do not propose to discuss the first two categories; their value is obvious. We are being forced, however, increasingly to discuss the third category. It includes schemes for fixing such minimum wage rates as do not increase productivity; cost of living standards when they attempt something other than the maintenance of the normal wage; schemes for subsidising certain sections of wage-earners, such as systems of family allowances; and schemes for stretching normal wages to cover certain costs, such as compulsory insurance schemes.

Where these schemes ensure a given rate of wages their advocates desire that it should be secured without unemployment ensuing. Where, as in compulsory and contributory insurance schemes, a charge is levied on employer and employed, it is presumably not desired that unemployment benefit should be provided by measures which, by making labour costs high, increase unemployment, or that hypothetical widows and fatherless children should be provided for by schemes which, by reducing wages, stint actual wives and the children whose fathers are living.

Minimum wage rates may be maintained without unemployment following when, as has already been suggested, through their reaction on efficiency they increase the value of the work done, and also where the demand for the labour employed is inelastic. Trade boards have proved this. It may further be argued that, when normal wages are too low to provide adequate maintenance for all workers belonging to a given grade,

it is better to enforce a wage adequate for the maintenance of a certain number, and, having so produced a certain amount of unemployment and defined the problem, take steps to deal with the unemployment.

When the question is one not of the minimum needed for efficient sustenance but of the relative rates in different occupations, according to the degree of skill required and the customary rates for work of a given kind, the problem becomes different, as in the case of cost of living standards. There is nothing sacred about relative wage rates; they are exceedingly arbitrary as between different occupations and between different types of skill in the same occupation. Wage rates normal in the past are not normal in the present and will not be normal in the future. They are subject to infinite variations. The balance is mobile and cannot be stereotyped. It is a pointed commentary on this fact that the Cave Committee reporting on the Trade Board Acts in 1922 advised that the boards should in future confine their activities to the settlement of wages when such wages are unduly low and no other adequate machinery exists for their effective regulation.

This report and consequent legislation marked the abandonment of one attempt to legislate on relative wage rates. But if one attempt was abandoned, others remain. The minimum wage rate in the coal-mining industry is being hotly discussed, and, apart from legislative enactments, cost of living standards as a basis not for wages but for fluctuations in nominal wages are commonly enforced by trade union action. A wage which is "above the normal" is in effect a subsidy given to the worker in respect of a particular type of work. In a sense, nomenclature matters little. We tend to call anything a wage which is given by an employer to a worker, and to call anything a subsidy which is given to a worker or an industry or any one or anything else by the State, and to dub as taxes revenue collected by the State. But when we analyse payments above or below normal wages, we find that we are generally tracing their incidence and dealing with transferences of wealth rather than with costs. Sir Alfred Mond's scheme is frankly a subsidy. Nor is there in effect much disguise about the "tax and subsidy" nature of the family allowance system. Bachelors are to be taxed, or to tax themselves, for the sake of men who have families. It is recognised that it is on the whole unwise to put the administration of the "tax and subsidy" in the hands of the employer, lest he should mistake a tax and subsidy scheme for a new wage system under which it would be greatly to his advantage to employ bachelors instead of married men. Once it is frankly admitted that large families neither force nor enable employers to pay high wages, we can if we wish settle down to a discussion of the ethical and economic advantages of family endowment; and we can contrast the advantages of making provision for families within each industry separately or through a more general scheme of taxation.

From the suggestion to tax certain wage-earners for the benefit of other wage-earners we may pass to the practice of taxing wage-earners for their own benefit, as embodied in unemployment and health insurance schemes, in the various pension schemes already adopted in the Civil Service, and as proposed in the Pensions Bill. It may be said that here we are not

dealing with taxation but merely with deferred pay; that the contributions, covering as they do the workers' own risks, are a forcible method of saving, but cannot fairly be called taxation. This is perfectly true when the saving would or could be made voluntarily. But when wage-earners are too poor to save, enforced saving leaves them for the time being poorer than before, and Mr. Neville Chamberlain's hope that the Pensions Bill "would encourage people to try to add to the benefits and thus achieve complete independence for themselves" is likely to be frustrated by the reduction in their means. We are agreed that the benefits of these schemes must be secured. We are, I believe, agreed that they must be augmented. But the provision of future benefits by taxes on present wages may not be the best method of giving such benefits when wages are low. The wage may be too small to be deferred. Nor does the fact that employers pay a larger proportion when the wage is exceedingly low help those who are on the verge of unemployment and may by this arrangement be pushed over it.

It is to be feared that if normal wages be not adequate to cover calculations for the future, contributory schemes, however advantageous, may make things more difficult than before for workers belonging to a grade in which numbers are great in proportion to demand. It cannot be assumed that the demand for such labour is inelastic. In many instances it is, as when labour paid at a low rate is employed in co-operation with better-paid labour and in industries in which its cost is but a small proportion of total cost. But frequently the demand is elastic, as in agriculture, where we are constantly told that labour cannot profitably be employed even at minimum wage rates which seem to many of us less than moderate.

Contributory insurance schemes have occupied much attention lately, probably more than they deserve. The contributions demanded by each individual scheme are no great matter; even taken together they do not amount to a vast charge per worker. But, small as they are, they are of interest as being attempts to stretch the normal wage to meet the needs of maintenance when, in terms of that wage, the worker is not always worth a rate which will enable him to meet all the demands made upon him for his own immediate support and that of his family.

The normal wage is defiantly rigid. It is also brutally erratic. It will not be stretched to meet any but the most immediate needs of workers in low grades; it is capable in times of depression of falling below even that low standard. In the process of asserting itself it drives men ruthlessly from occupations for the products of which demand has fallen. The secret of its mastery lies in the fact that it offers the one price at which all labour of any given grade can be absorbed in the occupations to which it is admitted. Whatever be the rights of the coal dispute, it is true that a point may come at which any industry or any single firm in an industry may be unable to pay a living wage to all those occupied in it. The normal wage commonly offered in other occupations for the same grade of labour will only be given in such an industry when enough men have left it to make the rate even throughout the grade. In the meantime labour may suffer greatly, and the productive power of all industry may suffer, since nothing is

so destructive to a man's capacity or more likely to force him into a lower scale of labour than a prolonged spell of unemployment.

There are those who hope that in time the normal wage may in all ranks of labour be at least adequate to maintain workers and their families through all uncertainties and vicissitudes. They believe that the progress of invention will immensely increase productivity; that improved business methods on one side and rising standards of work on the other will make each worker more productive; that ultimately education will raise all workers to the ranks of those whose work is worth much. But until that Utopia arrives it is well to recognise that, except by making wages abnormal, we cannot at present expect them in all cases to do what is required of them.

It is blindness to pretend that the normal wage must necessarily provide for all needs, or that the worker is necessarily to blame if it does not. Those more fortunately placed among the workers, as well as among other classes of the community, often gain by the cheapness of the goods made by workers whose work is worth little because their numbers are great. But the community as a whole does not gain, because the workers receiving low wages are part of the community.

It is roughly true that the normal wage distributes labour well through distributing wealth ill. Redistribution of wealth is therefore necessary. Redistribution in the name of wages tends to interfere with the distribution of labour; for this reason it might be well to leave wages to mean normal wages and to redistribute wealth by other methods.

Obituary.

SIR WILLIAM SCHLICH, K.C.I.E., F.R.S.

THE death of Sir William Schlich, who succumbed to an attack of bronchitis on September 27, at eighty-five years of age, removes from the world of forestry one of its outstanding figures of the past half-century. A native of Hesse-Darmstadt, Schlich studied at the University of Giessen, taking his degree of Ph.D. in 1866. The same year he was offered and accepted a post in the Indian Forest Department, then in its infancy, and was posted to Burma, where he served as deputy conservator of forests until 1870, when he was transferred to Sind, where he remained for two years. In 1872 he was promoted to the conservatorship of Bengal, which in those days comprised the present provinces of Bengal, Assam, and Behar and Orissa. For seven years he threw himself with energy and conspicuous success into the arduous work of organising forest operations in this huge tract. After a spell of leave to Europe, followed by a short period of service as conservator of forests in the Punjab, he was appointed towards the end of 1881 to act as inspector-general of forests to the Government of India: he was confirmed in this appointment in 1883, when his predecessor, Dr. Brandis, retired from the service, and held it until 1885, when he proceeded to England to take up the post of professor of forestry in the newly created forestry branch at the Royal Indian Engineering College at Coopers Hill.

During Schlich's period of service in India, the work to be done consisted largely of preliminary organisation, and the conditions were by no means easy. In the earlier years the superior staff consisted for the most part of men without any scientific training in forestry, although by the time he left India matters had improved vastly, owing to the steady flow of British recruits trained at the Nancy Forest School in France, and to a smaller extent in Germany. These earlier years of the forest department were marked by strong opposition, not only from the timber trade and other interested parties, but also from Civil officials, many of whom regarded the conservation and national management of the forests as an uncalled-for innovation. Perhaps the most important advance which marked Schlich's term as head of the department was the creation of a special working plans branch in the office of the inspector-general of forests; this provided for the expert

scrutiny of all forest working plans before they received final sanction, thus ensuring their preparation on correct lines.

So far as his work and activities were concerned, Schlich's appointment in 1885 to the professorship of forestry at Coopers Hill marked the beginning of a new era. From that year onwards he was destined to devote himself to the teaching of forestry, and it is in this sphere of activity that he was best known to the present generation. Combining sound knowledge and judgment with an enthusiasm for his subject which was infectious, and possessing a keen sense of humour and a remarkable capacity for winning the confidence and affection of his pupils, he was the embodiment of those qualities which go to make the ideal teacher. What the British Empire owes to him may be realised from the fact that his old pupils are to be found throughout its length and breadth. Immediately prior to the War, some ninety-five per cent. of the Indian Forest Service, from the inspector-general to the latest joined assistant conservator, were old pupils of his, while at the present time there is not a single senior officer of that service who was not trained by him.

Schlich became a naturalised British subject while at Coopers Hill. His educational duties there covered a period of twenty years, during which time he was responsible primarily for the training of recruits for the Indian Forest Service, although a few forestry students of the College obtained appointments in other parts of the Empire. On the abolition of Coopers Hill in 1905, its forestry branch was transferred to Oxford. Here Schlich, although sixty-five years of age, threw himself energetically into the work of organising the school of forestry in its new home and making it worthy of the great University which had adopted it. Through the generosity of St. John's College, aided by other benefactors, a building was erected with lecture rooms and a museum. In 1911 Schlich severed his official connexion with the India Office when he retired under the Civil Service rules; he was thereupon appointed reader and, by decree of Convocation, given the status of professor of forestry. By this time the Oxford school of forestry had fully established its reputation, and had become responsible for the training of numbers of forestry students destined not only for the Indian service, but also for many other parts of the empire. Schlich's

chief ambition while at Oxford was to bring forestry into line with the other main scientific departments of the University and to obtain for it that recognition which its growing importance deserved. He therefore set to work to collect funds for the endowment of a permanent chair of forestry, and his appeal met with a sympathetic response from various sources, both official and private. He had the satisfaction, not long after the conclusion of the War, of seeing the realisation of his dreams, for a permanent professorship of forestry was constituted in 1919, and in the same year a statute was passed placing forestry among the degree subjects until then it had ranked as a diploma subject only. He finally laid down the reins of office on January 1, 1920 when he was succeeded by one of his old pupils.

Schlich was an honorary fellow of St. John's College, Oxford. He was elected a fellow of the Royal Society in 1901, and was created K.C.I.E. in 1909. His best-known work is his "Manual of Forestry," in five volumes, of which three were written by himself and two by his former colleague, the late W. R. Fisher. Among his other publications may be mentioned "Afforestation in Great Britain and Ireland," "Forestry in the United Kingdom," and a large number of papers, reports, and other writings. He was a member of the Forestry Sub-Committee of the Reconstruction Committee which was appointed in 1916 and issued its final report in 1918. He held the office of president of the Royal English Arboricultural Society in 1913-14, and was on the governing council of the Empire Forestry Association at the time of his death. In spite of his advanced age, he retained his mental vigour unimpaired until the end, and worked hard at the revision of his "Manual of Forestry" after retiring from his post at Oxford; he brought out new editions of vol. 1 in 1922 and vol. 3 in 1925. He was married twice, and is survived by a widow, a son, and four daughters.

R. S. TROUP.

✓ PROF. ANDREW GRAY, F.R.S.

THE many old students of emeritus Professor Andrew Gray, some of whom are scattered all over the world, will be sorry to hear of his death. His strong personality, ability as a teacher, and unwearying patience in explaining difficulties, must have endeared his memory to many thousands of students. There are few men who worked harder or have left a greater record of work. His life was a full and a happy one, and his sympathy with the early struggles of young men considerably lightened his onerous duties as a professor. He belonged to the diminishing band of mathematical physicists, and he once told the present writer that what he called the "Laodicean" attitude of many scientists towards mathematical physics was seriously discouraging research in this direction. In a letter some years ago, written when revising his "Absolute Measurements," he complained of feeling tired, but added that he must finish his work for *ἐρχεται νύξ*. The night has now come, and he sleeps well who toiled during many years to advance our knowledge of Nature.

Born in 1847 at Lochgelly, in Fifeshire, Gray began his mathematical studies in the subscription school at the time of the Indian Mutiny. His text-book was "Practical Mathematics," by John Davidson. Modern

educationists might consider the book a collection of mathematical scraps, but Gray often spoke of the intense interest it excited in the boys. By means of a measured base line, 10,110 feet long; they could measure the distance of Nelson's monument on the Calton Hill at Edinburgh, the lighthouse on the island of Inchkeith, the Martello Tower at Leith Harbour, North Berwick Law, and so on. The solutions of such problems had an interest that no mere diagrams with their letters A, B, C . . . could ever give.

At the University of Glasgow, Gray studied very hard and gained many honours. He once told the writer the reason why he did not obtain more. On one or two occasions he had to leave a fortnight before the end of the term in order to assist in farming operations at home. On one occasion this probably lost him the gold medal which is given to the best student in the senior Greek class. He ever put duty before personal ambition. He graduated as M.A. with honours in mathematics and natural philosophy. Gray was an excellent classical scholar, and in his later years he derived much pleasure from reading Latin and Greek poetry. Like his friend Prof. Chrystal, he was a great admirer of Schiller's poems and knew many of them by heart. His Greek testament was his constant companion.

Gray was private secretary and assistant to Sir William Thomson (Lord Kelvin) from 1875 until 1880; and official assistant to him from 1880 until 1884. About this time electric lighting was gradually coming into use, and electrical measurements became of practical importance. Gray wrote a series of elementary papers on the subject for NATURE, which attracted considerable attention. They formed the nucleus of his treatise on "Absolute Measurements in Electricity and Magnetism."

To be an assistant to Lord Kelvin was not an easy post. Having many interests which took him away from home, his assistant could never tell before the lecture what aspect of the subject the professor was going to discuss or what apparatus he would want. He kept all his staff busy with his work and their individuality was apt to be submerged. In 1883 Gray published the first volume of "Absolute Measurements," which has been a great help to many. Kelvin told him that he ought not to have published it so long as he was his assistant. Nowadays this would be an impossible attitude for a professor to take up. No one, however, had a higher opinion of Kelvin's abilities than Gray, or more revered his memory.

In 1884 Gray was appointed to the chair of physics in the newly founded University College of North Wales. Amongst his new colleagues were Henry Jones, the distinguished philosopher, James J. Dobbie, later the principal of the Government Laboratory, and George Ballard Mathews, a mathematician possessed of rare gifts, with whom he co-operated in writing the well-known "Treatise on Bessel Functions." While in Wales he took the leading part in the foundation of the County School for Girls in Bangor, and championed the cause of the higher education of women. At this time he was also an enthusiastic mountaineer, and made weekly excursions with some of his colleagues into the Welsh hills.

On the death of Lord Kelvin in 1907, Gray was

installed as his successor to the Glasgow professorship. He delivered the University Oration in memory of Kelvin. This he later expanded in his book called "The Scientific Work of Lord Kelvin." In this book he gives an excellent account of the life and manifold activities of his famous predecessor.

Gray planned the present Natural Philosophy Institute of the University of Glasgow, a task which absorbed all his energies for several years. The Institute was opened eighteen years ago by the King and Queen, then Prince and Princess of Wales. He also took a leading part in arranging for the comfort of the students, a subject barely considered by the professors of fifty years ago.

Of Gray's literary work we can only mention his "Treatise on Magnetism and Electricity" (1898), "Dynamics, and Properties of Matter" (1901), which was translated into German by Prof. Auerbach, "A Treatise on Dynamics" (1911), in conjunction with his son, Dr. J. G. Gray, and "Gyrostatics and Rotational Motion" (1919). This last treatise stands as a monument to the vigour and industry of the author, and also to his thorough understanding of the fundamental principles. In 1921 he published a revised edition of his "Absolute Measurements." The work was practically rewritten and involved an immense amount of labour. The early edition was found to be a great help by those who determined our electrical standards at the National Physical Laboratory. The late Dr. Rosa also, of the U.S. Bureau of Standards, Washington, much appreciated his formulæ and constructed an electro-dynamometer to Gray's instructions, which was found most useful.

Gray communicated many papers and gave several lectures before learned societies. In particular, the writer remembers the sixth Kelvin lecture he gave to the Institution of Electrical Engineers. He showed the gyrostatic apparatus Kelvin used in his lectures, and explained clearly the dynamical principles which they illustrated. He also obtained complete solutions of, and generalised, some of Kelvin's theorems. In his opinion, the teaching of dynamics and gyrostatics was badly neglected in nearly every university, and in many cases the old Newtonian philosophy had become a byword. Young mathematicians and physicists revelled in discussing relativity and quanta: the former possibly leading to higher orders of relativity and the latter to fruitless metaphysics. He did not mind these metaphysical discussions, provided the speakers had a sound knowledge of rotational dynamics, but he was afraid that few of them had.

Prof. Gray was very happy in his home life. He is survived by his widow, three sons, and four daughters. There was an interesting family gathering when he and his wife celebrated their golden wedding five years ago. He was glad when his second son James gave up engineering and followed in his footsteps; a decision which has since been justified by the excellent work he has done in gyrostatics and his appointment as professor of applied physics in the University of Glasgow. His two youngest daughters are well known in musical circles in Glasgow.

Gray was a strong swimmer, and when he was at Bangor he rarely missed his morning bathe in the Menai Straits. In his later years he loved to spend his

vacations in the Perthshire Highlands, where golden eagles are still to be seen holding their own in the struggle for existence. He always stood with deep reverence before the great problems of the soul and the destiny of man. •What he said of Kelvin we can also say of him: "He believed that Nature, which he had sought all his life to know and understand, showed everywhere the handiwork of an infinite and beneficent intelligence, and he had faith that in the end all that appeared dark and perplexing would stand forth in fulness of light."

ALEXANDER RUSSELL.

DR. CHARLES F. SONNTAG.

By the sudden death of Dr. Sonntag on October 10—only two days before the thirty-eighth anniversary of his birth—the Zoological Society of London has lost a Prosector who by temperament and enthusiasm for patient anatomical investigation had ideal qualifications for this office. At University College, where since 1922 he had acted as a part-time demonstrator of anatomy, Sonntag endeared himself to students and colleagues by loyal service and geniality, and to a wider circle by the lucidity and interest of his public lectures on the evolution of man.

Dr. Sonntag was born in Glasgow, his father being a naturalised Swiss and his mother Scottish. He was educated in the University of Edinburgh, where he took the M.D. degree with honours in 1912. After a varied experience of hospital work he received a Commission in the Royal Army Medical Corps when War broke out. On active service at Salonika he had the misfortune to contract phthisis and was invalided home. When convalescent he resumed work at the Red Cross Clinic in London and afterwards (1917–1919) in the Special Military Orthopædic Hospital at Shepherd's Bush. There he attracted the attention of Prof. Wood Jones, who recommended him to apply for the vacant prosectorship of the Zoological Society.

Although Sonntag had been interested in zoology from boyhood and had attained distinction in anatomy as a medical student, he really began his serious apprenticeship to anatomical research in 1919, when he was elected to the prosectorship. The distinctive quality of his service to the Zoological Society and University College has been aptly described in the *Times* of October 12 in these words: "Sonntag was an indefatigable worker, apparently with no interest in life except dissection and the encouragement of other dissectors." In spite of his ill-health and physical weakness his intense enthusiasm sustained him during the brief six years of his career as an anatomist, which produced an enormous output of original observations in the Proceedings of the Zoological Society. For four years he contented himself with recording facts, apparently without any definite aim in view. But the discipline of preparing (in 1923) his book on "The Morphology and Evolution of the Apes and Man" seems to have shaped his purpose. In 1924 and 1925 he marshalled the evidence he had been accumulating since 1919 on the comparative anatomy of the tongue; and at the summer meeting of the Anatomical Society last July he gave a masterly exposition of his investigations, carefully building up his argument that certain easily observed features of the tongue could be used as trust-

worthy criteria of affinity in the Primates and other mammals and as tests of the presence or absence of specialisation. The skill and insight displayed in this discussion of the fundamental principles of mammalian evolution revealed the fact that Sonntag had suddenly attained the maturity of his powers. Hence the magnitude of the loss his death inflicts upon the science of anatomy is more readily appreciated.

WE regret to announce the following deaths:

Mr. J. Y. Buchanan, F.R.S., chemist and physicist to the *Challenger* Expedition and Vice-Président du Conseil de Perfectionnement de l'Institut océanographique de Paris, on October 16, aged eighty-one years.

Prof. E. D. Campbell, professor of chemical engineering and analytical chemistry in the University of Michigan, distinguished for his work on the constitution of steels and hydraulic cements, on September 16, aged sixty-two years.

Mr. J. S. Gamble, F.R.S., lately Conservator of Forests in India and Director of the Imperial Forest School, Dehra Dun, on October 16, aged seventy-eight years.

Prof. H. Maxwell-Lefroy, professor of entomology in the Imperial College of Science and Technology, South Kensington, on October 15, aged forty-eight years.

Prof. H. C. Lord, professor of astronomy since 1900 at the Ohio State University, who made contributions to our knowledge of stellar motion in the line of sight, on September 15, aged fifty-nine years.

Mr. A. R. McCulloch, curator of fishes in the Australian Museum at Sydney and chief fishery expert of Australia, on September 6, aged seventy years.

Prof. Urban Pritchard, emeritus professor of aural surgery at King's College, London, president in 1899 of the sixth International Congress of Otolaryngology, and author of a "Handbook of Diseases of the Ear" and of papers on the structure and function of the cochlea, on October 16, aged eighty years.

Current Topics and Events.

THE Right Hon. Sir Horace Curzon Plunkett, F.R.S., sometime vice-president of the Department of Agriculture and Technical Instruction for Ireland, enters on his seventy-second year on October 24. A member of one of the oldest pre-Cromwellian Anglo-Irish families, he was educated at Eton and University College, Oxford. Soon after attaining his majority he took up (and very successfully) the development of a ranch in Montana, gaining a mass of practical knowledge and full acquaintance with American agricultural methods. He returned to Ireland in 1889, and thereupon engaged in propaganda work embodying the need for economic legislation which might revive and encourage individual enterprise and promote practical rural education. The ultimate outcome was the establishment of a Department of Agriculture. From time to time Sir Horace met with much criticism and opposition from parliamentarians of the day, his ideals of a new civilisation in Ireland not being, apparently, consonant with their political vision. Nevertheless he can look back to many notable accomplishments. Sir Horace is an Hon. D.C.L. (Oxon.) and Hon. LL.D. (Dubl.).

SIR FREDERIC L. NATHAN, the new president of the Institution of Chemical Engineers, an authority in the chemistry of explosives, was born on February 10, 1861. Educated professionally at the Royal Military Academy, he entered the Royal Artillery in 1879. For the period 1888-1892 he was second assistant to the Director-General of Ordnance Factories, and afterwards became Superintendent of the Royal Gunpowder Factory, Waltham Abbey; later he went to Nobel Explosives Company's Ardeer Factory as works manager. He was attached to the Ministry of Munitions during the War. Sir Frederic had as a brother the late Sir Robert Nathan, distinguished for his War services in secret service work. In 1909 Sir Frederic Nathan delivered an evening lecture at the Royal Institution on "Improvements in Production and Application of Guncotton and Nitroglycerine."

PROF. J. P. POSTGATE, writing on "Our Classics To-day" in the October issue of the *Fortnightly Review*, expresses satisfaction that the position of the classics has greatly improved during the past twenty years; and he traces the improvement largely to the activities of the Classical Association, which now comprises 2300 members and possesses a dozen branches. During the War, he says, it seemed as if the fanatics of modern materialism must carry the day; but the report of the Government Committee on "The Classics in Education" gave welcome proof to the contrary. He adduces evidence of the revival of ancient learning, and is gratified that a committee of the British Association did not fail to consider the claims of Latin to be chosen as the international auxiliary language, though he omits to add that the committee unanimously rejected the claims. For our part, we also rejoice that modern materialism has not carried the day. Like the antagonism between religion and science, that between humanistic and scientific learning has lost much of its old venom, for we realise that truth has more than one aspect, and that the desire for perfection may be stimulated in more ways than one.

In the past the autocracy of the classics was kept alive mainly by the force of tradition and the conservative instincts of our ruling classes; to-day classical learning is tending to rank side by side with natural knowledge as a master-key to the knowledge of man and as a superb implement for promoting accuracy of word and thought. Prof. Postgate views with approval the growth of literature designed for those who, not knowing Latin or Greek, yet desire to know about them; but he maintains that experiences recorded, thoughts intended, and speech employed constitute an indivisible trinity, and only through the last can the first two be reached. He laments the lack of Greek and Latin etymological dictionaries in English, condemns wholesale our school Latin dictionaries, and criticises the accentuation of Greek

and the want of appreciation of classical metre in our schools of to-day. Another object of criticism is the excessive cost of books for classical education, for which the intermediaries—the printer, book-binder, and book-vendor—are held to be responsible.

CONSIDERABLE interest has been aroused by the reports which have appeared of the performance of a novel type of flying-machine known as the Cierva autogiro. Test flights were made with the machine at Farnborough on October 19 by Capt. F. T. Courtney before representatives of the Air Ministry and a number of men of science and air-craft designers. The machine, which is the invention of Don J. de la Cierva, consists of an Avro fuselage with the wings removed, their functions being supplied by a four-winged windmill revolving freely on a central upright pillar. The four narrow wings, about 17 ft. in span, are pulled round by means of a wire in spinning-top fashion so that they revolve at about 120 revolutions per minute, and afterwards the forward speed of the machine keeps them moving at sufficient speed to give the lift required to maintain the machine in the air. The wings are articulated to allow them to rise and fall while the "windmill" is turning. Elevators and rudder are used as normally for control purposes. Capt. Courtney demonstrated that it is possible to land safely at a very steep angle, there being no need of great forward momentum as in other types of heavier-than-air machines. Descending at an angle of about 60° with the horizontal, the machine stopped in about two yards, while, when making a more normal descent, the machine came to rest within its own length. Another great advantage claimed is that, in the event of engine failure, the machine sinks downward and forward under the control of the elevators, and can be landed with safety.

THE September issue of the *Journal of Scientific Instruments* contains the address of Mr. F. Twyman, president of the British Optical Instrument Manufacturers Association, to the Association in July last. It deals with the present position of the optical industry in Britain, and it is most encouraging to find that, notwithstanding the small amount of business which is being done, the improvements in quality of the instruments produced in the last decade has been very great. The varieties of optical glass now available exceed 80 as against 26, and three British firms produce them as against one ten years ago. The work of the Research Association has given the industry a new and better abrasive, and has greatly improved the methods of colouring glass. The National Physical Laboratory has done work of a fundamental character on the theory of lenses and has turned out diffraction gratings of good quality. Microscopes, cameras, and telescopes have all been improved to a point which no foreign competitor has reached, and the testing of optical surfaces has been refined to such an extent that surfaces correct to one-millionth of an inch are obtained. An industry which shows so much vitality is bound to come through the present depression with its reputation enhanced.

IN addition to his many previous contributions to the science of spectroscopy, Prof. Kayser has now compiled a book of tables intended to lessen the labours of the ever-increasing number of workers in this field. Published by S. Hirzel of Leipzig under the title "*Tabelle der Schwingungszahlen*," the tables give the wave-numbers for wave-lengths between 2000 Å.U. and 10,000 Å.U. The wave-lengths have first been reduced to vacuum and then the reciprocals calculated. In the region 2000 Å.U. to 7000 Å.U. the wave-numbers are tabulated, to eight significant figures, for every 0.1 Å.U., while convenient interpolation tables on each page enable the reading to be made for every 0.001 Å.U. Between 7000 Å.U. and 10,000 Å.U. the entries in the table correspond to each Ångström unit. In addition, the value of $n - 1$, where n is the refractive index of air for the wave-length in question, is given for every unit, and also that of $\lambda(n - 1)$, so that the wave-length *in vacuo* can be readily obtained. In view of the great importance of optical frequencies and frequency differences to the theory of atomic structure, an immense amount of work is being devoted to the theory of spectra; up till the present, owing to the lack of tables such as these, this work has involved a great deal of laborious calculation. Much of the time spent in this way will, in the future, be saved by the use of these tables.

MIDDLEMEN'S profits and the level of retail prices have recently become important subjects of discussion. The public feels that the gap between wholesale and retail prices is too great, and this impression has been strengthened by the evidence brought forward by the Food Council. Systematic study of the facts is essential since the economic problems involved are of considerable complexity. In the *Economic Journal* for September 1925, Mr. W. R. Dunlop essays such an investigation of "London's Retail Meat Trade." He states that in London the weekly consumption of butcher's meat is 2.41 lb. per capita. Retailers are in a strong position because both the demand and the supply are fairly constant, but in practice he considers that competition is preventing abuse of this power. It might, however, be objected that tacit agreement among the retailers may serve to keep prices higher than they need be. Mr. Dunlop directs attention to the State-owned butchers' shops in Queensland. There meat is sold at 1d. to 2d. per lb. cheaper than in the private shops and the average net profit has been 0.2d. per lb., while on turnover the profit is 4.05 per cent. as against say 0.75d. per lb. and 6 per cent. in London. He points out, however, that it is not safe to argue from this that municipal shops would give satisfaction in London. Difficulties would probably arise from temporary shortage of supplies and also during the Saturday "rush hours," since London shops are much busier than those of Queensland. Moreover, Queensland produces all its own meat and exports a surplus.

THE history of the dyestuffs industry in Great Britain affords an excellent example of the precept that it is not enough to practise patriotism in time

of war: by the exercise of judgement and foresight during peace, we must seek to stave off the evil day and to prepare for any possible emergency. Organic chemists and plant for making organic chemicals are every whit as important as the production of dyed fabrics to deck our persons and our surroundings; and it is therefore a matter of national importance to keep the electorate aware of the vital nature of such so-called key industries. The Worshipful Company of Dyers is one of several City companies that has given practical recognition to these truths, its latest effort in this direction is the organisation of a series of lectures on dyestuffs to be given in London during the coming winter. The course of lectures is as follows. October 22, Sir Max Muspratt: How Dyes are made, November 19, Dr. E. F. Ehrhardt: The Patent Law as it affects the Dye-making and Dye-using Industries; December 14, Prof. G. T. Morgan: Recent Researches on Mordant Dyes, January 11, Mr. C. M. Whittaker: Artificial Silk Dyeing; February 15, Mr. R. F. Thomson: Vat Dyes and some recent Developments, March 25, Dr. H. Levinstein: The Dyestuff Industry and the State. Tickets may be obtained free of charge from the Clerk, Dyers' Hall, Dowgate Hill, London, E.C. 4.

MEMBERS of the British Association who took part in the Canadian visit, and who wish to be reminded in pleasant fashion of the delightful and varied vegetation of that vast dominion, cannot do better than read the entertaining article contributed to the Journal of the Royal Horticultural Society, Vol. 50, Part 2, by the Lady Byng of Vimy, under the title "Some of Canada's Wild Flowers." Whilst revealing the characteristic personality of the writer, and so written as to appeal to the non-botanist with an interest in flowers, this article gives an excellent account of the main type of vegetation met with in the trans-continental journey undertaken by the British Association, whilst the vivid phraseology conjures up charming pictures of Canadian scenery which for many of the British visitors must now remain in the mind as the background of a very pleasant "busman's holiday."

At the fifth Congress of Industrial Chemistry, organised by the French Society of Chemical Industry, and recently held in Paris, a Chevreul medal was awarded to Prof. Henry E. Armstrong, and Sir Robert Hadfield, Bart., was elected an honorary member of the Society.

THE Baly Medal of the Royal College of Physicians, given for distinguished work in physiology, chiefly during the past two years, was presented on October 19 to Prof. R. Magnus, professor of pharmacognosy in the University of Utrecht.

UNDER the auspices of the Australian Salon of Photography (Box 298 F, G.P.O.), Sydney, New South Wales, the second International Exhibition of Pictorial Photography will be held on June 7-19 next. The latest date for receiving pictures will be May 3. Pictures from overseas may be mounted or unmounted, but must not be framed, and the Customs authorities require that a value should be placed on each.

▲ IN Our Astronomical Column of September 19, p. 445, reference was made to the series of articles on the changes of view in astronomy during the past year or two, which Prof. H. N. Russell is contributing to the *Scientific American*, beginning with the September issue. We are informed by the associate editor of that journal that Prof. Russell has contributed a monthly signed article to the *Scientific American* on current trends in astronomy since 1900.

A PAPER on "Science and Industry, Some Impressions from the Early Experiences of the British Non-Ferrous Metals Association" is to be presented by Dr. R. S. Hutton and Dr. O. F. Hudson, before the London Local Section of the Institute of Metals, on November 12. The meeting will be held at the Royal School of Mines, South Kensington, S.W. 7, at 7.30 p.m., and tickets can be obtained from the honorary secretary of the Section, Mr. W. T. Griffiths, Research Department, Woolwich, S.E. 18.

THE ninth lecture of the series "Physics in Industry," being given under the auspices of the Institute of Physics, will be delivered by Dr. B. A. Keen, Assistant Director of the Rothamsted Experimental Station, who will deal with "The Physicist in Agriculture, with Special Reference to Soil Problems." The lecture, which will be open to the public, will be given in the rooms of the Chemical Society, Burlington House, London, on Wednesday, November 25, at 5.30, and the chair will be taken by Sir William Bragg, president of the Institute.

THE establishment of sanctuaries for birds in the Royal Parks in Scotland, at Duddingston Loch in Holyrood Park, Edinburgh, and at Linlithgow Loch, has recently had the consideration of Lord Peel, First Commissioner of H.M. Works and Buildings, and a small committee has been appointed to investigate the matter. The members of the Committee are: The Right Hon. Lord Elphinstone (chairman), Dr. W. Eagle Clarke, Dr. James Ritchie, Mr. W. Home Cook, Surgeon Rear-Admiral J. H. Stenhouse, and Councillor T. G. Nasmyth. Mr. W. Wright, H.M. Office of Works, 122 George Street, Edinburgh, will act as secretary to the Committee.

THE Council of the Institution of Civil Engineers has made the following awards for session 1924-1925 in respect of selected engineering papers, published without discussion: A Telford Gold Medal to Dr. Andrew Robertson (Bristol), a Telford Gold Medal and the Indian Premium to Mr. S. A. S. Bunting (Bombay), Telford Premiums to Messrs. A. D. Swan (Montreal), C. H. Cruttwell (New Ferry), J. W. McLaren (Newfoundland), and J. L. Hodgson (Eggington); and a Webb Prize to Mr. A. R. Johnson (Penang), and in respect of papers read at students' meetings in London or by students before meetings of local associations during the same session: The James Forrest Medal and a Miller Prize to Mr. E. J. Rang (Tynemouth); and Miller Prizes to Messrs. D. Lloyd (Liverpool), H. F. Lea (Birmingham), H. A. Macnab (Glasgow), T. W. Marsh (Rochester), C. R. Smith (Manchester), and W. C. Knill (Gateshead-on-Tyne).

SIR CHARLES SHERRINGTON, president of the Royal Society, unveiled on October 19 the bronze memorial tablet to Sir Charles Wheatstone which has been placed in St. Michael's Church, Gloucester, by the City authorities. The ceremony marked the fiftieth anniversary of the death of Wheatstone, the pioneer of the electric telegraph. A number of instruments and pieces of apparatus designed by Wheatstone himself, or in collaboration with Sir W. F. Cooke, are preserved in the Science Museum, South Kensington. These have been brought together on this occasion in Gallery XXVI. of the new buildings and will remain there as a special exhibit for a fortnight. Early examples of stereoscopic apparatus; of two-, four-, and five-needle telegraph instruments, of his automatic telegraphic transmitting and receiving instruments, and of typewriting machines, are among the exhibits.

THE Egyptian Government Almanac for 1925 has been carefully revised and contains much useful information, among which certain chapters are of scientific interest. Agriculture and industries are fully treated, and there is an account of the various measures for the improvement of crops and combating plant diseases which are being undertaken by the Ministry of Agriculture. A chapter on the Nile gives a condensed account of the regime of the river.

COLOURED pictorial supplements form a feature of recent numbers of the *World's Health*, the monthly review of the League of Red Cross Societies. They illustrate the posters which are issued by the League for health propaganda and are adapted for the respective countries where they are to be utilised. Thus, in the July number the poster reproduced is that for India, and depicts various scenes in native dress and surroundings illustrating common dangers to health, e.g. the risk from flies on food, the danger of sleeping with consumptives, etc.

THE Carnegie Institution of Washington has published an account by Dr. Chester Stock of the Cenozoic gravigrade edentates of western North America, in which the Megalonychidae and Mylodontidae of the celebrated Rancho La Brea deposits come in for special consideration. The genera *Nothrotherium*, *Megalonyx*, and *Mylodon* are fully described from excellent material, and the account is fully illustrated by 47 plates and 120 text figures. Attention may be directed to the excellent quality of these text figures, both as to drawing and reproduction; the publication reflects great credit on author, as well as his artists and printer.

THE report of the annual meeting of the Indian Botanical Society held at Benares on January 12 last shows an active society in existence, with a membership of 171, which has assumed responsibility for the *Journal of Indian Botany*, edited by Prof. P. F. Fyson, and is doing its best to unite botanists in India in the task of promoting botanical survey and investigation. The report includes the presidential address by Prof. Shiv Ram Kashyap, an interesting account of the vegetation of the western

Himalayas and western Tibet, illustrated by some striking photographs of the cushion-like, shrubby perennial plants which alone can thrive in the cold dry winds in many of the desert regions of the Tibetan plateau.

A FOURTH part of the important work "Trees and Shrubs of Mexico," published as volume 23 from the United States National Herbarium, has recently appeared. In this volume the families Passifloraceae to Scrophulariaceae are dealt with by Mr. Paul C. Standley, assistant curator to the Herbarium, but Mr. Ellsworth P. Killip deals with the family Passifloraceae, whilst about 150 pages are devoted to an account of the Cactaceae of Mexico by Dr. N. L. Britton and Dr. J. N. Rose. That these authorities could deal with the Cactaceae is very fortunate, as a greater number of species of this family occur in Mexico than in any other part of the globe. The present volume contains pages 849-1312, with an index of species in an additional 39 pages.

THE annual report of the National Institute for the Blind (1924-25) supplies some interesting reading, which may come as a surprise to those unacquainted with its many-sided activities. There are homes for blind babies, a massage school, a college for blind girls, a guest house, and a hostel, in addition to departments concerned with the publication of Braille embossed books, with the training and after-care of the adult blind, with the supplying of materials for the blind to work with in their homes, etc.; in addition, technical and research work is undertaken with the object of still further alleviating the lot of the blind. The work is of the utmost importance, first, because by adequate training the separation of the blind from their fellows is minimised, and secondly, it is of interest to all scientific people, for by a study of those deprived of one sense we gain some insight into the part played by that sense in the normal person.

MR. CHARLES NOWELL, librarian of the Coventry Public Libraries, sends us a class-list of the periodical publications currently displayed in the city libraries. The list contains entries of no less than 623 publications, exclusive of annuals, and includes the large number of 60 periodicals devoted to motor engineering. Many of these works are no doubt presented to the library; but it is evident that Coventry does not stint expenditure in the purchase of the more expensive publications. For example, nine of the current co-operative periodical indexes and professional abstracts are taken in, such as the Subject Index to Periodicals, the Wilson Co.'s Indexes, Chemical Abstracts, and the Abstracts of the Metal Institute. Against the entry of each periodical in the list is a number indicating in which of these nine indexes and abstracts the periodical in question is analysed. This is a novel and valuable feature in class-lists of the above nature, and we commend it to the notice of other librarians. The list is being sent gratuitously to firms and individual residents who are likely to be interested in its contents. The work is well printed and arranged, and reflects credit upon all who have taken part in its compilation.

A CATALOGUE, recently issued by Messrs. J. W. Atha and Co., Winsley House, Wells Street, Oxford Street, London, W.1, the British agents for Messrs. Carl Zeiss of Jena, contains a description of all modern types of Zeiss microscopes and accessories. The particulars given indicate the many important changes that have been made by Messrs. Zeiss, during the past few years, in the construction of the optical and also the mechanical parts of their microscopes. A new form of mechanism is applied to all their stands for the production of the slow micrometer motion. In this mechanism, the motion is transmitted by accurately cut, toothed wheels. The reaction of a spring ensures continuous pressure in the direction of motion, so that there is no backlash. The component lenses of the objectives are now mounted in small cylinders, which are finally assembled one above the other within a hollow cylinder. This mode of mounting obviates such centring defects as were liable to be introduced in the course of the screw assemblage formerly adopted. The accessories have also been remodelled and improved, and many new and useful devices have been added. Among these may be mentioned the change-over condenser for bright and dark background illumination, the micromanipulator which enables an observer to operate on the smallest microscopically perceptible objects, and special eyepieces, such as the stereoscopic eyepieces, the photographic eyepiece, and the comparison eyepiece.

MESSRS. Reynolds and Branson, Ltd., of Leeds, have recently issued a new edition of their well-known catalogue of chemical and physical apparatus and chemicals. A feature of this publication is its division into sections, each complete in itself, which can be easily found by means of thumb-indexes distinctively marked and coloured; and the relatively small size of the book (9½ in. × 6 in.) makes it much more easy to handle than ordinary catalogues of this nature. Of the nine sections into which the book is divided, that on optical projection apparatus strikes one as being especially valuable and comprehensive, whilst the photographic reproductions and diagrammatic plans of chemical and physical laboratories, designed and fitted by this firm, cannot fail to interest all heads of departments in schools, colleges, and factories.

READERS interested in Latin America should apply to Mr. F. Edwards, 83a High Street, Marylebone, W.1, for Catalogue 472 relating to books, etc., dealing with Central and South America, British Guiana and the Falkland Islands. Nearly 700 works are offered for sale.

No. 797 of "Sotheran's Price Current of Literature" has just been circulated by Messrs H. Sotheran and Co., 140 Strand, W.C.2. Like its predecessors, it contains many bibliographic notes of interest and value on the works listed, of which there are some 1465 titles. The catalogue includes the library of the late Mr. J. E. Campbell, F.R.S., and a selection from that of Prof. A. R. Forsyth, F.R.S. It should be seen by all mathematicians on the look-out for additions to their libraries.

MESSRS. Bernard Quaritch, Ltd., 11 Grafton Street, W.1, have just issued Catalogue No. 394, which gives particulars of many rare books on astronomy, chemistry, engineering, mathematics and physics, offered for sale by that firm. An item of great interest in the catalogue is "The Wooden and Metal Numbering Rods called Napier's Bones," being the actual calculating instrument invented and used by Napier. The box containing the rods bears the inscription, "This box was the identical property of the author of *y^e Log^s*. Napier 1824."

MESSRS. Wheldon and Wesley, Ltd., 2 Arthur Street, W.C.2, have just issued Part 3—Invertebrata—of their Zoology Catalogue. It contains nearly 4000 titles arranged under the headings Mollusca, Insecta, Economic Entomology, Parasitology, Arachnida, Myriapoda, etc., Crustacea, Vermes, Echinodermata, Coelenterata, Protozoa, Aquaria, Marine Biology, Microscopy, and Miscellanea. We notice that the same firm offer for sale as a whole the collection of pamphlets and separates mainly on entomology formed by the late Dr. Péringuey, of the South African Museum.

AN extensive variety of instruments is contained in a catalogue of second-hand scientific apparatus which has just been issued by Mr. C. Baker, 244 High Holborn, London, W.C.1. Microscopes and microscope accessories, surveying and drawing instruments, spectroscopes and projection apparatus, telescopes and binoculars, astronomical instruments ranging from students' models to large equatorials, and apparatus for general physical measurements, are detailed in classified lists, which contain, in all, about 2500 items, and each item is priced. The apparatus and instruments have all been tested and are guaranteed by the firm to be in perfect adjustment before being offered for sale. Copies of the catalogue can be obtained on application being made to the firm.

MESSRS. Dulau and Co., Ltd., 34 Margaret Street, W.1, have just circulated an interesting and useful catalogue (No 132) of second-hand gardening books and botanical and horticultural works. Of the 1100 odd books offered for sale, many are from the libraries of the late Sir Isaac Bayley Balfour, Mr. C. Harman Payne, and Mr. William Watson. Copies of the catalogue can be obtained free upon application.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: A lecturer in agriculture and farm costings at the Hertfordshire Agricultural Institute, Oaklands, St. Albans—Clerk of the County Council, 28 Castle Street, Hertford (November 3). A director of the botanical and plant-breeding section of the Ministry of Agriculture, Egypt, and an economic botanist—The Egyptian Legation, 7 Charles Street, W.1, or the Under-Secretary of State, Ministry of Agriculture, Cairo (November 20, endorsed "Research Staff"). A laboratory steward at the Central Secondary School, Sheffield—Headmaster.

Research Items.

THE "SUN GOD" IN INDIAN ART.—The development in the iconography of Sūrya in Brahmanical art is the subject of a study by Jitendra Nath Banerjee which appears in the September issue of the *Indian Antiquary*. In Vedic ceremonies symbols such as the spoked wheel, rayed disc, etc., were used to represent the sun. Anthropomorphic images of the sun god do not appear until late in Indian art owing to the disappearance of monuments, other than Bhuddist, prior in date to Asoka. The characteristic features of the type of the sun-god images which have been discovered in Northern India are top-boots, a close-fitting bodice-like garment, and a waist zone which has been identified with the sacred woollen girdle of the Zoroastrians. This type has been assumed to be Iranian, derived from Mithra; but the anthropomorphic representation of Mithra is due to the Hellenisation of Mithra and is derived from Apollo-Helios. The type first appears in India on a coin of Kamaska. The medieval booted sun god of India is thus derived from the Hellenistic Apollo with certain added characteristics—the boots and heavy tunic—to be attributed to the Scythian invaders who followed the Hellenes. Ingenious myths were invented to account for these alien characteristics. In Southern India they were forgotten, and the sun god is there represented without his boots and heavy draperies.

THE ETHNOLOGY OF NEW ZEALAND.—In Vol. 2 of the Cawthorn Lectures (Cawthorn Institute, Nelson, N.Z.) Te Rangi Hiroa (P. H. Buck) surveys present knowledge bearing upon the question of the origin and composition of the Maori and pre-Maori population of New Zealand. The traditional settlement of New Zealand is analysed into three periods: (1) a pre-Toi settlement occurring a fairly long time before A.D. 1150; (2) the Toi expedition of A.D. 1150; (3) the Hawaiki migration of A.D. 1350, which was composed of the Fleet of five vessels with the well-known canoes. The Toi people failed to bring cultivable food plants, though acquainted with them. As they were a mere handful among a numerous people of food gatherers, agriculture as well as a number of useful arts disappeared until introduced by the later migration. A detailed study of culture areas has still to be made, but the Southern culture appears more typically Polynesian than the Northern, which contains elements pointing to Western affinities from a non-Polynesian source. Among the Moriori of Chatham Island there are long-headed and broad-headed elements associated with a narrow nose; but there is complete absence of the broad-nosed Melanesian type. On the mainland, Melanesian and broad-headed elements of two types, which appear especially in remoter areas, are present. It thus appears that there were really two distinct waves of pre-Toi people coming from different regions and having distinct characteristics, one from Eastern Polynesia, the other from the Western Pacific area and bringing with it a culture with non-Polynesian elements.

SECTIONS OF THE HUMAN EYE.—A series of seven photomicrographs of sections of the human eye, the work of E. F. Fincham, are reproduced in the Transactions of the Optical Society, Vol. 26, No. 3. Several of these illustrate the distribution and size of the rods and cones in different areas of the retina. A transverse section through the bases of the rods and cones in a peripheral part of the retina shows their irregular arrangement. Here and there in this region two cones are in contact with one another, and there is a much greater number of rods than cones. The

maximum diameter of the rods is 1.5μ , while that of the cones is 6μ . At the border of the fovea, the cones exceed the rods in number. Here the maximum diameter of the cones is 4.5μ . Nearer the centre of the fovea they are smaller, measuring only 3μ , and very few rods are present. The foveal cones shown in another photograph are thin and elongated, the maximum diameter being 2μ . No rods are seen in this area. The hexagonal section of the cones and their packing at the fovea, as described by Helmholtz, are well illustrated in a photograph (magnification, 1000) of a transverse section of the cones in that region. Another interesting photograph is that of a section of the ciliary region of the eye, which has been so cut as to expose a complete zonule fibre extending from the inner surface of the ciliary body towards the anterior capsule of the lens.

HERRING INVESTIGATIONS.—A first report on the investigations made by the Ministry of Agriculture and Fisheries with regard to the age, length, and maturity of the herrings of the southern North Sea is given us by Mr. W. C. Hodgson (Fish. Invest. Ser. II., vol. 7, No. 8, 1924). The Norwegian scale theory has been accepted by the Ministry as a working hypothesis. The calculated sizes of the fish at the formation of the first winter ring show variations, and these group themselves about 8, 10, and 12 cm. For these three groups corresponding stages of young fish have been found in the winter. It is stated that a foundation for solid investigations will have been laid when the origin of these groups has been established and when it can be said a given year-class comes from a certain spawning. Growth, as shown by the scales, was found to begin in April and cease in September. The younger fish began their growth earlier and had a longer growing period than the older fish. From data obtained during the period May to October 1924, it is shown, for fish with four zones on the scales, that growth was most active during May and June, and in September it slowed down considerably. These data give a curve which shows close agreement with the observations made by Hardy on the feeding of the herring.

—EVOLUTION BY HYBRIDISATION.—Dr. L. Cockayne states that amongst the vascular plants of New Zealand, 206 wild hybrids are known between Linnean species. In these circumstances it was a natural and happy idea to invite Dr. J. P. Lott to visit that dominion, study the vegetation, and give some lectures upon his views as to the part played by hybridisation in evolution. These lectures are now published by Carterbury College under the title "Evolution considered in the Light of Hybridisation," and provide a useful brief statement in English of the reasons why Dr. Lott attaches such significance to sexual reproduction and the possibility of hybridisation in connexion with the process of evolution. He precedes the statement of his own views with a very trenchant examination of theories of transmissible variability, whether neo-Lamarckian or mutationist.

THE SOURCE OF SANTONIN.—T. E. Wallis and Ellinor J. Mowat, of the Pharmacy Research Laboratory, have done a useful if laborious piece of work in clearing up the systematic position of various samples of Artemisia, the worm-seed of commerce from which santonin is prepared. Microscopic examination of the foliage leaves and the tracts of the flower head has made it clear that the true source of the drug is *Artemisia Cina* (Berg) Willkomm, which is a different species from that given in the British Pharmacopoeia, whilst yet another species is given in the United States

Pharmacopœia. Seven commercial specimens devoid of santonin were examined and could be distinguished by the hairiness of the leaves and other minute characters. The specimens thus examined seemed all to be of the same species, but unfortunately it still remains unidentified.

INDIAN BAMBOOS FOR PAPER PULP.—*Indian Forest Records*, vol. 11, part ix., records the very successful large-scale trials by Mr. W. Raitt of his methods for utilising the bamboos and savannah grasses of India as material for paper pulp. The methods now successfully applied at the Forest Research Institute, Dehra Dun, with a small plant capable of handling 20 tons a week, are based on prolonged laboratory experiment, and, as is stated by Mr. R. S. Pearson, Forest Economist, in a preface, it appears that they "at once bring the utilisation of bamboo for paper pulp on to an absolutely sound foundation." The key to the method seems to lie in a process of "fractional digestion," in which a large bulk of soluble material, mainly carbohydrates, is got rid of by the use of dilute alkali, thus preventing dark-coloured decomposition products, which arise from these soluble compounds in time, from staining the final cellulose product. At the same time economy of alkali is effected as stronger percentages are only used on a smaller bulk of material at a later stage, whilst the high density of soda then used enables both time and temperature to be reduced in the process of lignin digestion, which follows upon the removal of the more soluble products. The lignin hydrolysis yields a clear liquid which can be removed from the pulp with great facility without leaving any stain. The large paper mills of India are said to be adapting their plant to this "Fractional Digestion" system. It deserves consideration outside the bounds of India: thus Prof. F. W. Oliver has described experiments on the utilisation for paper-making of spartina, the grass which is now colonising vast sheets of mud in the neighbourhood of Southampton, and was studied with interest by many members of the British Association this year. Prof. Mangham gives a brief account of this grass, with some striking photographs, in *Conquest* for September 1925.

AMMONITES OF THE FAMILY ECHIOCERATIDÆ.—The importance of Ammonites as zone fossils, and as affording clear evidence of evolutionary processes in the past, has led to their intensive study in an ever-increasing degree. Buckman's work on them in this direction is well known, and the studies initiated by him have been taken up by various successors. The latest and a most valuable contribution is one by Dr. Trueman and Miss Williams entitled "Studies in the Ammonites of the Family Echioceratidæ" (*Trans. Roy. Soc., Edinburgh*, 53, pt. 3), members of which have been most frequently recorded in the past as *Ammonites raricostatus*. After discussion of general considerations, the authors proceed to systematic descriptions. Here they increase the five genera which they found when they took up their investigations, by the addition of nine new ones. In making these genera, and in indicating their limits, attention was paid so far as possible to the presumed phylogeny of the family, but the authors suggest the possibility that further researches may entail the foundation of yet others. This implies, of course, the creation of additional new species to the thirty-three such named in the present paper. There is a short but sufficient section devoted to the stratigraphical distribution of the family as well as an altogether admirable series of excellent plates.

AN ARCTIC OIL OCCURRENCE.—In a short bulletin of the United States Geological Survey (No. 772), by

Messrs. Paige, Foran, and Gully, some details are given of the results of an expedition to the Point Barrow region of extreme northern Alaska in 1923, made primarily to search "Naval Petroleum Reserve No. 4" for evidence of petroleum. The expedition seems to have been quite successful despite the remoteness of the area, inaccessibility, rigid climatic conditions, and other obstacles to routine survey, and two large oil seepages at Cape Simpson were discovered. Practically the entire area of this Naval Oil Reserve lies north of the sixty-ninth parallel, and thus comes well within the Arctic Circle. The Cape Simpson seepages seem to emanate from Mesozoic rocks (Upper Jurassic or Lower Cretaceous), which are the predominating rocks of the Point Barrow region, but owing to the drift and moss-covered character of the coastal plain country and absence of contiguous solid rock, it has so far been found impossible to discover definite relationships between the petroleum and local geology. It is clear from the tests carried out on samples of the oil, however, that it is much inspissated, and probably has migrated from considerable depths. It showed a specific gravity of 0.943 and contained 6.36 per cent. of sulphur and 7.5 per cent. of water, distillation indicated chiefly gas oil and lubricant fractions, lighter products having evaporated. The results of these tests, coupled with the available geological evidence, justify a continuation of the explorations, and a further expedition has been sent out at the instigation of the United States Naval Department to prove the value of the discovery.

UPPER AIR TEMPERATURES IN EGYPT.—The Meteorological Office, Air Ministry, in Professional Notes, No. 41 (London: H.M. Stationery Office, 3d. net), by Mr. E. V. Newnham, discusses upper air temperatures in Egypt. The discussion refers to observations made at Ismailia and at Helwan. Mean values of temperature corresponding with pressures of 950 or 900 to 650 or 600 millibars are given, and these are taken to be also the means corresponding with the average heights at which these pressures occurred. The difference between the mean temperatures for January and August are given, these being the months with lowest and highest means at all heights, and some figures for south-east England are added. The range with height is seen to be rather greater in Egypt than in south-east England. At a height of about 3300 ft. the lowest temperatures occur generally with winds having at least some component from north and often with nearly due north winds; the directions corresponding with the highest temperature are very variable. At 12,000 ft. and 14,000 ft. the fluctuations of temperature are much smaller, and they do not correspond very closely with the fluctuations lower down. The discussion is a praiseworthy effort to advance our knowledge of the general circulation of the atmosphere.

A HIGH ALTITUDE OZONE LAYER IN THE ATMOSPHERE.—In the *Comptes rendus Acad. Sci.*, Paris, August 24, Messrs. J. Cabannes and J. Dufay describe observations on absorption bands due to ozone in the spectrum of the sky at the zenith, in the middle of the day and towards evening, in which their relative intensities were compared. The mass of ozone traversed by vertical rays reaching the ground is equivalent to a layer of the pure gas at atmospheric pressure with a mean thickness of 0.3 cm., and if this gas were uniformly distributed in the atmosphere the amount in that portion of it in which ordinary determinations can be made would be about ten times as great as that actually observed. The natural conclusion is that the amount of ozone is greater at high elevations than lower down, and since the light

passing through this high layer of ozone strikes it more nearly perpendicularly in the middle of the day than in the early morning or the evening, the absorptions will differ. In either case the light passing through this layer will be diffused by the air into which it passes, and will be observed as sky light. The authors deduce from their measurements a height of about 50 km. for the ozone-rich layer of the atmosphere, 48 km. from observations on March 10, 53 km. for June 4, and 48 km. for June 8.

RADIATION DUE TO ELECTRONIC BOMBARDMENT.—An article in the *Zeitschrift für Physik* for July 18, by Prof. G. Mie, deals with the relation between the radiation produced by bombardment with swift electrons (*Bremsstrahlung*) and the new emission theory of Bohr, Kramers, and Slater. It is difficult to reconcile the existence of this "braking radiation" with the new theory. When an electron enters an atom with a high velocity it travels in a hyperbolic orbit, and may jump from this into a hyperbolic orbit with smaller energy, or even into an elliptical orbit, with an emission of braking radiation. According to the new theory of emission, radiation takes place during the time before the jump, when the electron is moving in the higher orbit; but it is difficult to see how this can take place for the braking radiation, since an electron moving in a straight line with uniform velocity certainly does not radiate, and the short time during which it remains in the hyperbolic orbit near the nucleus will not suffice for the emission of a long wave train. It seems necessary to assume that the electron itself can act as an oscillator, and that a free electron at a distance from any atom can take on an infinite number of conditions in each of which it contains a different amount of internal energy. In an ordinary stream of electrons, each of them is in the most stable condition and does not radiate, but when one of them meets an atom it may undergo a collision of the first kind and a portion of its kinetic energy will be suddenly converted into internal energy, the electron passing into a higher valued condition. It will at once begin to radiate with constant intensity, and with a definite wavelength, until it either falls back into the most stable condition at the end of the natural "life" (*Verweilzeit*), or possibly until before this it loses its capability of vibration as the result of a collision of the second kind, and again gains kinetic energy. Collisions are also possible in which the atom absorbs or gives out energy. Compton's scattered radiation is the fluorescent radiation of the free electrons, which are excited by optical resonance. If they radiate undisturbed to the end they form the recoil electrons; if their radiation is stopped by a collision of the second order they form the swift photo-electrons.

TERNARY ALLOYS OF IRON, CARBON, AND NICKEL.—Owing to their industrial importance, many papers have been published on the constitution of nickel steels, but there has as yet been no systematic study of the ternary alloys of iron, carbon, and nickel. T. Kaser, in the 104th Report from the Institute for Iron, Steel, and other Metals, Japan, gives an account of his investigations on the equilibrium of this system. The chief previous investigations on the binary alloys have been carried out by Ruer and Schütz, and by D. and H. Hanson. The present author has also investigated the binary systems, iron-nickel and nickel-carbon. He finds that carbon and nickel form a eutectic at a concentration of 2.22 per cent. of carbon and a temperature of 1318°C . The solubility of carbon and nickel is 0.55 per cent. at the eutectic temperature, and about 0.25 per cent. at room temperature. In the ternary system the author finds no ternary eutectic, but a binary eutectic of a

solid solution consisting of iron-nickel and carbon. The sum of the combined and dissolved carbons in the ternary alloys at room temperature rapidly decreases to 0.30 per cent. in 30 per cent. nickel-steel, and afterwards remains constant. The field representing the existence of cementite in the ternary alloys has been determined. It almost coincides with the range in which combined or dissolved carbon exists. With the addition of nickel the A1 transformation is lowered and is scarcely visible at 10 per cent. As the nickel content increases, the carbon content in the eutectoid compound decreases down to 0.30 per cent. at about 35 per cent. of nickel.

A NEW LOCAL ANÆSTHETIC.—The British Drug Houses, Ltd., have prepared a new substitute for cocaine, called borocaine, which is an efficient, non-toxic, surface anæsthetic. The original paper on borocaine, by Copeland and Notton, appeared in the *British Medical Journal* for September 25. It is prepared as a soluble white crystalline powder and is the borate of ethocaine.

A SIMPLE PRECISION CRYOSTAT.—In the *Journal of the American Chemical Society* for September a simple precision cryostat is described, a modification of that of Henning, able to maintain any required temperature from 0° to -180° for three hours. The liquid in the bath, gasoline for temperatures to -140° and butane for temperatures to -180° , is cooled by aged liquid air flowing through a copper spiral, under pressure of a hand-regulated water-head, at such a rate that the bath tends to become too cold. Temperature change is shown by a sensitive galvanometer used as a null instrument, a heating coil in the bath being operated by a switch to restore the needle to zero. The maximum error at -150° is 0.01° and at -180° is 0.015° .

ESTIMATION OF OXYGEN.—It has been known since 1863 that the estimation of oxygen of high purity by adsorption in alkaline pyrogallol solution is rendered inaccurate by the liberation of carbon monoxide. The results of some work on this subject by Drakely and Nicol appear in the *Journal of the Society of Chemical Industry* for September 25, 1925. They recommend the use of a solution prepared by adding 15 gm. of pyrogallol to 100 cc. of potash solution of $d = 1.55$, in the usual gas analysis vessels; agitation is of utmost importance; the solution must not be used after absorbing one-tenth of its specific adsorption volume, and the oxygen content of the gas should be reduced to 25 per cent. with nitrogen. With these precautions the analysis may be considered sufficiently exact for industrial purposes.

CATALYTIC ACTIVITY OF THIN FILMS.—The results of some experiments on the catalytic activity of thin films of nickel and platinum in the reaction $\text{C}_2\text{H}_4 + \text{H}_2 \rightarrow \text{C}_2\text{H}_6$ are published in the September *Journal of the American Chemical Society*. Thin films of nickel and platinum were deposited on glass wool in evacuated vessels by electrical heating of filaments coated with these metals. The mixture of gases containing 20 per cent. ethylene and the catalyst were heated to 200° , but no reaction was observed. Similar negative results were obtained when oxygen and water vapour were admitted. The results indicate that the importance of the extent of surface has been overestimated. From the method of preparation of the surface it is likely that the electronic configuration of the molecules in the film is the same as that in the bulk metal and differs from that in the catalyst prepared by the reduction of the oxide. It is supposed that the surface of the catalyst consists of molecules having electrons on different energy levels from those in the crystalline metal.

Palæontologists at Weimar.

THE annual meeting of the international Palæontological Society, which, as already announced in *NATURE*, was held in Weimar on September 24 to 30, was attended by about sixty members. Germans naturally predominated, but Austria, England, Hungary, Russia, and Sweden were also represented.

FIG. 1.—At the bottom of the Kämpfe Quarry in the travertine of the Ilm terrace near Ehringsdorf, Weimar. The white paper label marks the level of the Mousterian culture-layer.

Weimar is a delightful town in which to stay, but the historical interest of the best available meeting-room scarcely outweighed its unsuitability for a modern scientific conference, nor did the rainy weather conduce to the pleasure of the excursions. On the other hand, the immediate neighbourhood has, during the past few years, furnished the Weimar Museum für Urgeschichte with a remarkable series of Pleistocene remains, which have been studied and arranged mainly by Prof. W. Soergel and Custos Moeller. These come from the travertine and gravel deposits of the Ilm valley. An excursion had been planned to the travertine quarries of Ehringsdorf, where in the lower beds is to be seen a culture layer of Mousterian age. In clearing a fresh surface of this layer for inspection by the palæontologists, the unexpected discovery was made of a battered skull of Neanderthal type embedded among the charred fragments of wood and bone. The mode of occurrence suggested that this might be a case of cannibalism. Another recent find, announced by Prof. Freudenberg, was of human bones from Mauer, possibly belonging to the original *Homo heidelbergensis*.

Inspired by the morphology of Goethe, Prof. Jaekel opened the proceedings with a most interesting lecture on the problem of the skull. His main conclusion was that the primitive skull consisted of four parts, two in the cranium, two in the lower jaw, with the addition of a quadrate. Prof. Sewertzoff, on the other hand, claimed for the primitive cranium a large number of ossification centres. The Russian morphologist also discussed the origin of the quadrupeds. Dr. Ehrenberg attempted, from his studies of cave-bears, to throw some light on the epiphysis found at the back of the head in young skulls. Prof. Jaekel introduced a Devonian fossil as a direct ancestor of the sturgeons, in which case the Liassic

sturgeons would be a side-branch. Prof. Wiman discussed minor points in the skeleton of Mesosauria, Dr. Gürich showed photographs of Triassic Deinosaur foot-prints from German S.W. Africa, and Dr. Schmidtgen described a huge *Elephas trogontherii*, with a pelvis 183 cm. wide, recently obtained by the Mainz museum. The most fundamental paper on vertebrate anatomy (scarcely palæontology) was by Prof. Weidenreich of Mannheim, who demonstrated a continuity of the organic stroma from bone, through dentine, right into the enamel of the teeth.

Among the papers on fossil invertebrates may be mentioned Prof. Kessler on the siphonal structures of various cephalopod shells, illustrated by many preparations, including some transparent specimens from Spitsbergen; Dr. Scheurlen on pustulate ammonites from the Upper Brown Jura, showing that various species of *Strigoceras* were really growth-stages of a single species; and Dr. Beurlen on some stratigraphical and palethological questions concerning Jurassic Crustacea, in which Eryon was regarded as tending towards *Brachyura*. *Arenicoloides* was the subject of papers by Prof. K. Andrée and F. A. Bather, the former regarding it as identical with *Diplocraterion* (Torrell) and *Arthraria* (Billings), the latter seeking to explain it by similar structures in the Yorkshire estuarine oolites. The curious markings and other peculiarities of the Flysch were held by Prof. Abel to indicate formation under the conditions of a Florida mangrove-swamp.

Two papers of historical interest directed attention to modern evolutionary views in pre-Darwinian works,

FIG. 2.—A block of the Mousterian culture-layer showing the battered Neanderthal cranium *in situ* as found.

Prof. Wüst dealing with Ludwig Rütimeyer (1825–1895) and Prof. Pompeckj with Reinecke (1818).

The meeting was brought to a close by an excursion to Jena, where members were invited to a special demonstration of the marvellous Zeiss planetarium; that at Munich was described in *NATURE* (December 27, 1924), and we believe there will soon be one in London. Then followed an inspection of the Phyletic

Museum, under the guidance of Prof. L. von Plate. In the afternoon members examined the Muschelkalk at Gdschwitz, where the rock is worked on the plateau in a succession of funnel-shaped quarries. A tunnel leads to the bottom of each funnel and the rock is tumbled down into the waiting waggons, which are transported by an aerial line to the cement works in the valley. Since the rock is cut out in steps, each quarry resembles a Roman amphitheatre, but with no arena. Thus ended an exceedingly interesting meeting, at which one would like to have seen more palaeontologists from the British Isles.

Cotton-Growing in the British Empire.

A USEFUL account of the present position of cotton-growing in Uganda is given by Col. C. N. French in a recently published report to the Empire Cotton-Growing Corporation on his tour through the cotton areas of Uganda, Kenya, and the Mwanza district of Tanganyika. The rise and promise of Uganda as a cotton-producing region are well known. Under the careful guidance of the agricultural department, cotton has become by far the most important export of the country, the annual production amounting to nearly 200,000 bales. Practically the whole of the crop is raised by the natives, who send their seed cotton to the ginneries established at convenient centres under European or Indian control. The type at present grown is a variety of the famous "Nyasaland Upland". The quality of the cotton is good and the yield not unsatisfactory, while so far no serious pests have been encountered. Col. French considers that for the time being the producing area should not be extended, but efforts made to consolidate the present position by the application of science and improved agricultural methods with the view of producing increased quantities of cotton of better and more uniform quality from the area already under cultivation. He believes that the most immediate need for the attainment of this object is the strengthening of the scientific side of the agricultural department, and he puts forward suggestions for the reorganisation he considers desirable.

A further illustration of the work of the Empire Cotton-Growing Corporation is afforded by the "Reports from the Experiment Stations for the Seasons 1923, 1924, and 1925 (South Africa only)." In South Africa, F. R. Parnell has established the fact that resistance of the cotton plant to the attacks of "jassid" (*Chlorita fascialis*, a small winged bug forming a menace to cotton-growing in the lower veldt) is hereditary, and considerable progress has been made in the direction of breeding a jassid-resistant variety of cotton. R. C. Wood reports on the selection and other experimental work carried out at Mpanganya (Tanganyika). One of the varieties resulting from the selections made in 1922 will be the first seed to go out into general cultivation (it is hoped) in the season 1926-27. The work of establishing and laying out the experiment station at Makwapala (Nyasaland) during 1924 is described by H. C. Sampson, while details of a variety test with Sea Island cotton in St. Vincent, B.W.I., are recorded by L. H. Burd. This latter work was undertaken with the object of investigating the relationship, if any, existing between the yield and other "growing" qualities of the cotton plant, and the spinning characters of the fibre. The inconclusive results illustrate the difficulty of complicated work of this nature, but an encouraging practical outcome of the experiments is the evidence afforded by the spinning tests (carried out by the Experimental Department of the Fine Spinners' and Doublers' Association) of the superiority of all the strains of

cotton tested over the control standard sample of West Indian cotton: reduction of comber waste was considerable, and in one case a superiority of 47 per cent over the control cotton as regards the relationship between hair strength and weight of lint was recorded.

The Empire Cotton-Growing Corporation has evidently recruited men of overseas experience in addition to scientific knowledge in their task of widening the area under cotton cultivation in the British Dominions Overseas. The October number of the *Empire Cotton Growing Review* contains reports of their activities in all parts of the Empire. H. C. Sampson points out how cultivation implements adapted from Indian experience may be applied to cultivation with native labour in East Africa, whilst Col. C. N. French discusses the possibility of adapting the methods of administration of large-scale estates in the Punjab to the problems of cotton-growing in the Mandated Territory of Tanganyika. Mr. Youngman describes the short staple Oomras cotton and the factors leading to the cultivation of this coarse type of cotton in a vast area of Central India. It is thus once more apparent what a reservoir of experience to be applied in problems of tropical administration is rendered available through Britain's long responsibility for India's development. In a review dealing with cotton-growing, insect pests are naturally well to the fore, and H. A. Ballou discusses them in general relation to cotton, F. R. Parnell's work on breeding jassid-resistant cottons is also described, whilst incidentally, in discussing insect pests under Australian conditions, E. Ballard gives it as his experience that jassid infestation is only serious when the soil is very poor, e.g. deficient in potash.

University and Educational Intelligence.

APPLICATIONS are invited by the Harveian Society of London for the Buckston Browne prize, consisting of a medal and 50*l.*, for the best essay on "The Etiology of High Blood Pressure and of the Respiratory Phenomena associated with High Blood Pressure and Chronic Nephritis." The latest date for the receipt of essays is November 1, 1926. Particulars of the competition may be obtained from Dr. G. de Bec Turtle, 81 Cambridge Terrace, Hyde Park, W.2.

THE President of the Board of Education and the Minister of Labour have appointed a committee "to inquire into and advise upon the public system of education in England and Wales in relation to the requirements of trade and industry, with particular reference to the adequacy of the arrangements for enabling young persons to enter into and retain suitable employment." The committee consists of Mr. Dougal O. Malcolm, Miss Violet Markham (Mrs. Caruthers), Mr. Max J. Bonn, Mr. W. B. Kennick, Mr. Arthur Shaw, Mr. Christopher H. Turnor, and Mr. D. Milne Watson. Mr. H. B. Wallis, Board of Education, and Mr. W. H. Lowe Watson, Ministry of Labour, are joint secretaries, and all communications should be addressed to them at the Ministry of Labour, Montagu House, Whitehall, S.W.1. The absence from the committee of any one familiar with the place of science in education, or education in science, is particularly noteworthy. Oxford and Balliol predominate in the membership of the committee, and they represent the characteristic official attitude towards scientific teaching or its relation to modern needs.

A NEW Diploma Course in Agriculture is announced by the Edinburgh and East of Scotland College of Agriculture. Hitherto the College diploma course has extended over three years, like the degree course, from which it has differed but little in scope. Neither course has attracted more than a very few prospective

farmers. Nearly all those who have taken them have done so with the view of becoming teachers or departmental officials. The college authorities have determined that the new diploma course shall meet so far as practicable the needs of the ordinary farmer, and have therefore limited it to two winter sessions, and reduced to a minimum the purely theoretical instruction. The new regulations appear in full in the College Calendar for 1925-26. The subjects are agriculture, agricultural chemistry, agricultural botany, agricultural zoology, farm accounting and agricultural economics, land surveying and agricultural engineering, veterinary science, and agricultural law. The Calendar shows that during the past session the central classes were attended by 407 students, namely—day classes, 121, evening classes, 184; rural schools' course, 86, and farmers' class, 16.

The government of the Welsh National School of Medicine has formed the subject of prolonged consideration by the Council of the University of Wales, which has come to the conclusion that the School, at present governed by the Council of the University College of South Wales and Monmouthshire, assisted by a Board of Medicine and a Faculty of Medicine, should be constituted an independent School of the University. At a special meeting of the Court of the University presided over by the pro-chancellor, Lord Kenyon, on October 16, a resolution to this effect was submitted by Mr. William George, of Criccieth. It was asserted, as one of the grounds of the motion, that unless the School was made truly national it would be difficult and perhaps impossible to secure rate aid from the North Wales councils, and the Privy Council grant of 7000*l.* would not be available. The motion was opposed by Principal Trow, of the University College of South Wales. After discussion it was carried by 71 votes to 41. It is proposed to petition the Privy Council for a charter of incorporation for the School, the status of which in the University of Wales would thus approximate to that of the College of Medicine, Newcastle-on-Tyne, in the University of Durham.

The University of Leeds has launched a public appeal for half a million pounds for structural expansion and increased equipment. This sum is not far short of the total of the donations and subscriptions (excluding those of the Clothworkers' Company, amounting to about a quarter of a million) received by the University and the Yorkshire College of Science during the past fifty years. The appeal organisers have set themselves the task of raising it in ten years, hoping that it may be possible to proceed with the building programme meanwhile at the rate of 50,000*l.* a year. The staffing of the University has, in the past, been treated always as of first importance, and to this policy is largely due the substantial success it has achieved in the pursuit of its aims, but a situation has now been reached in which "its present efficiency is severely hampered and its future efficiency is imperilled both by the want of accommodation and by the unsuitability of much of the existing accommodation." In particular a new library building with accommodation for 200,000 volumes, new laboratories for the medical school, new buildings for nine or ten departments, new residential hostels; and a properly equipped students' union building are urgently needed. With the appeal, which is addressed especially to the local patriotism of Yorkshiremen, is circulated a booklet prepared for the jubilee celebrations of last year, giving an account of the growth of the University and a summary statement of its activities. The first list of subscriptions in reply to the appeal includes donations and promises amounting to more than 110,000*l.*

Early Science at Oxford.

October 24, 1683. Several members of the Royal Society and others, met at Oxford for making experiments. There was communicated an observation of the weight of the earth of the Nile about the time of the overflowing of that river, but especially a relenting of a piece of nitroon or nitre, brought from Ægypt, which continually wet the papers, on which it lay, both in rains and dry weather, from the middle of June till about the end of September.—There was also an intimation of fish having lived in a cistern upon rain-water only for half a year, till upon the freezing of the water they died by breaking of the ice.—There was also mention made of a probable way of tinging white marble black.

October 26, 1683. The Company meeting, in ye Naturall History School, desired Dr. Wallis, to take on him ye trouble of ye Chair; and appointed Mr. Musgrave, to take ye Minutes of their discourse; after which, Dr Plot made a learned Discourse on Earths. Upon ye account of the last branch of his Scheme, it was ordered by ye company, that some person should try, whether Boles burnt will apply to ye magnet? Dr. Plot was pleased to take this province on him: This gave occasion to a farther discourse concerning Magnetism; twas delivered as an observation, by Mr. Ballard, that a magnet, carried up, and down, in his pocket, has been found to attract sometimes more, then at other times.

'Twas ordered to be tryed, whether bricks, heated, and afterwards growing cold, in a posture North, and South, will acquire a verticity? Mr Ballard promised ye Society to try this experiment.

After this, an enquiry was made into ye nature, and reason, of striking fire; 'twas proposed as a quære? how tobacco-pipes (in which there is not ye least suspicion of a Sulphur) come to strike fire? 'Twas given in as an observation, that hardened iron (such as horse-shoes are made of) will yeild flakes of fire, larger, and of a deeper red, than steel will? This led ye Company to discourse of hardening Iron.

Dr. Plot was desired to give an account of ye methods used by ye smiths at Wolverhampton in these cases: 'Twas observed, that an ingenious smith of Oxford, us'd to soften his iron, by heating it moderately, then dawbing it over with tallow, and afterwards heating it red hot, and letting it cool gradually in the fire as that went out.

October 27, 1685. The Company being small no papers were read.

October 28, 1684. A bottle of water, sent the Society, by Mr. Maunder, from a well near Milton-Abby in Dorsetshire, was delivered in at our meeting by Mr. Crouch; and ordered to be examined as to its principles; which office Mr. Welstead took on him. The well from whence this water came, does sometime purge, sometimes vomit, and is said to cure ye gout.

Dr. Plot communicated an abstract of a letter dated from Minehead, October 17, 1684, in which Mr. Cole acquaints ye Doctor, that he was lately met with a shellfish on ye Severn shore, containing a white viscous phlegm, which being laid on cloth, turns greenish, within a minute or two; then being put out into ye Sun, for a little while, turns to a deep red, which grows somewhat lighter by ye first washing, but after that never decays, tho ye cloth be often washt. He adds farther, that this Tincture is extremely fetid, so that the ill smell is not easily taken away. He was pleas'd to send us Patterns of ye green, ye deep, and lighter Reds, which sufficiently answered their descriptions. The thanks of the Society were ordered to be returned him, for this considerable peice of newes.

Societies and Academies.

LONDON.

Royal Anthropological Institute, October 6.—Geza Roheim: Hungarian calendar customs. Three groups of customs connected with the calendar were discussed. In Hungarian winter dances a bull plays a conspicuous part. One of the performers may be called a bull, or the bull is a musical instrument used by these dancers. The identity of a demon and a musical instrument reminds us of primitive initiation ceremonies, and the Hungarian rites in question are actually connected with the initiation of lads. The fertility customs of St. George's day are based on the unconscious concept of birth, and it is in this sense that the Pahlia, the Roman prototype of St. George's day, was the birthday of the community. The kings and queens of Whitsuntide in Hungary show that these embodiments of fertility are really the survivals of primitive divine kings, for even in the seventeenth and eighteenth centuries, Hungarian Whitsuntide kings enjoyed certain privileges and wielded authority over the lads of their village for a year.

NAPLES

Academy of Physical and Mathematical Sciences.—Among the papers published in the issue of the *Rendiconti* of the Academy for April-August 1925, are the following: (1) Prof. R. Biazzo describes a modification of the thiocyanate method of determining the proportion of copper in commercial copper sulphate, in which the excess of thiocyanate used is ascertained by titration with permanganate in the presence of sulphuric acid. The iron present is previously eliminated by oxidation with chlorine and precipitation as ferric hydroxide, and, for the reduction of the copper to the cuprous state, potassium cyanide must be used in place of sulphurous acid. (2) Arnaldo Piutti is unable to find any relationship between the hafnium contents of samples of zircon from different localities and the densities of the minerals, but confirms von Hevesy's observation that a connexion exists between the proportion of hafnium present and the degree of radioactivity. (3) From the capacity of certain samarium minerals to form homogeneous mixed crystals with the corresponding compounds of calcium, strontium, and lead, Dr. G. Carobbi concludes that the isomorphism of samarium towards metals of the isomorphogenic calcium group is more pronounced than that exhibited by other metals of the cerium group. Such conclusion is in accord with the existence of the chloride, SmCl_2 , and the iodide, SmI_2 . (4) Antonio Carrelli extends to the phenomenon of diffusion of electromagnetic waves the method given by Lorentz for visible radiations and for X-rays, account being taken of the index of refraction, the existence of which Compton has demonstrated for such waves. In this manner he arrives at Rayleigh's classic formula for the coefficient of diffusion, and shows also that, in the case of X-rays, this formula coincides with that derived by Debye on the hypothesis that the wave-length of the radiations is not excessively small.

ROME

Royal Academy of the Lincei. Communications received during the vacation.—Achille Russo: A siderophilic substance emitted from the micro-nucleus of the impure garnets derived from the second division of the impure gametogens in *Cryptochilum echini*, and its destination.—Alfredo Sabbatini: Singularity of the solution of integral equations with variable limits.—Lubomir Tchacaloff: A general

property of differential equations (a theorem of Ernesto Pascal).—B. Caldonazzo: Movements of a liquid which leave unaltered the local distribution of the pressures.—E. Persico: Experiments on the amplitude of the oscillations produced by a three-electrode lamp.—Carlo Perrier: Method for the determination of the principal refractive indices of birefractive substances by means of Federow's plate.—Luigi Rolla and Giorgio Piccardi: Chemical statics of electronic phenomena. A simple method is outlined for the determination of the dissociation coefficient and the equilibrium constant of the reaction, $A \rightleftharpoons A^{++}$ electron.—G. Bargellini: β -Phenylcoumarins.—G. Bargellini and P. Leone: Glucosides of chalkones.—G. R. Levi and G. Natta: Crystalline structure of perowskite. Röntgenographic examination by the Debye-Scherrer method indicates for perowskite a face-centred cubic lattice, but the symmetry is only pseudo-cubic, the pseudo-cube being composed of the two rhombic forms (001) and (110). The apparently higher symmetry of the crystals is possibly the result of superposition of differently orientated lamellae.—R. Perotti: Root bacilli of *Diplotaxis erucoides*.—Roberto Savelli: A collateral effect, and a rapid method of study of the ionolysis of pollen.—P. Pasquini: Genesis of the pecten in the development of the eye in birds.—C. Jucci: Hereditary behaviour of the type of larval development in crosses between silkworms of three and four mutations.—Ettore Remotti: Embryonic metabolism of the Teleostei. The amino-acids derived from the degradation of the capsule and their relation to the embryo.—Mariannina Levi: The excitability of the retina in relation to the duration of the stimulus.

Official Publications Received.

Quaternary Climates. Geologic History of Lake Lahontan, by J. Claude Jones; On the Pleistocene History of the Great Basin, by Ernst Antevy; The Big Tree as a Climatic Measure, by Ernst Antevy; Tree Growth and Climatic Interpretations, by Ellsworth Huntington. (Publication No. 852.) Pp. 1+212+10 plates. (Washington: Carnegie Institution.)

Physiological Features of Roots, with Especial Reference to the Relation of Roots to Aeration of the Soil. By William Austin Cannon. With a Chapter on Differences between Nitrogen and Helium as Inert Gases in Anaerobic Experiments on Plants, by Edward Elway Free. (Publication No. 868.) Pp. iii+168. (Washington: Carnegie Institution.)

Ministerio de Agricultura de la Nación República Argentina. Memoria correspondiente al ejercicio de 1924. Dirección Meteorológica. Pp. 17. (Buenos Aires.)

Union of South Africa. Department of Agriculture. Bulletin No. 3 of 1925. Some Further Remarks on Tobacco Cultivation for Nicotine. By J. Verneil Cutler and J. J. Theron and J. du P. Oosthuizen. Pp. 28. (Pretoria: Government Printing and Stationery Office.) 3d.

S. A. Sugar Association. Proceedings of the Third Annual Congress held on March 25th, 26th and 27th, 1925, at Umbagogwin, Mount Edgecombe and Durban. Pp. 72. (Durban: South African Sugar Association.)

Proceedings of the Royal Irish Academy. Vol. 27, Section B, No. 6: The Brachyopoda of the Coasts of Ireland. By Anne L. Massey. Pp. 37-48. 1s. Vol. 27, Section B, Nos. 7, 8: The Action of Hydrazine on the Halogen Derivatives of Malonamides and Acetosuccinic Esters, by Dr. Edmund Langley Hirst, Dr. Alexander Killen Macbeth and David Traill; Condensation Reactions of Indoxyl and 8-Oxy (1) thionaphthyl, by Dr. Alexander Killen Macbeth and Dr. James Craik. Pp. 47-57. 1s. (Dublin: Hodges, Figgis and Co.; London: Williams and Norgate, Ltd.)

Diary of Societies.

SATURDAY, OCTOBER 24.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (South-Western District) (at Bridgwater), at 11.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Newcastle-upon-Tyne), at 8.30.—A. M. Hedley: Presidential Inaugural Address.—H. T. Foster: Rescue Work in Mines.—Discussion upon Papers by P. S. Lea on A Few Notes on the "Safety First" Movement, and W. McLaren, O. N. Kemp, and J. L. Thomson on The Scientific Control of Coal-Washing by the Combined Application of Ash Characteristic Curves and X-Ray Examination.

BRITISH PSYCHOLOGICAL SOCIETY (at King's College), at 3.15.—B. Stevanovic: Conational Phenomena in Processes of Judgment.—Miss Ethel Stoneman: Apparatus used to investigate Electrical Changes accompanying Emotional States in the Insane. The Waller Emotometer and the Godefroy Tachogram.

MONDAY, OCTOBER 26.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Mr. Shattock: Demonstration of Cysts.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—R. A. Chattock and others: Discussion on How can the Cost of Distribution be Cheapened?

INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—R. W. Gregory: Chairman's Address.

INSTITUTION OF AUTOMOBILE ENGINEERS (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30.—H. K. Thomas: The Automobile Engineer (Presidential Address).

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—J. L. Payne: Presidential Address.—A. T. Pitts and J. H. Mumery: A Melanotic Epithelial Odontome in a Child.

MEDICAL SOCIETY OF LONDON, at 8.30.—Clinical Evening.

INSTITUTE OF CHEMISTRY (Manchester and District Section) (Annual General Meeting, at Manchester)—F. Scholefield: Account of the Discussion on the Registration of Chemists, at the York Conference.

TUESDAY, OCTOBER 27.

ROYAL SOCIETY OF MEDICINE (Medicine Section) (at Middlesex Hospital), at 5.30.—Clinical Meeting.

INSTITUTION OF AERONAUTICAL ENGINEERS (at Junior Institution of Engineers), at 6.30.—Dr. A. P. Thurston: The International Aircraft Navigation Congress.

INSTITUTION OF ELECTRICAL ENGINEERS (East Midland Sub-Centre) (at the College, Loughborough), at 6.45.—H. D. Symonds: Insulation.

INSTITUTION OF AUTOMOBILE ENGINEERS (Informal Meeting) (at 83 Pall Mall), at 7.—Discussion on Petrol Gauges.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—T. W. Ridley: Railways.

ROYAL ANTHROPOLOGICAL INSTITUTE (Indian Section), at 8.15.—S. M. Edwards: The Population of the City of Bombay: A Few Facts concerning its Origin and Growth.

ROYAL SOCIETY OF MEDICINE, at 9.30.—Sir St. Clair Thomson: Shakespeare as a Guide in the Art and Practice of Medicine.

WEDNESDAY, OCTOBER 28.

ROYAL SOCIETY OF MEDICINE (Comparative Medicine Section), at 5.—F. T. G. Hobday: Presidential Address.—Dr. W. H. Andrews: Some Recent Advances in our Knowledge of Plant Poisoning, followed by a discussion.

INSTITUTION OF AUTOMOBILE ENGINEERS (North of England Centre) (at 244 Deansgate, Manchester), at 6.30.—H. K. Thomas: The Automobile Engineer (Presidential Address).

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at Bolbec Hall, Newcastle-upon-Tyne), at 7.—Chairman's Address.

SOCIETY OF CHEMICAL INDUSTRY (Newcastle Section) (at Armstrong College), at 7.30.—Prof. H. V. A. Briscoe: The Phenomena of Intensive Drying and their Significance.

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications of the Microscope Section), at 7.30.—Dr. F. J. Brislée: Dark-Ground Illumination for the Examination of Textile Fibres.—J. P. Strachan: The Microscopical Structure of Paper making Fibres in Relationship to their Manufacturing Properties.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (jointly with the Psychiatry Section of the Royal Society of Medicine) (at 1 Wimpole Street), at 8.30.—Symposium on The Early Treatment of Mental Disorders.—For the Royal Society of Medicine, Psychiatry Section: Sir Maurice Craig; for the British Psychological Society, Medical Section: Dr. W. Brown.

THURSDAY, OCTOBER 29.

ROYAL AERONAUTICAL SOCIETY (at 7 Albemarle Street), at 5.30.—W. L. Cowley: Aircraft Transport Economy.

INSTITUTION OF CIVIL ENGINEERS (jointly with Institution of Mechanical Engineers, Institution of Electrical Engineers, Institution of Naval Architects, Institute of Marine Engineers, North-East Coast Institution of Engineers and Shipbuilders, Institution of Engineers and Shipbuilders in Scotland, Institute of Chemistry of Great Britain and Ireland, Institution of Gas Engineers, British Electrical and Allied Manufacturers' Association, British Engineers' Association, Admiralty, War Office, and Air Ministry), at 6.—G. J. Wells: Standard Codes for Tabulating the Results of Trials of Gas-Engines and Gas-Producers.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Miss Marjorie Gullian: The Teaching of Poetry.

INSTITUTION OF LOCOMOTIVE ENGINEERS (at Engineers' Club, Coventry Street), at 7.—R. W. Reid: Presidential Address.

ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—R. H. J. Swan: Some Reflections upon Villous-covered Tumours of the Bladder (Presidential Address).

INSTITUTE OF CHEMISTRY (Glasgow Section) (at Glasgow).—Annual General Meeting.

FRIDAY, OCTOBER 30.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Preparations and Dissections to illustrate the Evolution of the Human Mechanism of Hearing.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—L. Pendred and others: Discussion on Recent Locomotive Progress at Home and Abroad.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—The Construction and Assembly of 50,000 K.W. Turbo-alternator Plant for Chicago at the Works of Messrs. C. A. Parsons and Co., Ltd. (Kinematograph Lecture).

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch, Graduate Section) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—G. Jervis: Manufacture of Coal By-products.

DENTAL BOARD OF THE UNITED KINGDOM (at Royal Society of Medicine), at 8.30.—Prof. L. Hill: Circulatory Changes in Anesthesia, and the Use of Oxygen.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

PUBLIC LECTURES.

SATURDAY, OCTOBER 24.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—H. N. Milhigan: The Defences of Animals.

MONDAY, OCTOBER 26.

KING'S COLLEGE, at 5.30.—Rev. Dr. F. A. P. Aveling: Psychology and Industry.

WEDNESDAY, OCTOBER 28.

UNIVERSITY COLLEGE, at 5.30.—Viscount Grey of Fallodon: The Open Air Sanctuaries of the National Trust.—At 5.30.—Dr. E. A. Baker: The Use of Reference Books.

THURSDAY, OCTOBER 29.

BEDFORD COLLEGE FOR WOMEN, at 5.15.—H. Peake: Cave Art and some Modern Counterparts.

KING'S COLLEGE, at 5.30.—Prof. T. P. Nunn: The Influence of Education and Tradition in Social Hygiene.

UNIVERSITY COLLEGE, at 5.30.—Prof. E. G. Gardner: Italian Universities in the Middle Ages.

SATURDAY, OCTOBER 31.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—C. D. Forde: Stone Age Man in Brittany.

SATURDAY, OCTOBER 31. 1925.

Research in Engineering.

ENGINEERING research may be said to have had its birth in the investigations of Smeaton on wind and water power and in the work of Watt on the steam-engine. Almost contemporary with their investigations we see in France the application of mathematical science to the forms and masting of ships, and the establishments of the École des Ponts et Chaussées and the École des Mines, the former having for its director the distinguished civil engineer Perronet. These various activities were among the firstfruits of the extension and application of the experimental sciences, and ever since there have been men, in increasing numbers, who have concerned themselves with the scientific principles underlying the work of the engineer and the adaptation of scientific discoveries for everyday needs. There can be no question that material progress in the past half-century has been principally due to this co-operation of science and industry, and it is in this direction hopes for the future lie. Huxley many years ago wrote: "As industry becomes more complicated and competition more keen, the sciences are dragged in one by one to take their part in the fray, and he who can best avail himself of their help is the man who will come out uppermost in the struggle for existence."

At first engineering research was but a sluggish stream confined within narrow channels, but with the coming of the steamship and the railway and all the great works they included, the sluggish stream was quickened into life, and it has now become a mighty river having tributaries in every branch of practical work. Watt, Smeaton, Perronet, and Réaumur were followed by Rennie, Barlow, Tredgold, and Navier, who in turn were succeeded by Carnot, Clapeyron, Wohler, Tresca, Bauschinger, Froude, Hirn, and Rankine, whose names are known to every student and whose labours are the heritage of the engineering world. Then, too, institutions for mechanics, such as the Andersonian at Glasgow, paved the way for our technical schools and colleges, the leaders of engineering formed themselves into societies for the discussion of both theory and practice, engineering professorships and engineering laboratories were founded, organisations such as the British Association fostered research in engineering, eminent captains of industry invited the assistance of chemists and physicists in their undertakings. State departments also initiated original investigations, and governments, convinced by the ever-accumulating mass of evidence of the importance of research, established institutions such as our own National Physical Laboratory, while another landmark was passed when in 1915 the British Government created a new public office under the title of the Department of Scientific and

Industrial Research, which already has a budget of nearly half a million.

The total amount of research carried out in engineering all over the world to-day can best be gauged by a review of the innumerable periodicals and journals, the transactions of the engineering societies, blue books and reports, of which there is a never-ending succession. But in spite of this, just as the Romans called for roads and still more roads, so the insistent demand to-day is for research and still more research. Its methods, its scope, and its results are referred to in practically every presidential address, and the foremost engineering institutions make its energetic pursuit a part of their programme. Of recent addresses referring to this topic, mention may be made of the presidential address of Engineer Admiral Sir George Goodwin to the Institution of Engineers-in-Charge, of the autumn lecture to the Institute of Metals by Sir John Dewrance, the president-elect, and of the address of Mr. H. Kerr Thomas to the Institution of Automobile Engineers.

Mr. Thomas regards the automobile engineer as a man who adapts the ideas of the inventor and the theories of the man of science to the needs of the public. Just as it is essential for him to organise his factory, so he should organise both inventor and scientific investigator for the benefit of the community. Many automobile engineers have failed to do this; and Mr. Thomas gives it as his considered opinion that if the automobile engineer has been careless of the money of his patron, and occasionally has been apathetic towards the inventor, his attitude towards the man of science has been simply inexplicable. "I will go further," Mr. Thomas continued, "and say that if this attitude does not alter, and that speedily, although the statement may sound exaggerated, it is my belief that this industry, one of the largest in the country, will be found to have passed its zenith, and will more or less rapidly decline until it is faced with extinction."

Dealing with the questions as to who should carry out the research, and how to obtain the fullest value, Mr. Thomas declared that the whole training of the automobile engineer, whose work consists of manufacturing something to be sold, unfits him for the work of research. "It is no more possible for him to do his own research work than it is for him to make the tracings in his drawing office, or to operate his capstan lathes." But it is needful for him to organise the work of the research laboratory, and this implies the capacity of working with other people, "for in government laboratories, universities, and technical colleges all over the world, there are men concentrating on just the problems which daily confront the automobile engineer." Co-operation with other manufacturers is necessary also, for the old plan of secrecy is in the end impracticable, and it is happily

coming to be regarded as more advantageous in the end to give away information than to withhold it.

In his final paragraphs, Mr. Thomas refers to the cost of research. Since 1920 there has been a Research Association under the Association of British Motor and Allied Manufacturers. The funds were provided by the motor industry, which disburses in wages some 30,000,000*l.* a year. But only about $\frac{1}{100}$ th of 1 per cent. of this sum was set aside for communal research. If but $\frac{1}{10}$ th of 1 per cent. were set aside, there would be a fund of 30,000*l.*, which, together with the help from the Department of Scientific and Industrial Research, would enable work to be attempted on a scale hitherto unknown. The American engineering institutions have formed an Engineering Foundation, a trust in which all participate. It has invested already 550,000 dollars, and now there is a serious proposal put forward by the president of the American Institution of Electrical Engineers to provide a community fund of 20,000,000 dollars. Engineering research should not be carried out in watertight compartments, and it is plain that if Great Britain were to pool its research the greatest economy could be achieved, but, says Mr. Thomas, "it would be necessary for the automobile engineers to accord to the joint research body their whole-hearted support."

The general recognition of the value of research in engineering has come about during the last thirty years. In the first James Forrest lecture to the Institution of Civil Engineers in 1893, Anderson, having for his subject "The Interdependence of Abstract Science and Engineering," remarked: "It seems to be the fate of peoples to attack social problems from the wrong end, to solve them by the painful and dilatory process of trial and error, rather than by means of investigations based on first principles, and this method is commonly applied to engineering problems. Random trials, as a rule, are the methods by which great results have been achieved, while the application of the scientific principles involved has been left to other heads, long after the results have been attained at much needless cost and by much unnecessary expenditure of labour and of time." These words were uttered when the motor industry was still in its cradle. Rolls did not import his first motor-car into England until 1895, and nearly ten years passed before Henry Ford offered his first car to the public. No one then dreamt that thirty years later the world would possess 20,000,000 motor vehicles or that a single factory would be able to turn out 8000 motor-cars a day. But such are the achievements of to-day, and they have been rendered possible only by the close co-operation of the chemist, the physicist, and the metallurgist, with the skilled engineer and the business man.

Greek Myths and Mycenaean Realities.

The Ring of Nestor: a Glimpse into the Minoan After-World and a Sepulchral Treasure of Gold Signet-Rings and Bead-Seals from Thisbe, Boeotia. By Sir Arthur Evans. Pp. ii + 75 + 5 plates. (London: Macmillan and Co., Ltd., 1925.) 12s. 6d. net.

TO-DAY even the most old-fashioned admirer of Hellenism has to admit that classical Greek civilisation was not only preceded by but also actually rooted in the Minoan culture of Crete and its continental daughter, the Mycenaean. The excavator of Minos' palace at Knossos, who so dramatically found the key to the riddle of pre-classical Greece, has himself taken the lead in tracing the influence of the Minoan civilisation on the classical; again and again he has illuminated the dark background of Hellenic life by a reference to the remains of the prehistoric age or interpreted the monuments of that still dumb epoch from the records of historic Greece.

Fresh evidence pointing in the same direction is presented in the monograph before us. Its first section describes thirteen gold seals allegedly found together in a Mycenaean tomb near Thisbe in Boeotia. Some of the seals are engraved with religious subjects and serve to extend the already large series of Minoan prototypes for classical rites and Minoan deities in the Greek pantheon. The scene of a goddess rising from the earth on Seal 6 comes startlingly close to later representations of the *anodos* of Kore. Yet there is really nothing surprising in this; Persephone (Pherséphassa) has a "pre-Hellenic" name, her "mother" came from Crete, her cult-centre at Eleusis is the site of a Mycenaean village. Those commentators who see in Persephone a corn-maiden should observe that the goddess on the seal holds poppies in her hands, a feature paralleled later in the art of Magna Grecia. Another novel suggestion is that the two girl attendants of the Minoan goddess who figure on Seal 5, as on other Minoan gems, are in a sense forerunners of the Dioscuri. Sir Arthur Evans, however, unlike Dr. Farnell, admits that the Heavenly Twins were Aryan deities, blood-brothers of the Vedic *divo napātā*, and supposes that they had assimilated the pre-Hellenic figures, as happened in other cases.

It was, however, above all through the Homeric epics and heroic saga that the Mycenaean age lived on into the classical. The centres of the great cycles of heroic myth—Mycenae, Thebes, Tiryns, Iolkos, Kalydon—are precisely the centres of Mycenaean culture, as Prof. Nilsson has recently shown. The correspondence between the heroic and the Mycenaean geography of Greece is, indeed, so exact that a study of the legends enables us to locate in advance the prehistoric sites;

it was thus that Dörpfeldt was led to the discovery of the rich tombs of Kakovatos, the half-forgotten site of Nestor's capital. Ever since Dr. Schliemann's first discoveries, the Mycenaean objects have been used with conspicuous success to illustrate Homeric descriptions of houses, works of art, weapons and methods of fighting, though other passages in the poems seem to reflect a different environment. Finally, names celebrated in Homer, Achaeans and even Atreus himself (if Dr. Forrer's interpretation of a tablet from Boghaz Keui be correct), have been discovered in historical Hittite and Egyptian texts. Such discoveries have naturally invested the old "Homeric question" with a new significance and revolutionised our view of the Heroic Age; the towns and figures of saga are becoming historical, the splendours of the epic concrete realities. Three seals from Thisbe are now presented as marking a quite new and decisive step in linking up the Mycenaean age with the Heroic and so with the Classical; they seem to imply that some of the legends at least existed, in very much the form that has come down to us, so early as the fifteenth century B.C. Two intaglios represent concrete episodes from the Oedipus cycle—the hero's encounter with the Sphinx and the killing of Laius in the Hollow Way. The third is interpreted as depicting the vengeance of Orestes on his guilty mother and her paramour, Aegisthos.

Hence some of the material used by the epic poets would have existed in saga form by the fifteenth century B.C., when the Thisbe seals are said to have been engraved. This evidence, if it be accepted, would have a decisive bearing on the whole Homeric controversy; it would afford brilliant confirmation for the theory of a "Minoan epos," already suggested by Sir Arthur Evans in 1912 to account for the Mycenaean traits in Homer; and this Minoan epos might easily be identified with the "Heroic Chronicle" inferred by T. W. Allen from the literary data as the source from which "Homer" drew much of his material.

Now if a body of saga really existed in a form from which later rhapsodes could borrow descriptions of actual works of art—our author cites Nestor's cup as an example—and embodied accounts of historical events, like the death of Aegisthos, which were "transferred" to a different context, the attractive theory of an "Achaean period" at the end of the Mycenaean becomes superfluous. Commentators have identified the epoch of Achaean domination described in the Iliad with the archaeological period known as Late Mycenaean B, when, after 1250 B.C., "Homeric" innovations—cremation, iron, slashing swords and breast-plates—begin to appear within the framework of Mycenaean culture, just in order to reconcile the Mycenaean and un-Mycenaean aspects of Homeric life; the contem-

porary Hittite and Egyptian references to Achæans—in Asia Minor and Libya—are merely invoked incidentally as confirmatory evidence. The “nameless Mycenæans” would be the Achæans of Homer, the un-Mycenæan traits in the present poems anachronisms introduced by the later minstrels who used the older saga.

It is true that the Heroes would not then be Greeks. Sir Arthur Evans in this volume again insists that the Mycenæan civilisation was implanted in Greece by actual conquerors come from Crete, and even invokes the Keftian word *Akashau*, found in an Egyptian school-book, to prove that Aegisthos at least was a Minoan. At the same time their subjects may, he admits, have included Greeks. It would then be easy to comprehend how such civilising conquerors became Hellenised in the imaginations of their Greek subjects and were appropriated by later generations as national heroes. Such, we submit, is the only logical conclusion to be drawn from the theory of a Minoan epos, though its author does not go so far, but seems still to adhere to the theory of an “Achæan period,” two or three centuries later than the Thisbe seals or the episodes they depict.

It is only fair to warn the reader, however, that the evidence of the seals cannot yet be accepted as conclusive; for their authenticity is still in dispute. Their owner can, indeed, add to his own authoritative opinion in their favour the judgment of two other experts. He further points out that two seals in the “same” group exhibit peculiarities in design, now paralleled on other indisputably genuine documents which could not have been known to a forger when the Thisbe treasure came to light. Finally, the existence of Mycenæan tombs near Thisbe is established. Nevertheless, the circumstances in which the jewels were discovered are shrouded in mystery. The treatment of the whole group as a unit rests on the subjective estimation of technical criteria; and it is precisely technical peculiarities in some of the seals, notably the three depicting heroic themes, that give rise to uneasiness. The unpleasant possibility must be borne in mind that a forger added these more striking specimens to a group of genuine but rather commonplace gems. That does not, of course, detract in the least from the enormous value of Sir Arthur’s commentary on the scenes, the masterly account of the evolution of the chariot, for example.

Fortunately no such suspicions attach to the unique gold ring which gives its title to this monograph. It is undoubtedly a remnant of the regal wealth once buried in the great tombs of Kakovatos, which had been plundered long before the Germans excavated them scientifically. The elaborate scenes engraved on this unique signet are interpreted by its present owner with

his usual penetrating insight and perfect mastery of comparative mythology. But the world of ideas thus revealed is quite un-Homeric. We see the World Tree and its canine guardian, prototype of Cerberus. From other details Sir Arthur is able to deduce that the Mycenæans conceived souls as butterflies and the chrysalis as a symbol of resurrection. With the aid of this idea, several curious objects from the shaft graves of Mycenæ can be explained, and the miniature balance comes to suggest the idea of a weighing of souls.

The author considers that the ring, like others from Minoan and Mycenæan funerary deposits, belongs to a special sepulchral type of signet, designed for suspension and not worn on the finger, the origin of which he finds in an ivory specimen from an Early Minoan tomb in Crete. It is true that the inner diameter of the hoop—14.5 mm.—seems too small for the finger of an adult. Nevertheless, the bosses adorning the hoop have been rubbed down a little, just as they would have been by actual wear on the finger, a point which is not noted in the publication.

V. GORDON CHILDE.

The Isle of Mull.

(1) *Memoirs of the Geological Survey, Scotland. Tertiary and Post-Tertiary Geology of Mull, Loch Aline, and Oban. (A Description of Parts of Sheets 43, 44, 51, and 52 of the Geological Map.)* By E. B. Bailey, Dr. C. T. Clough, W. B. Wright, J. E. Richey, and G. V. Wilson; with Contributions by E. M. Anderson, H. B. Maufe, Dr. G. W. Lee, B. Lightfoot, Dr. T. O. Bosworth, and G. A. Burnett; with Petrology by Dr. H. H. Thomas and E. B. Bailey; with Chemical Analyses by E. G. Radley and F. R. Ennos; and Palæobotany by Dr. A. C. Seward and R. E. Holtum. Pp. v+445+6 plates. (Southampton: Ordnance Survey Office; London: E. Stanford, Ltd., 1924.) 15s. net.

(2) *Memoirs of the Geological Survey, Scotland. The Pre-Tertiary Geology of Mull, Loch Aline, and Oban. (Being a Description of Parts of Sheets 35, 43, 44, 45, and 52 of the One-inch Geological Map of Scotland.)* By Dr. G. W. Lee and E. B. Bailey; with Contributions by S. S. Buckman and Dr. H. H. Thomas. Pp. iv+140+2 plates. (Southampton: Ordnance Survey Office; London: Edward Stanford, Ltd., 1925.) 4s. 6d. net.

(1) **T**HE larger of these two memoirs, that on the Tertiary geology of Mull, represents the results of work commenced by the Geological Survey in 1907. The title-page includes the names of five principal authors and of eleven other contributors. The task of the principal author and editor can have

been no easy one, and one is prepared for the complexities of the memoir by the opening words of the introduction: "It may safely be maintained that Mull includes the most complicated igneous centre as yet accorded detailed examination anywhere in the world." The reader should study the plan of the memoir in the opening chapter and refer to this again and again as he reads the successive chapters in which the intricate history of the island unfolds itself. The map which accompanies the memoir is a most complicated piece of detailed work, in which no less than 74 different symbols are employed. Its interpretation is greatly assisted by the provision of plates in the body of the memoir showing simplified maps, in black-and-white, of the various stages of the igneous cycle.

Those geologists who are fortunate enough to visit the island will welcome the "Itinerary" in Chap. i, and the wealth of detail in succeeding chapters which indicate where important sections can be seen. The second chapter, which gives a critical survey of geological research in Mull, will be read with great interest. There have been many controversies over the geology of the district, and the memoir brings new light to bear on them. Subjects of outstanding interest are: the type of volcanic activity prevailing in Mull, the causes of double-tier columnar jointing, and the distinctions between intrusive sills and lava-flows.

There are also many new conceptions, some of which cannot fail to find a place in the interpretation of other volcanic centres. The "propylite-area" of Judd is shown to be an area of pneumatolysis about a volcanic centre, within which the degree of freshness of the rocks and the type of weathering are profoundly affected. The "inclined-sheets" described by Dr. Harker in Skye are represented here by "cone-sheets," intrusive sheets, very numerous and of considerable thickness in the aggregate, which, viewed as a whole, "suggest the partial infilling of a number of cone-shaped fractures with inverted apices united underground." The intrusion of a series of cone-sheets characterises the second cycle of igneous activity in Mull following the formation of a Kilauean lava-dome with a central caldera some five miles in diameter.

Another mode of igneous intrusion which is wonderfully illustrated in the later stages of the volcanic history of the island is that of the ring-dikes. Few of these present complete ring-outcrops, but the Loch Bà felsite forms an almost complete ring, and follows a ring-fracture which outlines an area of subsidence similar to the first-formed caldera, but centred about a new focus which was the seat of the later phases of igneous action.

The various chapters on petrology contain contributions of the first importance. The sequence of igneous

intrusions is explained on the assumption of at least two magmatic cycles, in both of which the magma-sequence is from basic to acid, followed by a third intrusion of the parental basic magma as a swarm of north-west to south-east dikes, which are the last evidences of igneous activity left by subsequent denudation. The authors' explanation of the magma-sequence is briefly outlined in the opening chapter. Important evidence of gravitational differentiation is obtained from the ring-dike of Glen More, which is exposed for a height of about 1500 feet and shows a gradual transition from basic quartz-gabbro at the bottom to acid granophyre at the top.

The results of the careful study of very interesting sapphire-bearing aluminous xenoliths in the Loch Scridain sills has been the subject of a paper elsewhere, but the summary of the results given here will be none the less welcome. Only one new rock name—Craig-nurite—is introduced, but there is fresh information on little-known rocks described by two of the contributors to the memoir, and some welcome definitions of other names which have been widely used in British Survey nomenclature.

The only sedimentary rocks of Tertiary age in Mull appear below the lavas or very low down in the volcanic sequence. Fossils from the well-known plant-beds of Ardtun are described by Prof. Seward and Mr. Holtum, who confirm Mr. J. S. Gardiner's conclusion of their Eocene age and show that they are related to the Lower Tertiary flora of Greenland and other Arctic regions.

The last five chapters deal with the post-igneous history of the island, pre-Glacial, Glacial, and post-Glacial, and with its economic geology, the last amounting to nothing more than adequate supplies of good road-metal inconveniently situated for shipping, and some seams of Tertiary lignite of rather poor quality.

(2) The smaller of the two memoirs describes the pre-Tertiary rocks of Mull and other areas on Sheet 44 and adjacent sheets which have escaped denudation or have not been buried by the volcanic accumulations. Several interesting points may be mentioned. In the account of the Ross of Mull granite, particular attention has been paid to its contact metamorphism, and something is added to Dr. T. O. Bosworth's earlier account of this. A small patch of Carboniferous rocks on the mainland near Inninmore is of especial interest, as only two other occurrences are known in the Western Highlands. Rhætic beds containing the *Pteria contorta* fauna are described from the Gribun district: they are not known *in situ* elsewhere in Scotland. The Inferior Oolite is much thinner than in Skye; it shows close resemblances to the succession of rocks of the same age in the classical districts of England.

The Cretaceous rocks include the only known occurrence *in situ* of Upper Cretaceous rocks in Scotland. In the White Sandstone, which lies below the Chalk, the "millet-seed" character of some of the sands is regarded as evidence of desert conditions on the shores of the Cretaceous sea.

The final chapter on the economic geology includes an account of the building stone quarried in the very decorative Ross of Mull granite, and a record of a good glass-sand at Loch Aline, on the mainland.

Chemical Problems of Soil Fertility.

Base Exchange in Soils: a General Discussion held by the Faraday Society, December 1924. Pp. 547-617. (London: The Faraday Society, 1925.) 5s. net.

ONE of the directions in which little real progress has been made in agricultural science, in spite of an immense amount of careful work, is in the exact specification of soil fertility by means of chemical analyses. Such analyses have, in general, only qualitative significance, and their main purpose is to serve as a check to the direct field observations. In recent years considerable progress has been made, however, especially by American workers, who have paid especial attention to the concentration of radicles in the so-called "soil-solution." Progress in such a complex problem as the fertility of a normal soil is most likely to be made if extreme cases are taken, such as alkali and acid soils, where certain factors are thrown into high relief. The work of Kelly and others in California, on alkali soils, and of Bradfield in Missouri on acid colloidal clay, are good illustrations of the method. More recently Dr. Hissink and his collaborators at Groningen, Holland, have effectively used the well-known electrical double layer hypothesis as the basis of a reasonably complete theory of base exchange that can be applied to a wide range of soil conditions: the exchangeable bases are held on the surface of the clay particles by chemical attraction between them and the clay and humus acids. In a suspension of soil in water, some of the surface molecules are ionised, and an electrical double layer is formed, containing anions of soil acids inside, and outside the cations H' , Mg'' , Ca'' , K' , Na' . Students of soil science will recognise in this hypothesis a restatement in modern terminology of the essential features of Way's classic investigations of 1850.

Dr. Hissink, in his introductory paper, considers both the degree of saturation of the soil (which is the ratio of the quantity of adsorbed bases actually present, to the total amount the soil could hold) and the relative proportions of exchangeable bivalent and univalent bases. The relation of these factors to soil properties such as physical condition and pH value is discussed

in detail, and with special reference to Dutch land-reclamation problems. Messrs. Page and Williams present some important studies of base exchange in the classical Broadbalk permanent wheat and Park grass plots at Rothamsted. The long-continued treatment of these plots with various artificial manures would be expected to accentuate many of the base exchange processes, and thus to provide yet another illustration of the incomparable value to agricultural science of long-time experiments. The results show that on the acid soil of the grass plots from which chalk is absent, the amount of exchangeable calcium is correlated with the pH of the soil. On Broadbalk, where considerable quantities of chalk still remain, the relative proportions of the different bases vary consistently with the manuring, and there is some evidence of a gradual conversion of exchangeable potash to a non-exchangeable form or vice versa depending on whether potash manures are used or not.

The value of the base exchange theory in suggesting not only new view-points of known facts, but also fresh lines of work, is well shown by the remaining papers. Prof. Comber reviews earlier work based on the physical adsorption hypothesis and has some cogent observations to make on the part played by electro-negative ions. Messrs. Robinson and Williams, of Bangor, in a study of some Welsh soils subject to high rainfall, show that their lack of response to liming, although they appear "acid" by lime requirement tests, is due to the presence of considerable proportions of exchangeable calcium as determined by Dr. Hissink's method. These soils are "acid" in the chemical sense but not "sour" in the agricultural sense. Mr. E. A. Fisher contributes two suggestive papers on the relation of base exchange to adsorption phenomena, and the swelling of soil colloids. Mr. Saint, working in Prof. Comber's laboratory, shows that there is no consistent relation between the pH value, the "lime-requirement" and the Comber thiocyanate test of acidity for soils of different types.

The verbatim report of the discussion is at least as interesting as the papers, and there is much healthy criticism of both methods and results. Attention should be directed to Dr. T. P. Hilditch's discussion of industrial developments of synthetic aluminosilicates for water-softening purposes and the close relation of this to base exchange in soils.

This is the third general discussion on agricultural problems that the Faraday Society has held since 1920. The value of these discussions and the demand for the reports is shown by the fact that the accounts of the first two meetings are now out of print. The high level of the present discussion and its modest price will certainly ensure an equally gratifying demand for copies.

B. A. KEEN.

Our Bookshelf.

The Flora of the Malay Peninsula. By Henry N. Ridley (Published under the Authority of the Government of the Straits Settlements and Federated Malay States.) Vol. V. Monocotyledones (concluded), Gymnospermæ, General Indices.- Pp. v + 470. (London: L. Reeve and Co., Ltd., 1925.) 42s. net.

VOL. V. of this "Flora of the Malay Peninsula" deals with the remainder of the Monocotyledons, and with the Gnetaceæ, Coniferæ, and Cycadaceæ. Seven new species and specific names occur in the Palmaceæ, three in the Pandanaceæ, four in the Aroidæ, two in the Eriocaulaceæ, five in the Cyperaceæ, and thirty-nine in the Gramineæ. In this latter family many of the additions are from the manuscript of Dr. O. Stapf. In the Coniferæ the only new species is *Podocarpus deflexus* from high altitudes on Gunung Tahan.

Bound with this volume is a supplement in which is described material which has reached the author since the publication of the respective volumes dealing with the natural families to which the species belong. This occupies fifty-seven pages and includes several new species. The author also gives a brief discussion on the origin of Malay plant names. The remainder of the volume contains four general indices to the whole work; an index to English plant names, and what will be found particularly valuable, an index to Malay plant names; an index to the two hundred and twenty-eight illustrations, and an index to botanical names.

This "Flora," which is completed with the present volume, is one of the most outstanding accomplishments among floras of this magnitude. The author, after many years' residence in the tropics, during which he collected much of the material described, has not only worked over the whole of the specimens and written the manuscripts, but, unaided, has also supervised the entire publication. The general preparation of the work was well in hand before publication, and this has enabled the whole of the five volumes to be produced within a period of only four years, during a part of which the author was prevented from active work by illness. He has been fortunate in securing the services of Mr. J. Hutchinson for the illustrations, which are a distinctive feature of the work, and provide a welcome innovation in colonial floras. Mr. Ridley must be congratulated on having completed and produced during the first few years of his retirement a work of such first importance.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol. 30: *Copper Ores of the Midlands, Wales, the Lake District and the Isle of Man.* By Henry Dewey and T. Eastwood; with Contributions by Dr. Bernard Smith and R. G. Carruthers. Pp. v + 87 + 6 plates. (London: H.M. Stationery Office; Southampton: Ordnance Survey Office, 1925.) 2s. net.

THIS memoir deals with a large number of occurrences of copper ores outside Devon and Cornwall, which, although now of very limited economic importance, are nevertheless of considerable scientific interest because of the great variety of modes of occurrence which they present.

On this basis the ore-bodies are divided into (1) impregnations of the country rock, (2) lodes, and (3)

pipes and other irregularly shaped bodies. The first type includes the ores forming a cement in certain Triassic rocks in Cheshire and elsewhere. The curious occurrence at the Turf Mine, Dolfrwynog, in Merionethshire, where wood, leaves, and hazel-nuts lying at the base of a peat-bog were either coated or impregnated with copper or its ores, appears also to afford an interesting case of impregnation which might throw some light on the formation of the Triassic ores. It is, however, somewhat illogically discussed under the third category. The Ecton Mine in Staffordshire, belonging to the latter type, contained an irregular pipe-like mass of ore which has been worked to a depth of 225 fathoms below the surface.

The period of mineralisation is not known with certainty, but is suggested to be the same as that of Devon and Cornwall, i.e. post-Carboniferous. This conclusion appears to ignore a number of arguments that have been advanced in favour of an earlier age for the mineralisation of Wales and the Lake District, namely, post-Silurian. In this connexion, there is a serious contradiction in regard to the lodes of Caldbeck Fell, Lake District; on one page they are said to be later than the Wolfram veins of Carrock Fell, but on another page they are stated to be cut and displaced by those veins. We scarcely expected to see in these days the Ffestiniog beds (Cambrian) referred to in a Geological Survey memoir as Lower Silurian. Traces of this antiquated nomenclature occur also on other pages.

Department of Scientific and Industrial Research: Fuel Research Board. Technical Paper No. 14: The Enrichment of Coal Gas by the Injection of Oil into the Retorts during Carbonisation. Pp. vi + 61. (London: H.M. Stationery Office, 1925.) 1s. 9d. net.

THE volume of gas obtained from coal by carbonisation can be increased by gasifying a portion of the residual coke with the formation of water gas. The two processes can be either carried out in separate plants or combined as in the steaming of vertical retorts. Blue water gas has a low heating value which is, therefore, often increased by admixture of oil-gas as in a carburetted water-gas plant. This low calorific value of blue water gas also causes a reduction of the heating value of the mixed gas produced when "steaming" the charge in vertical retorts is practised. "Carburetting" the gas produced during this operation is a possible way of securing the gas-making advantages of "steaming" while maintaining adequate calorific value. Technical Paper 14 of the Fuel Research Board records tests made on the effect of injecting gas oil through a water-cooled tube into the charge of Glover-West Vertical Retorts while "steaming." It was found practicable to inject up to 10 gallons of oil per ton of coal carbonised, and by the combination of oil-injection with "steaming" to raise the thermal yield of gas by 14 per cent. per ton of coal. While the water cooling of the oil tube necessitated the expenditure of extra heat in the setting, in the cracking process itself this was inappreciable, and it seems possible that the water cooling can be dispensed with. The method gives promise of improving the gas-making efficiency of the continuous vertical retort and its adaptability to load-fluctuations. H. J. H.

Die Mumifizierung von Vögeln und kleinen Säugetieren ohne Abbalgen, bei Erhaltung des natürlichen Körpers. Von Ludwig Kirchroth. Pp. 74. (Klosterbeuburg bei Wien: Ludwig Kirchroth, 1923.) 2s. 6d.

THIS is the second edition of a pamphlet with a similar title published in 1906. It details the methods, worked out by the author, of preparing birds and small mammals as museum specimens, without skinning them in the manner usually adopted, and yet preserving the natural shape and form of the body. The method consists essentially in the injection of two media, one, a preserving fluid, and the other, a preparation of kaolin and fine siliceous marl, designed to prevent loss of shape due to shrinkage. The author gives full details of the instruments to be used, of the constitution of the media for injection, and of the preliminary preparations required before injection is done. Any wire supports which may be necessary for the subsequent mounting of the specimen can be inserted during the mummification process. The method is most applicable to specimens which are to be mounted for exhibition purposes. The author claims that it is easy to carry out, is cheap and speedy, and that it has stood the test of twenty years' experience. It certainly seems worthy of a trial and deserves to be more widely known. With this object in view, the author promises an English translation, at a cost of fifteen shillings, which may be obtained from him. Museum curators and taxidermists will find this pamphlet of great interest, and will be well advised to give the method a thorough and exhaustive test.

Pitman's Electrical Educator. Edited by Dr. J. A. Fleming. (Complete in 30 fortnightly Parts.) Part 1. Pp. 56. (London: Sir Isaac Pitman and Sons, Ltd., 1925.) 1s. 3d. net each part.

THE Preacher said that of writing books there is no end, and that much study is a weariness to the flesh. Judging by the contents of the first part of this popular educator, the second part of the above statement scarcely applies to this book. In the frontispiece it is stated that it is a highly valuable work for electricians, electrical engineers, contractors, apprentices and students. In addition, it is intended for those engaged on the commercial side of the electrical industry. Many eminent engineers and men of science are contributing to this volume. In the foreword, Dr. Fleming points out that electrical engineering has advanced so rapidly in recent years that it is quite impossible to deal with every part of the subject in a single volume. We are told that the student and the practical engineer desire to obtain a general acquaintance with the subject from a single book if possible, and that the articles will interest every engineer, whatever his status or knowledge. It will be seen that the programme is somewhat ambitious. We wish it success, but the first part does not enable us to judge of its practical value.

Woodcuts of British Birds. By E. Fitch Daglish. With Descriptions by the Artist. Pp. 165. (London: Ernest Benn, Ltd., 1925.) 25s. net.

MR. DAGLISH's work may be commended not only to bird-lovers but also to art-lovers. He is a master of decorative style and of his craft of wood-cutting, and

he knows his birds. Some of his portraits are triumphs—the red-backed shrike, for example, against bramble leaves; the reed bunting silhouetted upon a marvellous background of reed stems; the spotted flycatcher immobile on a laburnum perch; the long-eared owl among the most decorative of pine twigs; or the splendid blackcock busy with display. There is also the puffin and the crested grebe, the pied wagtail and the wren (the wren in a tangle of every kind of spring flower), the jay and the jackdaw—each one a penetrating portrait and at the same time a real work of art. Not all are so successful—the bullfinch looks stuffed, the dipper and the heron rather scraggy, the stonechat is enlarged too much, and is in a false pose. But the best are as good as they can be, and all are interesting. The notes on the habits and appearance of the birds are, we take it, designed to obviate the necessity of going to the library and taking down heavy histories of birds, and they are more than ample for this purpose, and pleasantly written. Would that more artists were naturalists, more naturalists artists!

Fuel Economy and Smoke Prevention. By John B. C. Kershaw. Being the third completely revised and rewritten edition of "Smoke Prevention and Fuel Economy," by W. H. Booth and J. B. C. Kershaw. Pp. xiii + 268. (London: Constable and Co., Ltd., 1925.) 16s. net.

IT is probable that the interchange of terms in the old and new editions of this work is due to the change in modern thought. Owing to the increase in the price of the raw material and the necessity for the working costs to be decreased as much as possible, it is natural that the emphasis should be placed on the fuel economy aspect of the problem rather than on the smoke abatement. The author has summarised much of the recent work on the constitution of coal, as well as some of the later work on the utilisation of low-grade fuels. The early chapters deal with the general preparation and treatment of coals, the remainder being devoted to the description and examination of the various processes for the combustion of fuels and the utilisation of waste products.

The Oxford Economic Atlas. By J. G. Bartholomew. Sixth edition, revised by John Bartholomew. Pp. xii + 64. (London: Oxford University Press, 1925.) 6s. net.

THIS is the sixth edition of an atlas first published in 1910. The number of plates remains the same, namely sixty-four, but a few desirable changes have been made, and all the plates have been revised. Prof. Lyde's interesting and suggestive introduction has also been revised. There is little to criticise in this useful work; certainly the high standard of cartography should be noted. Only a few minor matters require comment. The maps of world isobars still show low pressure in high southern latitudes. In the map of ocean currents more detail might be added in Arctic regions. The Marion and Crozet Islands are French, not British possessions, and in the map of religions the Falkland Islanders need not be shown as having no religion at all. In the map of fisheries, which includes whaling, there is no record of the valuable whale fisheries in South Georgian and South Shetland waters.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Investigation of the Origin of Insular Races of Land Mollusca in the Scilly Isles.

THE study of insular species of animals has for a long time been regarded as an important adjunct to evolutionary research, and the rôle of insular segregation as a factor in specific divergence has been stressed by numerous workers. It has of later years been held that one of the best ways of studying the effects of such isolation is the intensive survey of small groups of islands of tolerably recent formation, in which the divergence can be seen at its earliest stages and perhaps correlated with any incipient ecological divergence that may be manifest in the islands in question. Surveys of this kind have been made from time to time, but the result of such work seems as yet unsatisfactory for several reasons (*e.g.* insufficiency of material, lack of information as to the forms found on the adjacent mainland, and deficiency in ecological data). As a consequence an attempt has been set on foot in the present year to tackle the problem afresh, more particularly by means of intensive collecting and ecological study and in particular by detailed comparison of insular and mainland forms obtained from similar habitats. It is not claimed that more positive results will be obtained at once by these means than by the distinguished researches of previous workers; but it is hoped that a better approach to the problem may be provided. Thanks to financial assistance from the Government Grant Committee of the Royal Society and the Godman Exploration Fund of the Natural History Museum, a short reconnaissance was made last July in the Scilly Islands and west Cornwall for the purpose of studying the land mollusca of these areas.

It is needless to say that the choice of islands suited for such a study was not easy. The Clare Island Survey and other data showed that, so far as the land mollusca are concerned, no differentiation occurs in the British Isles in islands situated only a few miles from the mainland. The scantiness of molluscan groups, otherwise suitable for such a study, in certain areas (acid rocks, pine and heather formations) had also to be considered, while questions of access and transport were also of weight. Certain of the Hebridean islands were considered suitable, but the paucity of information as to the mainland fauna of the west of Scotland induced those responsible for the survey to prefer the Scilly Isles. So far as is known at present, there are no species of British mollusca restricted to any outlying islands. A survey of this nature had, therefore, to concentrate on the search for any varietal or racial differences which might be found between the insular and mainland forms. To that end a very exhaustive knowledge of the variability of the adjacent mainland forms from which the insular types may be derived or to which they may be most closely related, was indispensable. Indeed, the significance of a varietal form which might occur, *e.g.* on Scilly, could only be assessed on the basis of a fairly exhaustive knowledge of the total variability of the relevant species in the west of England. For it is quite possible that a varietal form found on Scilly might be absent from west Cornwall, yet occur in east Cornwall or Devon. The necessity for a fairly exact knowledge of the related mainland

fauna was a strong reason for choosing the Scilly Isles in preference to the Hebrides, as the mollusca of the west of England are far better known than those of the west of Scotland.

The Scillies are a group of some 140 rocks and islands situated about 30 miles from Land's End, being divided from the mainland by a channel about 40 fathoms in depth. They resemble the extremity of the adjacent Cornish mainland in being composed of a mass of granite with a certain amount of drift and recent deposits. The general physical conditions are largely the same in the two areas except that there is a heavier rainfall in west Cornwall, rather less sunshine, and a slightly lower temperature.

The work of this year's survey was confined to collection and observation on St. Mary (Scilly) and in the area west of a line drawn from Hayle on the north coast of Cornwall to Marazion on the south coast. It was thought that in the time available a better general indication of the amount of divergence would be obtained from this comparison than from a survey of a number of the Scilly Isles themselves.

A doubt was originally entertained that, owing to the horticultural business carried on in Scilly, there might not be a danger of contamination of the fauna of the latter through imported bulbs, etc. Further examination of this possibility showed, however, that it was not a factor to be considered seriously.

St. Mary may be regarded as ecologically similar to the Cornish area except in the following features: (a) It has a maximum height of only 160 feet as compared with the maximum of more than 800 feet found near St. Ives. (b) The atmosphere is probably damper at certain periods owing to the presence of sea-fogs. (c) There is no metamorphosed slate and greenstone, as is found round the granite nucleus of the Land's End mass. We have therefore for comparison an insular and a mainland area extremely similar in ecological conditions but differing in certain details. It is in conditions such as these that we would expect to find, if the conventional view as to the origin of insular forms is correct, the beginning of racial divergence.

It is undesirable to discuss at the present moment the evidence for the date at which the Scilly Isles were separated from the mainland, though this is obviously an important question.

The Conchological Society in its list (1921) of British land and freshwater Mollusca attributed some 25 species to the Scillies out of a total of 163, while west and east Cornwall are recorded as each having 74. This year's survey has enlarged the Scilly fauna by about ten more records. So far as we know at present, this group of islands seems to contain a rather impoverished sample of the mainland fauna.

The results of this survey are as yet uncertain, and some time must elapse before an opinion can be formed on the amount (if any) of divergence between the Cornish and Scilly land molluscs. It is likely that, after a preliminary survey of the material obtained, further collections of critical forms may have to be made. At present, however, it may be said that there seems at first sight to be very little difference between the two series. In one case which has been worked out in some detail—that of *Cochlicella barbara*—exactly the same varietal forms occur on St. Mary and in the Land's End area, and in the same numerical frequency. Actually there is more difference between colonies of *C. barbara* from Somerset and Marazion than between those of Marazion and St. Mary. It may be pointed out, however, that in the question of the origin of local or insular races negative evidence is just as important as proof of positive divergence; inasmuch as it enables us to form an idea as to the local rate of evolution.

iron is made 48 in. in length, 9 in. in depth, and 12 in. broad. It is divided by partitions 6 in. apart into 8 compartments. To the first is soldered near the top two brass tubes, one connected with the tap, the other with sink to act as an overflow. All the compartments are filled with water to the same level. The box is placed on iron legs and the water in the compartment farthest from the overflow is kept boiling with a bunsen flame. To prevent the water boiling away, U-tubes are inverted over each partition so that each siphons from its neighbour. In the compartment at one extreme, the temperature is kept about at room temperature by the circulation of the tap water: at the other, it remains at about 100° C. The temperatures of the intermediate compartments and the constancy obtainable when the apparatus is running may be judged from the following figures:

	Compartments.							
	1	2	3	4	5	6	7	8
Saturday, 12.50 P.M.	22.5	25	28.5	33.5	41.5	50.5	67.5	99
Monday, 9.30 A.M.	21.75	24.5	28.0	32.5	39.0	47.5	62.0	98

The only requirements are: a sheet of galvanised iron (or copper), solder, two short pieces of metal tubing, and a bunsen. The entire cost of the apparatus is well within ten shillings. By boring holes in strips of metal or wood to place across the compartments, each of the latter may be made to hold thirty or even more test-tubes. If compressed air is laid on, the water in each compartment may be kept in motion by bubbling a jet of air through it.

The Cause of Surface Tension.

THE reply by Mr. N. K. Adam, in NATURE of September 26, p. 464, to my note on the cause of surface tension, contains a very great deal with which I heartily agree. His method of calculating the shape and size of the drop from the surface energy is, of course, perfectly valid; as so often happens in mechanics, there are different ways of resolving the forces, each way bringing out features that the other ways do not. I can even agree with him that thinking in terms of the tension has not been found to be a good "means of gaining insight into the molecular structure of surfaces," and should not urge the actual use of this conception upon any one who prefers not to use it. Where I cannot quite follow him is in concluding that, because the tension has proved to be conceptual dynamite in practice, therefore the tension itself has no physical existence.

Perhaps a few words of further explanation might be added to my discussion of the statics of the drop. Just because the motion of the particles is so rapid, one can reason in terms of averages and proceed as in the kinetic theory of gases. Downward momentum is carried into the drop by molecules diffusing into it across the plane *P* which forms its upper boundary, and upward momentum is carried out by those that leave; the algebraic result is a steady average onflow of downward momentum into the space below *P*, equivalent to a positive downward pressure often called the "kinetic" or "thermal" pressure. In addition, there are forces acting across the boundary due to repulsion and attraction between molecules. The net result over the central part of the drop is

an average flow downward of downward momentum, equivalent to a pressure which is the ordinary "hydrostatic pressure"; its direction must be downward in the interior, because the reaction or converse aspect of the same process is an upward force or flow of upward momentum which supports the weight of the superincumbent water.

Of course, the identity of the molecules within the drop is continually changing, but that is immaterial for our present purpose. It is clear that downward momentum is, on the average, steadily flowing into the space below *P*, both for the reason just stated and through the action of gravity, and this momentum must obviously be escaping somewhere. The effect of cohesion has already been taken account of in arriving at the hydrostatic pressure. (Or, again, if cohesion holds the drop, then the drop is pulling downward on the water above instead of pressing upward upon it, and what in turn holds this water up?) The only possibility is that downward momentum is, on the whole, escaping upward through the surface skin; which is another way of saying that there is a genuine tension in the skin similar to that in a stretched sheet of rubber.

The very interesting question as to the structure of this surface skin is an entirely different matter. The particular line of attack to which I wished to direct attention merely reveals to us one of its activities.

The Isotopic Composition and the Atomic Weight of Chlorine in Meteorites.

HARKINS and Stone, in a letter under the above title in NATURE of September 19, state that they have found the atomic weight of meteoritic chlorine identical with that of chlorine as found on earth, within the limits of their experimental error. The question of the constancy of isotopic composition of chlorine has already proved of interest to several investigators, and one may recall the work of Curie in 1921 and of Gleditsch and others in 1922 and 1923, on the chlorine from certain ancient minerals. Their results are now confirmed by Harkins and Stone.

In the case of meteoritic chlorine, the matter is somewhat complicated by the question as to whether the rather small proportion of chlorine present is primary or secondary, that is, whether or not it is genuinely extra-terrestrial in origin. It may be recalled that the freshly cut iron surface of many chlorine-containing meteorites exhibits, in a humid atmosphere, a characteristic "sweating" that has been attributed to the presence of lawrencite or deliquescent ferrous chloride. Such meteorites rust rather rapidly, even on museum shelves. The late Prof. Mallet, a very keen observer and an analyst of a type now unfortunately very rare, became convinced, after work with meteorites of this kind, that the chlorine was secondary. He writes: "The exudation of watery drops containing metallic chlorides is observable only at points on the outside and on cut surfaces along the lines of fissures communicating with the outside."

Undeterred by knowledge of this uncertainty, in the autumn of 1921 the present writer determined the atomic weight of chlorine from the "shale balls" associated with the Canyon Diablo, Arizona, meteorite. Material for this investigation became available through the courtesy of a colleague, Mr. W. F. Magie. Sulphur was completely absent, a fact which weighs against the probability of contamination of the meteoritic matter by terrestrial

liquors. In the analytical work, silver chloride was reduced to silver in a current of hydrogen, and the atomic weight of "ordinary" chlorine compared with that from the meteorite. Had the result shown a difference in atomic weight, then one could have been confident that the chlorine was not of terrestrial origin. But the results were identical within 1 part in 2000, which was not outside the estimated experimental error. They were never published, because of the uncertainty as to the true source of this "meteoritic" chlorine.

It will be of interest to learn how Drs. Harkins and Stone have reassured themselves as to the extra-terrestrial origin of the meteoritic chlorine studied in their careful investigation.

The Spectrum of Si^+ (Once Ionised Silicon).

PROF. A. FOWLER has recently shown that the spectrum of Si^+ is similar in constitution to that of Al, that is, consists of doublets having $2p_2, 2p_1$, as the highest terms. A number of lines, ascribed by Fowler to Si^+ , remain, however, well outside his scheme of classification, and some of these can be arranged in a group of quartets.

MULTIPLIET 1.

<i>j</i>	1	2	3
	(0)	(1)	
1	17154.38 .. 116.0 ..	17038.38	
	62.19	62.25	
	(2)	(0)	(1)
2	17216.57 .. 115.94 ..	17100.63 .. 199.89 ..	16900.74
		134.56	134.96
		(1)	(3)
3		17235.19 .. 199.49 ..	17035.70

Interval ratio . . . 116.00 : 199.89 = $\frac{2.9 : 5}{3 : 5}$ observed
(Landé)

62.20 : 134.76 = $\frac{2.3 : 5}{3 : 5}$ observed
(Landé)

This is a pp' -combination.

The intensity rule is only roughly obeyed.

MULTIPLIET 2.

<i>j</i>	1	2	3
	(1)	(0)	
1	18382.63 .. 116.48 ..	18266.15	
	339.49	339.11	
	(0)	(1)	(2)
2	18043.14 .. 116.10 ..	17927.04 .. 199.86 ..	17727.18

This seems to be an intercombination between doublet P and quartet p -terms. But none of the known doublet P 's has 339 as frequency difference.

The differences occurring in these multiplets occur in other pairs which have not yet been classified, e.g.

$$\begin{aligned} & (0) \quad (0) \\ & 18402.19 - 18286.73 = 115.46 \\ & (0) \quad (2) \\ & 18415.41 - 18280.08 = 135.33 \\ & (1) \quad (1) \\ & 20573.45 - 20373.87 = 199.58 \end{aligned}$$

The group having the successive differences 199 and 116 correspond to p -terms of a quartet series. Evidently a quartet series is possible for Si^+ , but it is only feebly developed under the usual methods of excitation. Without more data on the spectrum of Si^+ , it is not possible to find out more information on the point.

NO. 2922, VOL. 116]

A Slow Process Method of Cyanide Fumigation for the Control of White-Fly in Tomato Houses.

EXPERIMENTS have shown that it is possible to generate hydrocyanic acid gas from a mixture consisting of 3 parts by weight of powdered sodium bicarbonate and 1 part by weight of high grade sodium cyanide (98 per cent. purity) for the purpose of fumigating tomato houses in the control of white-fly (*Trialeurodes vaporariorum*, Westw.).

The mixture is scattered on the dry paths of the houses at the rate of one ounce to every 1000 cubic feet space. The results show that mortality for adult fly is as great as that obtained where the gas is generated quickly from sodium cyanide and sulphuric acid in jars, but the percentage mortality for the scale stages is slightly higher in the latter method.

Economically the slow generation obtains practically as good a control as the quick method, and has great advantages in the saving of labour, and in minimising risk of scorching to plants which are grown soft. Whereas one man is required to each house in jar cyaniding, a large block of houses can be fumigated by one man when using the mixture described. The same precautions are necessary for the plants as in the case of jar cyaniding, but there is greater safety in fumigating by the slow process on windy nights. It is not advisable, however, to fumigate during heavy rain in leaky houses.

Retrograde Metamorphosis.

UNDER this denomination is understood the step-back from the normal state of an animal to that of a more primitive one. I was undergoing the strong sun-cure in Grado, an island in the Adriatic Sea, where the full sun shines for weeks together, with only slight interruptions, exposing to it the naked skin from morning until evening during the whole day. Belonging to the fair type, my body was only in some parts covered with spare hair. After some time perfectly new, very fine hair was formed on all parts of the body, and after the lapse of five weeks there was a remarkably thick cover of fine, very light hair even on those parts of the body where there was not a trace before, to prevent the body, which became dark red-brown, from being burnt. This observation has been made by me repeatedly for fifteen years, but it is not easy for others to repeat it.

Prof. Andrew Gray.

DR. ALEXANDER RUSSELL's memoir of Prof. Andrew Gray, which appeared in NATURE of October 24, will be read with sympathetic interest by Prof. Gray's many friends. I must be one of the oldest of them surviving, for I was Gray's fellow-student in my uncle's natural philosophy class in Glasgow in the session 1874-75, in which he carried off the second prize and I the fifth. From my knowledge of him at that time and since, I am able to appreciate the accuracy of Dr. Russell's notice, with the exception of one small error of date. Prof. Gray succeeded my uncle (Lord Kelvin) on his resignation of the natural philosophy chair in 1899, not after his death in 1907.

The Transformations of the Plant World in Geological Time.¹

By Dr. D. H. SCOTT, F.R.S.

THE record of plant life in geological time is especially interesting from the fact that it shows a definite succession of phases of vegetation, each with a distinctive character of its own. So distinct are these successive floras that a high authority has even doubted whether the evolution of land plants was necessarily continuous. While the theory of descent remains undisputed among biologists, it has been suggested that there may have been, at certain periods, recurrent invasions of the land from the sea, thus giving the terrestrial flora a fresh start. Whatever we may think of this bold hypothesis, it at least serves to show that the diversity of the successive phases of plant life is more marked than their continuity. At present, however, we are concerned with the story, rather than the theory, of the succession of floras through the ages.

The word "transformation" is used for the change from one type of flora to the next. Four such great transformations are known.

1. From marine to land flora. The time of this profound change is unknown: it may have occurred about the Upper Silurian period, but some botanists would put it much earlier.
2. From the early land flora to the typical Palæozoic vegetation. Time, about the Middle Devonian.
3. From the Palæozoic to the Mesozoic type of flora. Time, Permian to Trias. This was the transformation which suggested to Prof. Seward his idea of discontinuity, referred to above.
4. From the typical Mesozoic to the modern type of flora. Time, Cretaceous. This transformation was the most important from our own point of view, as it ushered in the reign of the true flowering plants.

All these transformations, as we observe them, are apparent, not real; they mark the obvious changes in the flora, when the new groups became dominant. The actual origin of the new types must always have lain much further back than the date of the conspicuous transformation.

Of the hypothetical "Plankton" stage, when the ocean swarmed with unicellular creatures, as yet neither plants nor animals, we can have no geological evidence. The succeeding "Benthic" phase (to use Dr. Church's term), the age of the rooted Algæ, is well represented from the Cambrian onwards. Calcareous seaweeds naturally lend themselves best to preservation. Highly organised seaweeds, allied to our living Corallines, are present in the Cambrian. Calcareous Algæ of another class (Siphonæ) are found at least so far back as the Ordovician. The history of their evolution, all through the succession of strata, has been traced by Dr. Julius von Pia of Vienna, while the importance of calcareous seaweeds as rock-building organisms has been demonstrated by Prof. Garwood. A huge Alga (non-calcareous) known as *Nematophycus*, goes back to the Silurian. In the Lower Devonian of Canada, specimens three feet thick were described by Sir William Dawson. There is reason to believe that *Nematophycus* could live on land, but its structure is that

of a complex Alga. The Cambrian and Ordovician records are sufficient to show that in the ages previous to the first transformation (the invasion of the land) plant life in the sea had already attained a high grade of development.

THE FIRST TRANSFORMATION.—We have no satisfactory evidence of a land flora before the Upper Silurian,² and even then the records are scanty and scarcely free from doubt. *Psilophyton*, characterised by its leafless, spinous, forked stems and long, terminal spore-sacs, has been doubtfully recorded from the Wenlock beds of the Silurian, and is well known from the Lower Devonian. Among other Lower Devonian plants we have *Arthrostigma* (like a magnified *Psilophyton*), the moss-like capsule called *Sporogonites*, and naked forked stems or fronds (*Hostimella*). All are very simple, practically leafless plants, but there is little to show how the transition from marine life was effected.

Our best knowledge of the early land flora is derived from the Middle Devonian, but we must be on our guard here, for recent work in Germany has shown that vegetation was already far advanced at that period. In fact the Middle Devonian flora presents a mixture of apparently primitive forms and quite complex types of plants. Among the famous plants of Rhynie, Rhynia and Hornea are no more elaborate in external form than quite ordinary seaweeds, though fully equipped with a vascular system and stomata for life on land. Kidston and Lang's new genus, *Hicklingia*, may perhaps be somewhat nearer the Algæ than Rhynia. The more advanced *Asteroxylon*, with a leafy stem, is of the same age. Dr. Kräusel finds that, in a German species, no less than three form-genera, *Hostimella*, *Psilophyton*, and *Thursophyton*, occur as parts of the *Asteroxylon* plant. This quite agrees with the conclusions of Kidston and Lang.

Asteroxylon has some primitive features, and is, of course, to be reckoned as a member of the Early Devonian flora. It is the more remarkable, that on the same slab with *Asteroxylon* Dr. Kräusel found a specimen of *Cladoxylon*, a plant of singularly complex structure, hitherto only known from the Lower Carboniferous or possibly the highest beds of the Upper Devonian. Other highly organised plants were obtained from the Middle Devonian, and it is evident that in this formation earlier and later floras overlapped.

One of Kräusel and Weyland's Middle Devonian plants, *Aneurophyton*, resembles the contemporary American plant *Eospermatopteris*, the chief constituent of the fossil forest of Gilboa in the State of New York. Both appear to have had the stature and habit of Tree-ferns, but *Eospermatopteris* is described as bearing seeds, and is thus regarded as the earliest of the "Seed-ferns," which played so important a part in the Carboniferous flora.

In anatomical structure *Aneurophyton* recalls the famous "cone-bearing tree" of Hugh Miller, described by him some eighty years ago, from the Middle Old

¹ Substance of a lecture delivered before Section K (Botany) of the British Association at the Southampton meeting, 1925.

² I leave out of account the problematic *Archæoxylon Krasseri*, said to be a vascular plant from the pre-Cambrian of Bohemia. In spite of Dr. Kräusel's careful investigation, there is room for much scepticism as to this sensational record.

Red Sandstone of Cromarty. In this case only the wood is known, but Miller's fossil afforded the first evidence of highly organised plants in the Middle Devonian.

THE SECOND TRANSFORMATION.—It has become a little difficult to know where to place this. We have been accustomed to draw a sharp distinction between Early (Lower *plus* Middle) and Late (Upper) Devonian floras. Now we know that some very high types had appeared before the Middle Devonian period was over. The general *facies*, however, of the Upper Devonian vegetation was so distinctive that we may still regard it as marking the first appearance of a typical Palæozoic flora.

Here we meet with many plants with the habit of ferns, as, for example, the noble *Archæopteris hibernica* of Kiltorkan. Among such fern-like specimens there is little doubt that both true ferns and the so-called "Seed-ferns" were represented. Great club-mosses, comparable to those of the succeeding Carboniferous period, were already well developed. Plants with whorled leaves, of families more or less akin to the later calamites and horse-tails, were present. Stems, as highly organised anatomically as those of any modern conifer, indicate that gymnosperms were already flourishing. Leaves recalling those of the maidenhair tree may have belonged to some unknown type of seed-bearing plant.

Then we come, without any marked break, to the rich vegetation of Carboniferous times. The Lower Carboniferous shows the Palæozoic flora in its purest form. Seed-ferns were abundant and varied. Higher gymnosperms were finely represented by the great *Pitys* trees with leaves something like stout pine-needles. True ferns, usually of types strange to us, were common everywhere. Club-mosses attained a gigantic stature, and some of them had developed a kind of seed, an organ not known in this group after Carboniferous times. The calamite trees appeared, and in a distantly related family the cone of *Cheirostrobis* was the most elaborate cryptogamic fructification known, either fossil or recent.

The still richer Upper Carboniferous vegetation is so well known as to need little description. New groups, both of true ferns and of the seed-ferns, appeared. The investigation of the vast Chinese flora of the period by Dr. Halle is now yielding fresh examples of the latter class.

The *Pitys* trees were replaced by the well-known Cordaitan family, of lofty stature, with long leaves like a dragon-tree, and little catkins, complex in structure. The club-mosses, calamites, and sphenophylls (a group remotely allied to the horse-tail stock) reached their zenith.

All this rich and varied flora lasted on with little change into the Permian period and then came to an end. This, at least, was the case with the northern flora. Towards the close of the Palæozoic age, botanical districts became differentiated; the vegetation of India and the southern hemisphere was then different from that which prevailed in the north. The southern type (which made some local incursions into more northern areas) is known as the Glossopteris flora, from its most characteristic genus. Glossopteris and Gangamopteris, plants with simple, fern-like fronds, were probably seed-ferns. The gigantic club-mosses were

absent from the southern flora and the calamites were of different kinds. The general *facies* of the vegetation was distinct from that of the north. The age of the Glossopteris flora is now determined as Permo-Carboniferous, but some of the genera still survived in early Mesozoic times. Hence the transition appears to have been less abrupt in the south than in the north.

THE THIRD TRANSFORMATION.—So far as the northern flora is concerned, the change was complete. From the Trias onwards we find no certain examples either of seed-ferns or cordaitan trees. So far as we know, the two great Palæozoic races of seed-plants had disappeared, though perhaps a few relics may have survived. The club-mosses of the Mesozoic are few and modest. The horse-tails begin to approach those of our own day; the ferns are exceedingly numerous and varied, and belong to more or less modern families, for the most part quite distinct from those of Palæozoic age.

The seed-ferns were replaced by a vast array of so-called cycads. These plants were no doubt allied to the recent family, but the great majority of the Mesozoic forms were far more highly organised in their reproductive apparatus. In like manner the cordaitans were succeeded by the conifers, of families not unlike those still living, and by the maidenhair trees, an important race in Mesozoic times. Further, the vegetation of the world again became, in a broad sense, uniform; the botanical districts of the late Palæozoic were obliterated.

Now all this was a vast change, for which we are as yet unable to account. Yet there are some indications that the transformation was initiated at an earlier period. Foliage of a quite cycadean character is known from Permian and even Carboniferous rocks, though the evidence from fructifications is doubtful. Among conifers we have *Walchia*, a well-known genus with probable Araucarian affinities, in the Upper Carboniferous and Permian. Leaves like those of the maidenhair trees also occur in Palæozoic rocks, though they are not entirely convincing by themselves. On the whole it seems fairly clear that some of the most characteristic Mesozoic groups had already begun to appear in Palæozoic times.

The desert conditions which were prevalent in the Triassic period may, as has been suggested, help to explain the rapid change in the character of the vegetation. It is also possible that the source of many of the Mesozoic races is to be sought in the Glossopteris flora of the south, where, as already mentioned, the transition seems to have been less sudden. We are not really driven to any such violent assumption as a new invasion from the sea.

THE FOURTH TRANSFORMATION.—This great change, which became manifest during the Cretaceous period (late Mesozoic), introduced the modern type of vegetation. It has been well said that "we are still living in the Cretaceous epoch." For us, the great point of interest is the sudden advent of the true flowering plants, the angiosperms.

It is evident that the transformation was already far advanced in Lower Cretaceous times, for Dr. Marie Stopes has found a number of dicotyledonous stems of that age, with a structure as varied and as complex as that of present-day trees. There is nothing primitive about these early dicotyledons.

The Lower Cretaceous flowering plants were contemporary and associated with members of the old Mesozoic flora, cycads, and so on, which were still predominant. In the Gault and Upper Cretaceous the angiosperms have gained the upper hand, and the vegetation assumes quite a modern character. Both monocotyledons and dicotyledons are present, in about the same proportions as in the living flora. Among the former, palms, reeds, and lilies, among the latter, willows, walnuts, beeches, oaks, planes, maples, bread-fruits (found in Greenland), laurels, gum trees, ebonies, and dogbanes indicate some of the families represented. In fact the evidence shows that, from about the middle of the Cretaceous epoch, flowering plants were flourishing very much as they are now, so far, at least, as families or even genera are concerned.

We still have no clue to what Darwin called the "abominable mystery" of the sudden appearance of the higher plants. We have seen that they already existed, fully developed, in Lower Cretaceous times. It is interesting to inquire whether we have any earlier records. They are very scanty. Prof. Seward has described, from the Stonesfield Slate of Middle Jurassic age, simple, ovate leaves, like those of a dicotyledon. We cannot be certain; for there are ferns such as *Drymoglossum* with fronds somewhat similar, but dicotyledonous affinities are strongly suggested.

Much more important are Mr. Hamshaw Thomas's

discoveries in the Lower Oolite of Yorkshire, a little older than the Stonesfield Slate. He has found fruits, ranged in two rows on a stalk, each fruit enclosing a number of seeds. Thus the structure was undoubtedly angiospermous in the literal sense, for the fruit was closed. Associated with these organs Mr. Thomas finds branched stamens, with four-lobed anthers like those of an angiosperm, and also compound palmate leaves. He gives good reasons for thinking that all these remains belonged together. It is evident that Mr. Thomas's fossils throw a new light on the early history of the angiosperms, though their relation to the main line of descent is still an open question.

The series of transformations we have briefly sketched is sufficiently striking. What has been called the succession of dynasties is, no doubt, the great feature in the past history of the kingdom of plants. We have, as yet, little to show by what means one dynasty succeeded another, or how the successive dominant races were related. That each new type arose much earlier than its full manifestation is obvious, and, as we have seen, there is often direct evidence of precursors in an age previous to the transformation of the flora. To unravel the course of descent in the transition, apparently so abrupt, from each flora to the next in succession, is at present a task beyond our powers; we have attempted nothing more than to state the problem.

Photochemical Problems.

THE subject of photochemistry is one to which increasing attention is being given at the present time, as is exemplified by the large attendance and spirited controversies in the meeting, very international in character, held by the Faraday Society at Oxford on October 1 and 2. Whilst as a specialised field for the study of the action of light on chemical substances it is not without interest, in a broader sense it is the most important of all the sciences, for not only does it provide a common meeting-place for physicists, astronomers, and chemists, but, as the botanists have long observed and the medical profession is now realising, life is in great measure dependent on photochemical action.

In all photochemical reactions it is necessary to distinguish between what are termed primary and secondary processes. The first action of the light in producing chemical change is to undergo absorption by a molecule, thus converting it into an "activated" or "excited" molecule. According to the quantum theory all molecules excited or activated in this way become a distinct species characterised by a definite energy constant, which, in certain cases, is directly related to the frequency of the radiation absorbed by the relationship due to Stark and Einstein, $E = h\nu$.

It is these activated molecules which are the reacting species in photochemical processes and, according to some investigators, notably Perrin, in thermochemical change also. If all reactions were simple, it is clear that for every quantum of light absorbed one molecule should enter into chemical reaction and we should obtain a very simple relationship between the amount of chemical action obtained and the number of light quanta absorbed. Closer consideration, however, indicates that this simple law may be but rarely fulfilled,

for such an excited molecule may perform one of three possible operations. It may fluoresce and thus lose its newly acquired energy by the emission of radiation. Again, it may collide with another molecule, when one of two possibilities are open to it: on collision the internal energy may be liberated in the kinetic form, resulting in what is termed a supra elastic collision, or the internal energy may be handed on to the molecule it comes in contact with, this molecule then departing as an active molecule, a process termed photosensitisation. Finally, the possibility of chemical reaction on collision is presented. It is little wonder that in many reactions the photochemical efficiency is low.

In addition to such reactions there exists an ever-increasing group in which the photochemical yield is much greater than is to be anticipated from consideration of the amount of light absorbed, or, one quantum apparently can cause several, in some cases tens of thousands of molecules to undergo reaction. Such reactions are now designated as "chain" reactions, and the various hypotheses as to their mode of action are at present a matter of heated controversy. One of the simplest explanations is that of the "atom" chain, which may be represented in operation in its simplest form by the following sequence of operations:

in which the primary photochemical process of activation (1) is followed by a series of steps 2, 3, 4. It is clear that 3, 4 represent two links in a chain which can only terminate when an atom is arrested in some manner.

The great ingenuity required in devising probable chain mechanism for reactions, such as the photochemical decomposition of hydrogen peroxide or the chlorination of hydrocarbons of the aromatic series, has caused many to reject this conception, originally due to Nernst, and to substitute in its place one of the following hypotheses. According to the "hot molecule" theory of Christiansen and Kramers, the products of a reaction such as

must contain not only the original energy of activation but also the energy liberated by the chemical reaction; they are thus more "active" than their neighbours. It is imagined that a "hot" molecule formed in this way may excite another reactant molecule on collision. Again, it may be imagined that this energy, instead of being contained in the products, may be liberated as radiation which is absorbed by the surrounding reactants activating them in turn; this conception has in fact been made even more concrete by the definite conception of a "quantum" chain.

More recently, due to the investigations of Frank and Cario, the scope of the methods of photosensitisation in which an excited molecule can, on collision with a reactant, hand on its energy of activation to it, thus causing subsequent chemical reaction, has been greatly extended by the employment of mercury vapour as sensitising agent. By such means the amount of energy capable of being conveyed in this manner is far greater than with the sensitising agents usually employed, such as molecules of the halogens or the dyes employed in the photographic plate. It is possible that the active nitrogen of Lord Rayleigh ($V = 9.5$ volt) may prove an even more powerful conveyer of energy than mercury atoms excited with the line $\lambda 2537$. The ready production of atomic hydrogen in this manner has opened up a path by which the properties of the organic radicals, such as ethyl, formed by the reaction

may be investigated.

Whilst these natural processes may be considered at the present time to be capable both of reasonably precise experimental investigation and their real existence capable of being demonstrated, the situation is quite otherwise in certain other phenomena, an adequate explanation for which is as yet not forthcoming.

It is found that in certain reactions hitherto considered as extremely simple in character, such as the decomposition of ozone, the photochemical efficiency may remain unchanged even for low pressures of the reactant and sensitising agent, chlorine, whilst the presence of indifferent gases exerts a marked influence on the reactant velocity. According to the experiments of Wien, the life of an excited molecule is of the order of 10^{-7} seconds and metastable forms of active molecules are as yet unknown. Whatever the active species may be in this particular reaction, it is clear that it must have a relatively long life; furthermore, it can suffer a number of collisions with indifferent gas molecules without losing its energy, this number varying with the nature of the gas. Various explanations, such as the existence of intermediate compounds, the restriction of the reaction to the walls of the vessel and replacing the concept of an excited molecule by an excited atom, have all been advanced on very slender foundation.

Finally, it would appear from consideration of the decomposition of nitrogen pentoxide at very low pressures, that the process of distribution of internal energy amongst these molecules can proceed at a rate much faster than is to be anticipated from the Maxwellian period of molecular relaxation. If, indeed, this process occurs through the agency of radiation, nitrogen pentoxide must be singularly opaque to its own self-generated radiation.

It may be anticipated that increased attention will be given to the subject of photochemistry, for it is clear that it opens a door to some of the most interesting and important fields in the region of atom dynamics, a subject on which, in the words of Goethe, we are anxious to have "more light."

ERIC K. RIDEAL.

French Contributions to Metallurgy.

THE well-known attention which has been devoted to the history of metallurgy by Sir Robert Hadfield receives an interesting supplement in a paper recently read (Oct. 5) in Paris at a congress of industrial chemistry organised by the French Society of Chemical Industry. The main theme of the address is the interrelation of British and French research in metallurgy, but the aspect, which to most readers will be found of the greatest interest, is the excellent résumé given of the debt which this subject owes to French men of science. As an example, the author pays generous tribute to the importance, in connexion with his own discovery of manganese steel, of the investigations carried out by the Terre Noire Cie. on the commercial production of ferrous alloys very high in manganese.

The paper, which is characterised by the pleasing discursiveness associated with similar lectures which Sir Robert Hadfield has already delivered on metallurgical history, contains, however, nothing more interesting than the photo-micrograph, now published

for the first time, of the structure of the iron of the famous Delhi pillar, to which the author has devoted considerable attention. To metallographers interested in the remarkable resistance of this pillar to corrosion this structure shown in Fig. 1 will be of more than passing interest. The almost complete freedom from slag throws more than a little doubt on the view that a large part in the resistance of wrought iron to corrosion, a fact still awaiting an adequate explanation, is played by inclusions of slag.

The account given of French contributions to metallurgy since the time of Réaumur (1722) is of considerable interest. In the 150 years which followed, there appeared a number of important metallurgical books in France, of which the titles of 27 are recorded. A brief account is given of the more important contributions to metallurgical knowledge during this period. Among the older names one meets those of Réaumur himself, Berthollet, Vauquelin, the discoverer of chromium, the metal which rendered the production of a rustless steel a possibility, of Berthier

and Le Play. In more recent years the tradition has been carried on by Le Châtelier, Moissan, Pourcel, Osmond, Dumas, and Guillaume, whose work on the special alloys of iron resulted in the discovery of "Invar," an iron-nickel alloy the coefficient of expansion of which at ordinary temperatures is negligible. Such a list shows how keen has been the interest taken by French scientific workers in metallurgical problems. The debt due to them is not readily appreciated, that due to Le Châtelier being even greater than Sir Robert acknowledges, since, in addition to the credit already

from so many countries to attend this Congress, I venture to point out that this very gathering itself affords an obvious testimony to the truth of the saying that "Science knows no boundaries."

We are met, here in Paris, the renowned capital of France, and, it may with truth be said, the city wherein, perhaps more than in any other throughout the whole world, science receives most help and most encouragement.

In a memoir which I communicated to the University of Oxford, towards the beginning of this year, I showed an engraving in which was represented one of the greatest scientists of medieval England, Roger Bacon, in the act of presenting a book, the record of his work, to the University of Paris, about the year 1250. During the fourteenth and fifteenth centuries Paris was, indeed, the centre of science.

The University of your city was, even then, exercising considerable influence on the universities at that time established in England. I might cite, as an example, Jean Buridan, Rector of the University of Paris, who was one of the founders of modern dynamical science. M. Picard, chief secretary of the Academy of Sciences, has already written, on this subject, a memoir most carefully and interestingly drawn up, with reference to the facts I have mentioned.

That which was true of the past centuries is still true of the present day. Paris has not lost her ancient renown in the sciences; she still preserves it, and it may very frequently be observed that the great ideas which spread through the world of science are ideas the origin of which may often be traced to distinguished Frenchmen.

I venture to believe that in uttering these sentiments I am expressing, not my own views alone, but those of my colleagues here present, and those, indeed, of the whole world. I trust that France will maintain, in the future, the position which the wisdom of her great men has won for her in the past."

FIG. 1.—Photomicrograph of a specimen from the Delhi iron pillar

given, there must be added that due for his researches on the transformations of silica at elevated temperatures, which in no inconsiderable manner paved the way for the recent advances in our knowledge of the refractory materials in general.

Sir Robert's concluding remarks are of wide interest and may well be quoted in full:

"In offering my contribution to this distinguished gathering of prominent scientists, who have come

One cannot but be impressed throughout the address by the intimate connexion of the work of French men of science with industrial problems, a liaison which has proved of the greatest importance. A quotation by Percy, in the preface to his classical work on the "Metallurgy of Iron and Steel," from Réaumur, remains as true to-day as it was two hundred years ago: "... L'utile bien considéré a toujours de curieux, et il est rare que le curieux bien suivi ne mène pas à l'utile..." F. C. T.

The Cierva Auto-Gyro.

By Prof. L. BAIRSTOW, F.R.S.

A NEW flying machine, quite unlike the normal aeroplane and bearing a strong resemblance to a helicopter, has flown very successfully and excited general interest. It is yet too early to see the full consequences of this notable achievement, but perhaps not too soon to attempt a preliminary statement of what appears to be its general principles, in order to prevent undue expectations.

The auto-gyro has the normal parts of an aeroplane except its wings; the latter are replaced by a screw

rotating freely about an axis which is nearly vertical in flight. Except when starting, this screw or auto-gyro, is not mechanically driven, but is maintained in rapid rotation by the play of aerodynamic reactions. The forward motion of the craft is produced by the normal airscrew and engine of an Avro biplane, the body, controls, and under-carriage of which are retained, except that a very large movement is given to the elevators. Ailerons have been fitted to the craft, but are said to be unnecessary.

In flight the body of the auto-gyro appears to be supported by a flat shuttlecock, and when flying slowly its performance is astonishing. The inventor claims the possibility of flight at ten miles an hour, and exhibition flights at Farnborough in the last fortnight have shown that, when flying in a light wind, the device can hover over the ground. Furthermore, after shutting off the engine, safe descent can be accomplished at an angle of 60° to the horizontal, the craft coming to rest with a forward run of a few yards only. As at present arranged, starting from the ground is primitive; a rope is passed round projections on the auto-gyro screw and rotation up to about 60 rev. per min. produced by hauling on this rope. Taxi-ing over the ground in the normal way then brings the speed to 120-150 rev. per min., when the machine may safely leave the ground. The run is rather long.

From remarks made by the inventor, it appears that the use of the engine for starting the screw has been contemplated, so as to make it possible to rise from a confined space. The auto-gyro screw as it exists at present is unsuited for driving whilst in the air, and it is not clear that such driving would be advantageous.

From some approximate data given publicly by the inventor, it appears that the complete craft weighs about 2400 lb. and has a highest speed of flight of 68 miles per hour. The Avro biplane with the same engine weighs 1800 lb. and flies at about 90 miles per hour near the ground. So far as I know, the height to which the new machine can climb has yet to be determined.

The auto-gyro screw has four blades, the total area of which is about half that of the wings of the standard Avro aeroplane, and this makes the average loading some 30 lb. per sq. ft. as against the 6 lb. per sq. ft. of the aeroplane. In flight the device seems to be very stable and easy to control, and in this respect the invention gives a solution of one of the very difficult problems connected with the production of a successful helicopter.

The stresses due to rapid rotation are dealt with by ingenious but not novel means, and one can only marvel that in reducing the stresses the inventor has also got a stable aerodynamic system with other good qualities. The auto-gyro screw is mounted on a fixed shaft almost in the plane of symmetry of the fuselage and some 6 or 8 feet above its centre line. The four wings of the screw are hinged to a sleeve which rotates freely on ball bearings on this fixed shaft. The axes of the hinges are close to the shaft and nearly normal to it.

On the ground the weight of the blades is taken by rubber springs and guy wires, but these cease to operate in flight. The lift of the blades produces a moment tending to fold the blades upwards, and this is balanced by a moment due to centrifugal forces. By suitably curving the blades, bending stresses are almost eliminated, and as the centrifugal forces are large, a balance of moments is obtained with an upward tilt of less than 10 degrees. The same agency—centrifugal force—is left to deal with stability, gyroscopic couples, and gusts.

Due to the hinging and the varying lift on the

separate blades in the course of a revolution, a certain amount of flapping occurs. It is claimed—without great emphasis—that the flapping is beneficial to the operation of the screw, although other experiments by the inventor have shown that rotation may be maintained with a fixed screw. It is remarkable to find that forces inclined ahead of the axis of rotation exist over a wide range of speed of flight. Even when the forward speed is only 20 miles per hour, these forces urge the advancing blades to speeds upwards of 150 miles per hour at the tips. As yet there is little knowledge of the effect of forward speed on the rotational speed of the auto-gyro, possibly because the pilot has so manoeuvred his craft as to maintain a specified minimum. One of the suspicions voiced is that rotation would tend to stop at high speeds. Further, it is possible that vertical descent would be too rapid for safety; descent at an angle of 60° appears to cover most requirements when landing, and vertical descent may not be required in any case of importance.

The existence of tip speeds of 150 miles per hour readily accounts for the high average loading of the blades, since, other things being unchanged, the force per square foot of wing varies as the square of the speed. An element of wing moving at 150 miles per hour has then more than fifty times the pressure of the same wing at 20 miles per hour. There is, in fact, no need to look for new types of air flow to account for the phenomena observed. No difficulties are anticipated in analysing the performance of the auto-gyro by existing methods of calculation and knowledge of aerodynamics. From the details which this analysis will give, new developments may perhaps follow, but one general conclusion may already be drawn with some confidence. It may be expected that the auto-gyro will be a less efficient organ of transport than the aeroplane.

The arguments for such conclusion have already appeared in *NATURE* in a discussion of the possibilities of the helicopter (August 18, 1923, vol. 112, p. 229). So long as wings are used in producing lift, there will be a consequential resistance which cannot fall below a certain minimum proportion of the lift. The least amount of work expended in producing a given lift and moving a wing through a prescribed distance is then determined by conditions of airflow beyond the control of a designer. Obviously the path taken by the wings of an aeroplane between two points is the shortest possible, and the longer coiled path of the wings of a screw requires a larger expenditure of work.

This summary leads to conclusions typical of most engineering problems, no single solution containing in itself the whole of the desired qualities at their maxima. Combination of aeroplane and auto-gyro is not yet suggested, and much research lies ahead before the benefits of the new invention can be translated into terms applicable to commercial aircraft. Should uses be found for a new type of craft in which high speed and high efficiency are not essential, the new invention gives valuable help at once. No combination remotely approaching the performance of the auto-gyro at low speeds has yet appeared in the history of heavier-than-air craft.

Obituary.

PROF. H. MAXWELL-LEFROY.

IT must be with feelings of very genuine regret that entomologists, and especially those occupied with economic work, both at home and throughout the Colonies and abroad, will have learnt of the tragic death of Prof. Lefroy, which occurred on October 14, as the result of an accident. Four days previously he had been found unconscious in his laboratory at the Imperial College of Science and Technology, South Kensington, and although removed immediately to St. George's Hospital, he succumbed without having once regained consciousness. At the subsequent inquest, death was attributed to the effects of a gas with which he had been experimenting as an insecticide, whilst already suffering from toxæmia due to exposure during previous work of a similar nature extending over a period of years. The funeral took place at Kensal Green Cemetery on October 17.

Harold Maxwell-Lefroy was born in 1877 at Itchel Manor, Crondall, Hants. From Marlborough College he went up to King's College, Cambridge, graduating with first-class honours in the Natural Sciences Tripos in 1898. At Cambridge he had specialised in his old hobby, entomology, and, after a brief interlude of teaching, in 1899 was appointed entomologist to the Department of Agriculture of the West Indies. His stay at Barbadoes was not long, but it served as a very excellent introduction to the study of the entomology of the tropics, and it was no doubt largely as a result of his work there that at the end of three years he was appointed Imperial Entomologist to the Government of India. At Pusa in Bengal he found unlimited scope for the exercise of his organising abilities, and soon succeeded in placing his Department on a sound footing, and bringing it up to a level of efficiency that has been well maintained ever since. The problems which confronted him were many and varied; they seem only to have acted as an incentive to greater energy, and India owes him no small debt for the work he put in during his eight years of office there.

Chief amongst Lefroy's publications during this period were "Indian Insect Pests" (1906) and "Indian Insect Life" (1909), both of which are of standard value, whilst the latter is still the only comprehensive work on Indian insects available. Lefroy was a great believer in good illustrations, and both works are profusely illustrated. The Entomological Series of the Memoirs of the Department of Agriculture of India from the time of their commencement by him in 1906, until his retirement in 1912, likewise bear eloquent testimony to his insistence on illustration and to the range of his activities. The first memoir, on the Bombay locust, was followed by a list of the more important insects injurious to agriculture in India. This list, the first of its kind, enumerated some 150 species, the majority of which were figured, and included in the case of each a brief account of what was known of its development and bionomics, much of this information naturally being quite new. There followed a series of memoirs dealing more fully with a number of particular pests, a valuable survey of the Eri silk question, an elaborate paper on the food of birds (in collaboration with C. W. Mason), others

on biting flies, etc., the final publications dealing with insecticides, an aspect of his subject which, curiously, seemed to attract him throughout the remainder of his career more strongly than any other.

Towards the end of 1910 Lefroy returned to England and commenced work at the Imperial College of Science, where later he was appointed professor of entomology. Here he showed ability and energy as great in the creation of a school for the training of entomologists as formerly he had shown in the tackling of the economic problems of the tropics, whilst his knowledge and experience, his remarkable capacity for dealing practically with the administrative and lay aspects of insect problems, and above all his never-failing enthusiasm, personal friendliness, sympathy and generosity, have been and will remain a source of strength and inspiration to numbers of his former pupils, now widely scattered throughout the Empire.

With the outbreak of the War, as was characteristic of the man, one of his first actions was to attempt to join the colours. He was turned down. Nevertheless he succeeded in serving in various capacities quite unconnected with his scientific qualifications. As an economic entomologist he primarily devoted the greater part of his time to the house-fly problem, and also made use of his great powers as a convincing lecturer in teaching sanitary officials, doctors, and Army officers. Later he was attached, as temporary Lieutenant-Colonel, to the Mesopotamian Field Force for the specific purpose of coping with fly pests, and afterwards he was called in to deal with the wheat trouble in Australia, where he successfully applied the methods already in use in America. On his return to South Kensington he again settled down to his work of teaching, and to investigations in various directions, and was so engaged at the time of his death.

One who had the pleasure of working with him during his earliest days at South Kensington will never forget the cheerful optimism with which he undertook the most herculean labours, the extraordinary speed at which he worked, the zest with which he attacked and demolished every new obstacle, and the unexpectedness of many of his actions. The writer well remembers how, in order not to waste the day, he would start it by rising at 4 or 5 o'clock in the morning, and then cycle some twenty or thirty miles into the country to spray several acres of some friend's crops, before getting a belated but always very excellent breakfast. He was always impatient to get on. It has been said of him that much of his work was wasted; it is probably equally true to say that he himself was always the first to recognise his mistakes, as he certainly was the first to forget them in his enthusiasm for the next line of investigation. Quite unable to disguise his disgust at carping, obstructive criticism, he had little use either for ineffective discussion. To use his own words, "the training [of the economic entomologist] will have to be that of the practical field entomologist . . . and the last thing it wants to be is the academic zoological training of the average English university." It was the practical side of his work, with its innumerable opportunities for the exercise of inventive ingenuity, that always appealed to him most; the systematic

arrangement of collections, and kindred subjects, he admitted were necessities, but, as he never failed to remind his students, "systematics are no part of an economic entomologist's work, and should be left strictly to those whose concern they are."

In recent years Lefroy published little of a scientific nature, confining himself in the main to devising methods and apparatus for applying the results of his investigations, and this with no little success. Apart from this, there can be no doubt that since the War, and even during it, he rendered great service to entomology in Great Britain by his continued efforts to force the general public to a realisation of the interest and importance of the subject to which he was devoted. If in the process he employed such varied and unconventional means as newspapers and popular magazines, broadcasting, and even the cinematograph, it is none the less true that a measure of success attended his efforts which would have been absent had less spectacular methods been employed. His death at the early age of forty-eight leaves entomology the poorer by the loss of a very remarkable man.

DR. BRAYTON H. RANSOM.

DR. B. H. RANSOM, Chief of the Zoological Division of the United States Bureau of Animal Industry, died, after a brief illness, in Washington on September 17, in his forty-seventh year.

In Dr. Ransom, America has lost one of its most brilliant parasitologists. The Division of the Bureau of Animal Industry which he had administered since

1906 has played a very prominent part in the solution of many urgent problems in economic parasitology and has contributed many invaluable discoveries to science—not the least important of which was the recent introduction of carbon tetrachloride in the control and treatment of hookworm disease in man. Dr. Ransom's personal contributions to this work are so numerous that it is impossible to do more than mention a few of the more outstanding. He demonstrated the transmission of the stomach worms of horses by flies; and developed many practical control measures for stomach worms of ruminants. He did much research on the life-history of the pig ascarid and was able to devise a practical means of eradication for this important swine pest. His work on the parasites of human importance in meat products—especially in connexion with the *Trichina* worm and "Measles" of mutton and pork—was of fundamental importance. He published monographs which have even now become standard works of reference on the cestodes of North American birds, on the intestinal nematodes of ruminants, on the Heterophyid trematodes of man and other animals, and on other subjects; and many other papers of a very high scientific standard on morphology, life-history, biology and classification of the parasitic helminths have appeared from his pen.

Dr. Ransom had many friends—some of whom he had never seen—and few enemies. No man was more ready to lend a helping hand to the beginner, and many a young parasitologist owes much to his friendly assistance. In his premature death the world has lost a valuable and conscientious worker, and parasitologists a considerate and helpful friend.

Current Topics and Events.

PROF. H. A. LORENTZ took his doctor's degree at the University of Leyden on December 11, 1875. His friends wish to take the opportunity afforded by the fiftieth anniversary of that event to offer to him some token of their esteem and affection. For this purpose, a general committee including physicists from all countries, and an executive committee consisting of Prof. Kamerlingh Onnes, Prof. Zeeman and Dr. Fokker, has been formed. It is proposed to raise a fund, to be called the Lorentz Fund, to be devoted to the advancement of theoretical physics. It is intended that the fund should provide for the continuance of the lectures on problems of modern physics which Prof. Lorentz has given at the University of Leyden since his retirement from his professorship under the age limit. Other objects of the fund are to assist Prof. Lorentz's own researches, to aid the publication of treatises and scientific papers, to provide research and travelling fellowships, and generally to assist whatever may be useful for the advancement of theoretical physics. The fund will have an international character, being available for foreign physicists for work in the Netherlands and for Dutch physicists for work at centres of physical research abroad. It will be administered by the Leyden University Council. Sir J. J. Thomson, Trinity Lodge, Cambridge, will be glad to receive subscriptions for the fund.

CONSIDERABLE interest has been aroused by the discovery of part of a human cranium during excavations on the site of Lloyds' new buildings in Leadenhall Street, in the City of London. It was found by a workman at a depth of 42 ft. below the level of the street. The deposit at this point is the blue clay below the Pleistocene gravel, and it is the same stratum as that in which a skeleton of a woolly rhinoceros has been discovered. The newly discovered fragment of a human skull, which is the posterior two-thirds of the brain case, was exhibited and described at a meeting of the Zoological Society on October 20 by Prof. G. Elliot Smith and Mr. Warren Dawson, to whom it had been sent for examination. The bone is definitely mineralised, and there would appear to be no reason to doubt that it is contemporary with the stratum in which it is found, and not an intrusion of a later date. The fossilisation of the bone at the line of fracture indicates that the skull was broken in ancient times and not recently. As regards the cranial fragment itself, certain features suggest that the muscles of the neck were not of the massive character that might perhaps be expected in an early type of man, and point to the skull being that of a female, while the condition of the sutures indicates an age of about forty-five years. The endocranial cast was very much flattened and showed resemblances to the Neanderthal type. Prof. Elliot

Smith, however, is definitely of the opinion that the skull belongs, not to Neanderthal man, but to *Homo sapiens*.

AN announcement in the *Times* of October 20, that Dr. Grimme, professor of Semitic philology at the University of Munich, had discovered a record of the rescue of Moses from the Nile by "Hatshepsut, daughter of Pharaoh," has aroused considerable interest in the newspaper world. According to a despatch from the Berlin correspondent of the *Times*, the discovery was made known at a private meeting of the Society of German Citizens of the Jewish Faith; but, as a matter of fact, Dr. Grimme's suggested decipherment of the inscription in question, which was found by Sir Flinders Petrie in Sinai in 1904, was published in book form in 1923, and is reviewed by Mr. T. G. Pinches in *Ancient Egypt* for September, where there also appears an illustration of the signs which have been identified as signifying "Hatshepsut" as they appeared on the original inscription; they appear with additions made out from a photograph, and as set out by Dr. Grimme. It is, of course, uncertain that the language is Semitic, but Dr. Grimme, working on a comparison of old Phœnician and Egyptian characters, concluded that the inscription is characteristically Old Hebrew. The identification of Hatshepsut (Hyatsepsu) and Yoseph suggests that some of the characters *may* be correctly interpreted. The reviewer, while acknowledging that "there seem to be good comparisons on the Egyptian side," is of the opinion that there are grave doubts as to the justification of the comparisons on the Old Hebrew or Phœnician side.

IN *Scribner's Magazine* for October, Prof. E. James Swift discusses quackery and its psychology. His purpose is to reveal the weak spots of the human mind which make it an easy prey for the infection of humbuggery. He gives examples from ancient and present times, from various countries, of beliefs firmly held for which, however, there was no objective proof. He places the onus of self-deception on the imagination, the lure of the mysterious, and the subtle influence of obscure explanations. He compares the activities of professed conjurors and spiritists, the former consciously setting out to play on the credulity of the audience, and the others less consciously using the same devices. Every scientific observer knows the importance of the negative instance and its elusiveness unless one is prepared. When, however, we have arraigned imagination as the culprit in self-deception, we have not answered the problem of why man lends himself to deception, why a scientific training in one direction is no guarantee of accurate observation in another. Is it that the attitude of credulity is the more natural as being that of the child, which we only give up after long and laborious training, and so, the scientific attitude being late in development both in the race and in the individual, is therefore much less stable?

AN account of the twentieth Norwegian expedition to Svalbard (Spitsbergen) is contributed by Dr. Hoel to *Aftenposten* (Oslo) of September 17. The chief

object of the expedition was to complete the survey of the eastern half of the coal-field between Van Mijen Bay and Is Fjord, a somewhat difficult task owing to the thickness of the superficial deposits. In the course of mapping, a saurian skeleton about two metres long was found in Jurassic shale, west of Store Fjord, but its excavation had to be left for another year. Large portions of fossil trees of Tertiary age were found on the hills at Van Mijen Bay. On Bear Island a seam of pure galena, 30 cm. to 40 cm. thick, with other seams of mixed barytes and galena, hold out a promise of profitable working. The inner part of Is Fjord was sounded, and the chart of the waters between South Cape and Cross Bay, on a scale of 1:100,000, was completed for publication. Oceanographic observations detected a considerable increase of temperature (so much as 2° to 3° C.) at nearly all depths. The atmospheric temperature was also relatively high, and a rapid decrease of the glaciers was perceived. Dr. Hoel also remarks on the considerable diminution of the reindeer stocks, and suggests the need of preservation by law.

THE September issue of the Journal of the Franklin Institute is of exceptional interest, as it contains the report of the presentation of Franklin medals to Prof. P. Zeeman and Dr. Elihu Thomson, the former being honoured for his discoveries in magneto-optics, and the latter for his pioneer work and inventions in electricity and electrical engineering. The addresses of the recipients are printed in the same issue. Prof. Zeeman's suggestive address on "Magnetisation of Spectrum Lines: Reminiscences and Prospects" contains a reference to the very powerful magnetic fields which the research worker can now command: the strongest statical field so far obtained is 63,700 gauss (Deslandres), and the strongest field of short duration (0.01 sec.) is 500,000 gauss (Kapitzka). Dr. Elihu Thomson's constructive address reviewed the mechanical, thermal, and optical properties of fused silica, and adumbrated the use of both fused sand and fused quartz on a greatly extended scale. Large quantities of the opaque material, made from sand, will probably be used for making insulators for high-tension transmission lines, singly capable of withstanding voltages so high as 200,000. Fused silica, owing to its highly elastic nature, is well adapted for making tuning forks of standard pitch. Fused quartz is suitable for making astronomical mirrors, condensing lenses for cinematography, the temperature-compensation mechanisms of clocks and watches, standards of length, and also for optical prisms and lenses, as it is now quite easy to remove internal striæ by fusing the quartz in a good vacuum, and then subjecting it to high pressure. Fused quartz will be used in increasing quantities for the application of ultra-violet radiation in therapeutics, and possibly also in the preparation of food.

CAPT. R. B. SEYMOUR SEWELL, I.M.S., has been appointed Director of the Zoological Survey of India. Dr. Sewell was educated at Christ's College, Cambridge, and is well known for his zoological writings in connexion with Indian zoology.

THE secretary of the Moscow Society of Naturalists informs us that, on November 7, M. A. Menzbier, president and honorary member of the Society, and professor emeritus of the First Moscow University, will attain his seventieth year. As no public celebration of this anniversary is to be held, letters and congratulations should be addressed to the secretariat of the Moscow Society of Naturalists, First Moscow University, Mokhowaya, N.II.

THAT the value of the work carried out at the Imperial College of Tropical Agriculture in Trinidad is appreciated throughout the Empire is shown by the steadily increasing list of donors to the special appeal, now being conducted by the Duke of Atholl during Lord Burnham's absence abroad. Recent donations and promises include 500*l.* from Platt Bros and Co, Ltd., and 100*l.* each from the Sun Life Assurance Co. of Canada and the United Alkali Co., Ltd. Contributions may be sent to Mr. Algernon Aspinall, Secretary, 14 Trinity Square, London, E.C. 3, or to the bankers of the fund, Barclays Bank (Dominion, Colonial and Overseas), 30 Gracechurch Street, E.C.3.

THE menace of foot-and-mouth disease is again threatening Great Britain, several outbreaks having been reported in districts widely separated from one another, the origin of which is quite unknown. In consequence the Ministry of Agriculture and Fisheries has issued a circular letter directing attention to the outbreak and advising stock-owners to obtain a copy of the leaflet issued by the Ministry on the subject. This deals with the chief symptoms of the disease, and gives directions for the precautions to be taken to avoid infection and what should be done if infection is suspected. The leaflet (Form No. A 129/T.A.) may be obtained free of charge on application to the Secretary of the Ministry, Whitehall Place, S.W.

At the annual statutory meeting of the Royal Society of Edinburgh, held on Monday, October 26, the following officers were elected:—*President*: Sir Alfred Ewing; *Vice-Presidents*: Prof. J. H. Ashworth, Prof. T. H. Bearé, Dr. W. B. Blaikie, Sir Robert Blyth Greig, Prof. T. H. Bryce, and Prof. E. T. Whittaker; *General Secretary*: Prof. R. A. Sampson; *Secretaries to Ordinary Meetings*: Dr. A. Lauder, Prof. W. Wright Smith; *Treasurer*: Dr. J. Currie; *Curator of Library and Museum*: Dr. A. Crichton Mitchell.

FROM a recent number of *Sperryscope*, the organ of the Sperry Gyroscope Co., we learn that Mr. Elmer A. Sperry has just been elected a member of the National Academy of Sciences, Washington, and has also received the honorary degree of D.Sc. from the North-western University, Evanston, Ill. In being presented for the degree, Mr. Sperry was described as "An electrical engineer and a physicist who has shown remarkable skill in applying scientific methods and knowledge to the solution of practical problems; inventor of the Sperry Gyro-compass; of many valuable aeronautic instruments; of the highest power searchlight; of fire control for the United States

Navy; a pioneer electrical manufacturer in America; and a founder member of the Society of the American Institute of Electrical Engineers."

THE current session of the Royal Society of Arts will be opened on Wednesday, November 4, at 8 30 P.M., when the inaugural address will be delivered by Sir Thomas H. Holland, chairman of the council, the subject being "The Organisation of Scientific Research throughout the Empire." Other meetings before Christmas include "Colour Printing," by Mr. David Greenhill; "Recent Progress in Indian Forestry," by Prof. E. P. Stebbing, and "The Imperial College of Tropical Agriculture," by Dr. H. Martin Leake, Mr. L. S. Amery, M.P., presiding. A course of three lectures under the Cantor Trust will be delivered by Dr. R. Lessing on "Coal Ash and Clean Coal." At meetings after Christmas the following papers will be read: "Investigations in Agricultural Science at Rothamsted," by Sir John Russell; "Religions and Races in the Punjab," by Sir Michael O'Dwyer (Sir George Birdwood Memorial Lecture); "The Work of the Imperial Institute," by Sir Richard Redmayne; "Women and Children in Indian Industries," by Lady Chatterjee; "Some General Problems of Fruit Preservation," by Prof. J. McLean Thompson; "The Propagation of Electric Waves," by Mr. J. E. Taylor; "Problems in Paint and Varnish Technology," by Dr. H. Houlston Morgan; "Domestic Heating," by Dr. Mary Fishenden; "Modern Views of Vitamins," by Prof. J. C. Drummond; "Horse Traction and Motor Traction," by Mr. James Paterson; and "Indian Maps and Surveys," by Colonel W. M. Coldstream. Courses of lectures will also be delivered by Dr. G. W. C. Kaye, on "The Production and Measurement of High Vacua"; by Mr. W. F. Higgins, on "Thermometry"; and by Mr. C. R. Peers, Director of the Society of Antiquaries, on "Ornament in Britain."

IN the annual report of the Otago University Museum for 1924, Prof. Benham gives the chief place to a valuable gift of ethnographic objects by Mr. Willi Fels. This consists of three main sections. First, 200 oriental fire-arms and other weapons. Secondly, a fine series of Maori objects, including a tiki with head erect as in the Marquesan ornaments of the same name. Thirdly, material from Pacific groups other than New Zealand, among which an extensive collection of lime knives from the Massim area, which is claimed to be one of the finest in existence. These large additions accentuate the need for more exhibition space, more work-rooms, and an increased staff. Another New Zealand museum, that of Auckland, also records the acquisition of a great collection illustrating Pacific ethnology. This is the Edge-Partington collection, purchased and presented by Mrs. Selwyn Upton and Mr. W. Cecil Leys as a memorial to their father, the late Dr. T. W. Leys, long a member of the council of the Auckland Institute. The report for 1924-25 announces the commencement of the War Memorial Museum, and the hope is expressed that its opening may be made the occasion for the holding of the Pan-Pacific

Science Congress in Auckland in 1928 or 1929. The curator of this Museum is now Mr. Gilbert E. Archey, and the assistant-curator is Mr. L. T. Griffin.

WE have received a copy of Catalogue No. 13, 1925, of second-hand books offered for sale by W. H. Robinson, 4 Nelson Street, Newcastle-upon-Tyne. The list is of a miscellaneous character, but includes sections devoted to voyages and travels (including Americana), folklore and archæology, and old scientific books. The prices asked appear to be reasonable.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: An assistant pathologist at Westminster Hospital—Secretary, Westminster Hospital, S.W.1 (November 6). An assistant lecturer in the department of pharmacy of the Brighton Municipal Technical College—F. H. Toyne, 54 Old Steine, Brighton (November 7). A lecturer in agricultural chemistry at University College of Wales, Aberystwyth—Secretary (November 14). An agricultural chemist, with experience in biochemical investigation, a mycologist, an entomologist, and a botanist, principally for physiological investigations, for the Tea Research Institute about to be established in Ceylon—T. Petch, the Tea Research Institute, c/o the Ceylon Association in London, 6 Laurence

Pountney Hill, E.C.4 (November 30). An editor for a Journal of Abstracts and Reviews to be established by the British Empire Cancer Campaign—Secretary, British Empire Cancer Campaign, 19 Berkeley Street, W.1 (November 30). A junior scientific assistant in connexion with Admiralty Research—Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1. A senior water works engineer in the public works department of the Government of Nigeria—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/13,684). A civil engineer in the public works department of the Government of Nyasaland—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/14,046). A lecturer in hygiene and public health at Charing Cross Hospital Medical School—The Secretary, Chandos Street, W.C.2. A chemical engineer and an organic chemist for the Research Station, Canadian Pulp and Paper Association—The Association, 701 Drummond Building, Montreal, Canada. A clinical pathologist at the Crichton Royal Mental Hospital, Dumfries—The Physician—Superintendent. An assistant mining lecturer under the Warwickshire Education Committee—Bolton King, County Education Office, Warwick. A lecturer in physics at the Royal Technical College, Salford—Secretary for Education, Education Offices, Salford.

Our Astronomical Column.

RETURN OF FAYE'S COMET (1925 *b*).—It is welcome news that this comet, after long search, has been photographed by Dr. Baade with the 1-metre reflector at Bergedorf. It was discovered in 1843, and has been observed regularly every $7\frac{1}{2}$ years, except for the returns of 1903 and 1918. One reason for its non-detection in 1918 was the fact that Fontana's search ephemeris was based on M. Fayet's period, published in 1910, which is now known to have been two months too short. It is inadvisable to publish periods of periodic comets deduced from short arcs, as they are subject to great uncertainty.

Before the present return, Mr. Cripps computed the perturbations and published the following elements in the Journal of the British Astronomical Association, Vol. 35, No. 6.

T	1925 Aug. 6.66 U.T.
ω	$199^{\circ} 43' 15''$
Ω	$206 13 46$
i	$10 36 31$
ϕ	$34 51 29$
n	$485.42''$

It now appears that T is actually Aug. 7.56, and Mr. G. Merton gives $484.87''$ as the corrected value of n . The other elements are not much in error.

Dr. Baade's observation is as follows:

	R.A. (1925 <i>o</i>).	N. Decl.
Oct. 20 ^d 2 ^h 36 ^m 5 ^s	$8^{\text{h}} 5^{\text{m}} 18.39^{\text{s}}$	$9^{\circ} 33' 2.0''$

The magnitude of the comet was 13. A small tail was shown on the photograph.

Once the exact place was known, Dr. Stobbe re-examined earlier Bergedorf plates, and has found images of the comet on those taken on Aug. 20 and Sept. 15. These are sufficiently distinct for measurement, and will be useful for improving the elements.

It is interesting to note that five of the six periodic comets due in 1925 have now been detected. The only failure has been Schorr's comet, which was very

unfavourably placed. There are already nine recorded perihelion passages of comets in 1925, a number that has only once been exceeded; in 1898 there were ten. It was equalled in 1886 only. This shows a reawakening of interest in the search for comets, which had somewhat fallen off.

The following ephemeris of Faye's Comet for o^{h} is from the corrected elements

	R.A.	N. Decl.	$\log r$.	$\log \Delta$.
Nov. 1	$8^{\text{h}} 22^{\text{m}} 36^{\text{s}}$	$7^{\circ} 12'$	0.2620	0.1774
9.	$8 31 52$	$5 42$	0.2709	0.1659
17.	$8 39 6$	$4 16$	0.2799	0.1539
25.	$8 44 14$	$2 59$	0.2892	0.1425

THE CAPE OBSERVATORY.—The annual report of the Cape Observatory for the year 1924 deals with a very large amount of work. Investigations of special interest described in it are the parallax of Mars observed both visually and photographically at the near approach in August 1924, and the determination of the moon's semidiameter ($15' 32.70'' \pm 0.04''$) and parallax inequality from a long series of occultations going back to 1880. Both these investigations gave a value close to $8.805''$ for the solar parallax, and the Mars investigation was the means of elucidating many points about atmospheric dispersion, etc., which will be useful at the opposition of Eros in 1931. The discussion of the motion of the moon's perigee and node agreed in giving $1.294.8$ for the earth's compression.

The plates of the Cape Astrographic Catalogue are now being retaken through the glass, which will facilitate the determination of proper motions by placing them, film to film, against the earlier plates. Meridian observations of stars and heliometer observations of planets are also being carried on as usual. The working list for the former includes all stars brighter than 7.5 magnitude south of Decl. 30° south.

Research Items.

ANTIQUITIES FROM THE RUSSIAN ALTAI—Dr. Alexis Zakharow, of the Russian Historical Museum, Moscow, describes in the *Journal of the Royal Anthropological Institute*, vol. 55, pt. i., some of the antiquities from two cemeteries on the Katanda Steppe, which were discovered by W. Radloff so long ago as 1865. These antiquities, however, have never been described. The first cemetery contained 30 to 40 tombs covered with mounds of round pebbles, and a row of flat barrows, which, however, Radloff considered to be places of sacrifice. In this cemetery were found skeletons of horses with bits of iron, human remains, male and female, knives of iron, and arrowheads of iron and bone. Spearheads with tubular sockets, and fragments of a bow, were among the objects found with male burials, copper ear-rings of spiral form were with the female skeleton. In the eighth and last kurgan excavated were fragments of garments. In the second cemetery, the most interesting objects came from a large kurgan more than seven feet high and 100 feet in diameter. The skeletons of at least six horses were found in this mound. There were also a number of garments and nine figures of horses carved in wood, of which five are in full profile, two with heads turned full face, and two lying down. Figures of other animals, such as a stag, a bear, and a dragon, were also found. Small kurgans in this second cemetery produced textile material of which the decorative pattern has been reconstructed. From this it is conjectured that it is Chinese in origin and belongs to the seventh or eighth century A.D.

THE NEOLITHIC AGE IN THE NORTHERN FAYUM, EGYPT—A preliminary report by Miss Caton-Thompson on important finds made by her in the Fayum last season on behalf of the British School in Egypt appears in *Man* for October. They consisted of bone implements and pottery of Neolithic age from sites along the northern shore of the Qarun Lake. The investigations were undertaken to inquire into problems relating to the flint industry of the Fayum, and one of the results was the first discovery of pottery and bone implements to be associated with that culture. Though prehistoric sherds abound on the sites, few pots were found in sound condition. Many were practically powder only held together by salt. These had to be measured and drawn *in situ* without attempt at removal. The forms found were: globular with flattened base, globular with restricted top, rectangular dishes, cups, saucers. Some showed traces of a slip. All were badly fired. In the rectangular dish were found five lumps of hæmatite, two quartz pebbles, parts of a flint nodule, and twelve freshwater bivalve shells of *Spatha caillardi* Martens. The bone implements, which were surface finds from lacustrine clays, consisted of harpoons, with barbs of a less acute angle than the Magdalenian specimens, and bone points, bevelled and showing striations for attachment. A unique specimen has a butt end which is squared off and a grooved spiral on the stem.

UTILISATION OF PEAT—At the recent British Association meeting at Southampton, Dr. F. Mollwo Perkin gave an account of recent progress in the peat problem. The various types of peat were described, and emphasis placed on the central difficulty of reducing the water content of freshly dug peat (90 per cent. in round figures) sufficiently to permit any form of manufacture to be economically attempted. Maceration, heating and compression, electro-osmosis, chemical treatment, and combinations of several of

these have been tried, mostly without success. It is believed that a combination of maceration, heating in an autoclave followed by sudden release of pressure, and briquetting will prove a solution. The briquettes are stated to prove well suited for use in domestic heating appliances, and are of course smokeless. A plea is made for the development of such a process for utilisation of peat to produce domestic and manufacturing fuel and useful by-products.

THE PLANT AS A MEASURE OF THE HABITAT—Frederic E. Clements and Glenn W. Goldsmith publish many data in the Carnegie Institution Publication, No. 356, "The Phytometer Method in Ecology," on the growth and upon the performance of measurable functions, such as transpiration, by plants or small plant communities, which they consider form the most trustworthy index to the habitat. They consider that the increasing standardisation of such "phytometer" methods will cause them to replace the less satisfactory of the instruments designed to measure individual factors of the environment, such as the atmometer, etc. This may be so, but the individual plant is such a complex recording instrument that the interpretation of its record of the habitat, even as a guide to the behaviour of other reasonably similar plants, is often a very difficult problem, and probably it will be long before the student of plant habitat ventures to plumb the possibilities of the environment without the aid of a battery of physical instruments, each designed to record the fluctuation in one separate physical factor, as rainfall, humidity, temperature, etc.

TRANSPLANTING CROP PLANTS—In the United States, the annual value of crops which are usually transplanted amounts to nearly 200,000,000 dollars, grown on an area of 1,289,000 acres, representing 57 per cent. of the acreage and 63 per cent. of the value of all vegetables other than potatoes. This renders the work by Loomis (Mémor 87, Cornell Experiment Station) on the value or otherwise of transplanting, of great commercial value. Transplanting is becoming recognised as an economic expedient not directly promoting the development of the plant. Experiments indicated that in the early seedling stages all vegetables could be transplanted with little or no injury, but with advancing maturity the injury increased in all cases, but more in some crops than others. The roots of transplanted plants were more branched than those not moved, but the general effect of the process was to retard development, the degree of retardation depending upon the plant, its age and the conditions of transplanting; to some extent, also, the total yield was reduced. All crops seemed to be equally resistant to rapid wilting at the time of transplanting, but they varied in their ability to withstand unfavourable conditions afterwards, presumably due to differences in the rate of re-establishment of their roots. The effects of hardening off seedlings were investigated by transpiration studies before and after transplanting, which showed a more rapid recovery of the normal rate in plants previously hardened, this recovery being apparently associated with quicker root development. A clear correlation has been established between ease of transplanting and rate of new root formation, plants seriously injured by transplanting showing normal rapid top growth and slow root replacement. Root replacement seems to be the largest single factor concerned in transplanting, though the age at which suberisation of the older roots occurs may also have some bearing upon the matter in its relation to the

power of absorbing water immediately after the root tips have been broken off when the plants are disturbed.

SOUTH AFRICAN WEEDS.—One of the heritages left to South Africa by the Boer War appears to be a number of troublesome weeds, and as "Weed No. 1" in the reprints issued by the Union Dept. of Agriculture appears such an introduction, the spear thistle, *Cnicus lanceolatus*. It is curious also to read in this series of the jointed cactus, *Opuntia aurantiaca*. Introduced in the Cape Province as a garden plant in 1878 the plant is now proclaimed as a most dangerous weed, which has rendered many farms quite valueless and will cost many thousands of pounds to eradicate. Thus its habit of growing from any small fragment, which pleases its cultivator under glass in Britain, is evidently very differently regarded now in South Africa. These reprints contain excellent illustrations in colour by K. A. Lansdell, the Botanical Assistant, Division of Botany, Pretoria. Whilst South Africa thus discovers invaders to the flora flourishing far too readily, it appears to be in danger of losing many valued native plants owing to the commercial traffic in these wild flowers. The Journal of the Botanical Society of South Africa (Part 11, 1925) therefore welcomes a new ordinance passed by the Cape Provincial Council which enables the police to seize protected flowers exposed for sale and the magistrate to inflict severer penalties. At the same time the list of protected flowers has been pruned so that the law is not unnecessarily invoked, and the hope is expressed that the law will now be generally respected and its provisions enforced. Apparently the trade in protected flowers has been so profitable that fines have been comfortably paid and the law has been dead letter in practice, so that during 1924-25 the Journal estimates that the native flora disappeared from this cause more quickly than ever before.

GLACIERS OF MOUNT EVEREST.—In an article in the *Geographical Journal* for October on the rocks and glaciers of Mount Everest, Mr. N. E. Odell describes a remarkable feature of the East Rongbuk glacier which takes the form of a corridor 50 feet deep and 100 feet wide, lying longitudinally in the glacier for about three miles between the altitudes of about 18,700 and 20,000 feet. The steep sides of this trough are buttressed or pillared with fretted ice. The trough lies about 400 yards from the left side of the glacier and seems to be coincident with a medial moraine, since moraine matter was found on many parts of the floor. At the upper end of the trough, when the winter snow had gone, Mr. Odell found clear evidence of severe stress in the form of "ribbon structure" in the ice, not to be confused with the bedded structure of glacier ice due to entirely different causes. From the evidence of foliation and faulting it would appear that the trough is due to actual fusion of the ice by heat engendered in the compression, accompanied by evaporation of the fused ice. The topography of the district and the course and gradient of the glacier flows show that this explanation is feasible. Mr. Odell believes the trough to be a permanent feature of the East Rongbuk glacier. In a later part of the article evidence is given for a former great extension of the glaciers of the Mount Everest region. A geological map accompanies the article.

THE CLIMATE OF ALEXANDRIA.—A discussion on the above, compiled by Mahmoud Hamed, has been issued by the Ministry of Public Works, Egypt, as Physical Department Paper No. 19 (Government Publications Office, Cairo, price P.T. 5). Meteorological

observations were first made at Alexandria in 1869. From 1875, observations were made daily at 9 h. and 21 h., and from 1888 until 1900, observations were taken eight times daily. Afterwards, observations were under the control of the Survey Department and were made three times daily at 8 h., 14 h., and 20 h. In the spring, depressions from the Sahara sometimes pass over Alexandria and these "Khamasin" depressions usually bring hot south winds. During the summer the pressure system over Egypt remains almost undisturbed, and settled weather with cool northerly winds, and rather high humidity at Alexandria, prevails. The maximum atmospheric pressure occurs normally in January, but sometimes so early as November, or so late as February; the minimum pressure occurs in July. The coldest month is January with a mean temperature of 14° C., and the warmest is August with the mean 26°·2 C. The highest temperature ever recorded, since 1888, is 43°·7 C. on June 16, 1915, during the passage of a shallow depression over the Delta. The highest black bulb thermometer in vacuo reading at 14 h. is 64°·0 C. in May and June 1915. During the summer the sun is obscured by clouds only for about an hour and a half a day, while in the winter time it is obscured on the average for about four hours. On an average there are about five gales in the year, the majority occurring in December, January, and February. Tables and diagrams are given showing the average meteorological results. The whole work is well carried out and is of considerable interest.

PETROLEUM IN THE NETHERLANDS.—During the period 1903 to 1923 a systematic investigation into the mineral resources of the Netherlands was carried out on behalf of the Dutch Government, chiefly with the object of locating concealed coal deposits. The undertaking involved the sinking of fifty borings from 500 to 1400 metres in depth, one hundred borings varying from 25 to 200 metres, and a large number of shallow test-holes for geological examination of the superficial rocks. Operations were carried out mainly in three districts, South Limburg, North Limburg and North Brabant, and parts of East Guelderland and East Overijsel. In the last-mentioned district an interesting discovery was made of petroleum associated with Permian salt deposits overlying coal beds. A boring at Corle (1921 to 1923) had yielded gas- and oil-impregnated cores of salt, and when Government operations ceased in 1923 it was resolved to examine this well more closely for oil. Since the boring had been made primarily for salt recovery, the casing had been constantly filled with water, under high pressure, and whatever oil indications there might have been, had thus been obscured. Accordingly the water was pumped from the boring and in February 1924, and for some time afterwards, a quantity of mineral oil accumulated, of which some 250 litres were collected and submitted to laboratory testing. Dr. P. Tesch, director of the Dutch Government Geological Service, gives some account of these results in *Economic Intelligence*, published at the Hague on August 1, and states that the oil was thin, had a specific gravity of 0·84, and yielded on distillation 10 per cent. of benzine, 30 per cent. of kerosene, 55 per cent. of fuel oil, and 3 per cent. asphalt, no lubricating fractions being found. Dr. Tesch concludes that the oil originated in the Permian salt beds, and having regard to the position of the particular locality on the border zone of the Munster basin, and probably to the fact that petroleum has often been found in association with the German salt deposits, he is of the opinion that prospects are not unfavourable but, in fact, justify a continuance of exploratory operations.

These have now been taken in hand by private enterprise, but whether commercial success will ensue is a moot point.

THE THEORY OF FERROMAGNETISM.—A new theory of ferromagnetism is put forward by Mr. L. W. McKeehan in the August number of the *Physical Review*. It is assumed that magnetisation is due to intra-atomic changes, involving changes in the orientation of electronic orbits which are governed by quantum dynamics, and to inter-atomic changes (stresses and strains between the atoms). Magnetostriction, the change in dimensions which takes place in the material, originates in the changes of electronic arrangement in the atoms producing atomic magnetostriction; this sets up the inter-atomic stresses and strains. Hysteresis loss and magnetic hardness are due to the energy required to produce the local deformations which take place when successive atoms or small groups of atoms are magnetised. The very low hysteresis loss and the very high initial permeability observed in permalloy by Messrs. O. E. Buckley and L. W. McKeehan, and described by them in the same issue of the *Physical Review*, result from the fact that magnetostriction has opposite signs for the two constituents iron and nickel of this alloy, and that in small groups of atoms the atomic magnetostrictions compensate. The differences between the magnetic properties of iron, nickel, and cobalt are regarded as due to the differences between their atomic magnetostrictions. The theory gives a satisfactory explanation of the form of the B, H magnetisation curve, and is not inconsistent with the observations of Buckley and McKeehan, which show that with about 81 per cent. of nickel the magnetisation curve of permalloy is practically independent of the mechanical tension.

SOLID PHASES OF THE ALUMINIUM-ZINC SYSTEM.—The equilibrium diagram of the aluminium-zinc system has been studied by many investigators, notably Heycock and Neville, Shepherd, Rosenham and Archbutt, Hanson and Tanabe. In all these diagrams the liquidus consists of three branches, in which, in the majority of cases, the results agree with each other. The solidus and solubility lines in the solid phases show, however, a great divergence from each other. Hitherto the majority of changes in the solid phases have been investigated by the quenching method. A recent investigation by T. Ishihara, published in the 97th Report of the Research Institute for Iron, Steel, and other Metals in Japan, was undertaken in order to find a correct equilibrium of the solid phases by determining the electrical resistance and volume changes of the various phases, and also by using X-ray analysis as a supplementary aid. As a result of this work a number of alterations are suggested for the diagram. The maximum solubility of aluminium in the α constituent is found to be 0.3 per cent. at room temperatures. The author regards the β constituent as a solid solution containing an unknown concealed compound. The range of the eutectoid transformation extends from 0.3 to 65 per cent. of aluminium. The actual eutectoid composition has been found to be 21 per cent. of aluminium. The solidus of the β phase varies from 380° to 440° C., according to the concentration of aluminium. The solubility of zinc in γ varies considerably with rise of temperature. Its maximum at room temperature is 23 per cent.

THERMAL DECOMPOSITION OF OZONE.—Some experiments are described by Griffith and McKeown in the Journal of the Chemical Society of September 1925 which help to eliminate the discrepancies existing

between the results of measurements of the thermal decomposition of ozone. The decomposition is carried out with ozonised oxygen under varying pressures, alone, and in the presence of argon, nitrogen, carbon dioxide, and helium. These gases exert a positive "catalytic" effect, but oxygen acts as a negative "catalyst." The explanation of these results is based on the idea that complexes are formed and these are decomposed by collision, the complex yielding ozone in the presence of oxygen, and oxygen in the presence of the inert gases.

INFLUENCE OF ULTRA-VIOLET LIGHT ON CHEMICAL REACTIONS.—The results of experiments on the effect of ultra-violet light on dried hydrogen and oxygen have been published by H. B. Baker and M. Carlton in the Journal of the Chemical Society for September 1925. The gases, prepared from baryta solution by electrolysis, were collected over mercury in pairs of carefully cleaned quartz tubes; one dried with a plug of phosphorus pentoxide, the other left undried. The tubes were exposed to the light from the lamp after periods of two to eight, and in one case twelve weeks. In all the experiments the reaction was greater in the tubes containing the undried gases. The water formed in the earlier stages assisted the reaction if the gases were exposed to the light again before the drying agent could remove it.

AN ALTERNATIVE VIEW OF THE STRUCTURE OF PROTEIN.—Prof. Keita Shibata has a very interesting preliminary note on new views and experiments upon protein structure in the Japanese journal *Acta Phytochimica*, vol. 2, No. 2, April 1925. Whilst the twenty or so amino-acids which form on the usual view the "bausteine" of the proteins have now been known for some time, there are still singularly few observations which throw any light upon the way in which they are linked in the natural proteins, and Fischer's classic suggestion, of chains of polypeptide character, is based mainly upon the synthesis of relatively simple and diffusible polypeptides by methods which are probably inapplicable in a living system. Of recent years the long peptide chain has come under criticism again, and the suggestion of anhydrides, a type of "peptin ring," been made. Prof. Shibata has been thinking of possible analogies with the complex carbohydrates, upon the structure of which so much light has been thrown of recent years, and thus has been led to the attempt to "depolymerise" proteins by analogous methods, such as heating in anhydrous glycerine. The method has met with considerable success, many proteins passing completely into solution, and the substances thus obtained are never free amino-acids and peptides, but considerable yields of crystalline bodies are obtained, which may be recognised as anhydrides of the type of diketopiperazin derivatives. Naturally amino-acids or peptides may be attached as short side chains to these bodies; Shibata thinks that the ammonia given off during the depolymerisation arises from the free acid amide groups of those anhydrides which contain asparagin or glutamin as components. During the progress of the depolymerisation the biuret reaction is lost, and it is known that anhydrides such as asparaginimid give the violet reaction with alkali and copper salts. Furthermore, by heating anhydrides of amino-acids in glycerine in the presence of small crystals of barium hydroxide, Shibata has obtained, on subsequent precipitation with alcohol, substances which enter into colloidal solution in water, do not readily dialyse, and give many of the reactions of proteins. Further details of this important work will be awaited with interest.

The Wheatstone Memorial at Gloucester.

AS was mentioned briefly last week, p. 623, on October 19 Sir Charles Sherrington, president of the Royal Society, unveiled at Gloucester a bronze memorial tablet to Sir Charles Wheatstone, who was born at Barnwood, Gloucester, on February 6, 1802, and died in Paris, October 19, 1875. The memorial tablet is placed on the outer wall of St. Michael's Church, and on it is reproduced in low relief the portrait of Sir Charles Wheatstone, by Samuel Laurence, in the National Portrait Gallery. The lettering beneath the portrait is as follows:

SIR CHARLES WHEATSTONE
D.C.L., LL.D., F.R.S.

BORN AT THE MANOR HOUSE, BARNWOOD,
GLOUCESTER, 6 FEBRUARY, 1802.

Pioneer of the Electric Telegraph and the first, with (Sir) Wm. F. Cooke, to render it available for the public transmission of messages, 1837. Inventor of the Stereoscope, 1838. Conducted the first experiments in submarine telegraphy, 1844. Contributed to our knowledge of Acoustics and of Spectrum Analysis. Invented the Rheostat, the Polar Clock, the Automatic Transmitter and Receiver and the Rotating Mirror for determining the speed of Electricity. Applied and improved the Resistance Balance of Christie, known as the "Wheatstone Bridge." Invented the self-exciting shunt-wound Dynamo, 1867. Knighted, 1868.

DIED IN PARIS, 19 OCT., 1875.

BURIED AT KENSAL GREEN CEMETERY, LONDON.

*To commemorate his Services to Science
this Tablet is placed here on the 50th anniversary
of his death.*

Previous to the unveiling, a meeting was held in the Gloucester Guildhall, at which the Mayor (Mr. F. W. Duart-Smith) presided. At this meeting Sir Charles Sherrington, representing the Royal Society, Mr. R. A. Chattock (president of the Institution of Electrical Engineers), Col. H. G. Lyons (director of the Science Museum), Mr. F. E. Smith (president of the Physical Society), and Mr. J. C. W. Reith (British Broadcasting Co.) paid tribute to the many achievements of Wheatstone, and particularly to his genius of application; he was one of the great experimenters of last century, and his discoveries led to marked progress in many branches of physics. The early advances made in telegraphic communication were in no small measure due to him, and his discovery of the self-exciting property of the shunt-wound dynamo was of tremendous importance. Mr. William Bellows, of Gloucester, spoke of the home life of Wheatstone; he was a man of extreme modesty and failed as a lecturer: on the other hand, he possessed a personality that inspired confidence, and his genial manner to those helping in his experiments endeared him to all in his laboratory.

Sir Charles Sherrington, in the course of his address, said that as the years go by, the recollection of what Wheatstone did, not only for Great Britain but also for the whole civilised world, becomes more and more significant and an inspiration to all who contemplate it. Last century brought to light an increased knowledge of the processes of Nature and a more complete understanding of the laws which govern them, thus putting into men's hands new means of harnessing Nature's powers for the service of man and of civilisation. Amongst those to whom that advance is due was Charles Wheatstone, who will for ever be regarded as one of the most outstanding men of his time. That

was apparent and recognised during his lifetime and he received many honours, yet the far-reaching character of his achievements could not have been so evident as they are now, viewed along the perspective of the years. The flight of time has brought still further an unexampled fruition to the scientific ideas and their practical application which his genius fostered and cultivated.

If the lessening of the great spaces and distances which sunder human communities one from another on the surface of the earth, and if the enabling of them to communicate and converse as though they were near neighbours, is to help human kind and to support and advance civilisation, then the telegraph is one of the most noteworthy of human triumphs, and Charles Wheatstone was one of the benefactors of the human race.

Wheatstone always strove to enhance the practical application of science to the needs of man, but he also strove unceasingly to penetrate philosophically the secrets of Nature for the sake of truth itself. The method of electrical measurement which goes by his name is a model of elegance and accuracy. His genius had that trait of creative imagination which enabled him to foresee whither the new facts he observed might lead the spirit of man in its analysis of material Nature. Thus in an early and fundamental contribution which he made ninety years ago to what has since become a special branch of physical science, spectrum analysis, he wrote a prophetic announcement, and it is not too much to say in fulfilment of those observations that the opinion of Wheatstone stands as precursor of some of the most far-reaching investigations that we possess to-day into the physical and chemical structure of the universe.

Gifted with musical tastes, Wheatstone was in early life a maker of musical instruments. He soon contributed a number of experiments of much beauty towards the analysis of musical sounds. Akin to those may be regarded his observations on vision, his invention of the stereoscope, and his discovery that the mind can, from two flat but slightly dissimilar pictures simultaneously presented to the eyes, obtain in full perspective and with startling distinctness the third dimension of sensual space. It is interesting that to Wheatstone, the physicist, should thus be due a fundamental observation in modern psychology bearing on the synthetic powers of the mind. This formed the subject of his Bakerian lecture to the Royal Society in 1852.

Wheatstone's connexion with the Royal Society was long and intimate. He was elected when quite young, and remained a fellow of the Society until his death—a period only a few months short of forty years. He had the unusual honour of receiving two Royal medals, and twice he delivered the Bakerian lecture to the Society. Finally he received the "blue riband" of the Society, the Copley Medal, which is awarded without distinction of country for research work.

Wheatstone was indeed a man of many gifts and activities. Perhaps the time is approaching when the advance of science will depend more and more on collective investigation—when individual share towards the achievement of great results will loom less large by reason of the completer organisation of the investigations, so that the grand total will come to be attained by the participation of many investigators. But in all such achievements there will be leaders. Such was Charles Wheatstone, and such is his memory to-day. He was a leader in the making of the intellectual edifice of his time.

The University of Leeds Appeal.

THE appeal of the University of Leeds for 500,000*l.* was launched on Friday, October 23, under excellent auspices. As patron of the appeal, the Duke of York was able to announce in the Majestic Theatre, at a large and representative gathering drawn from all parts of Yorkshire, that the campaign was opened with a total sum, in hand or promised, of 157,039*l.* Considering the depressed industrial conditions at the present time, this can very reasonably be taken as an excellent beginning. The comprehensive nature of the subscription list indicates the widespread interest that has been aroused by the case put forward by the University authorities.

The rapid growth of the University since the War has produced a situation in which it is almost impossible to carry on the work efficiently unless the accommodation is extended. The present number of students is more than twice as large as before the War; the staff has been doubled; but the buildings, save for some temporary erections, remain the same. The work is handicapped by overcrowding and by the use of unsatisfactory temporary sheds and converted dwelling-houses. Departments are split up into several parts separated from one another. The proper co-ordination of the work becomes extremely difficult, if not impossible. In particular, the library, so essential to university work, is in respect of housing most defective of all. With so strong a case to put before the public, it is not surprising that widespread interest has been aroused.

Founded as the Yorkshire College of Science in 1875, and granted a Royal Charter in 1904, the University of Leeds has grown with astonishing rapidity. At the coming of age celebrations last year, delegates from all parts of the British Empire showed their appreciation of the position which it holds at present in university life. The success which has attended it during the last twenty-one years is a measure of its embarrassments at present; and it is to get rid of these embarrassments that the appeal has been put forth. It is intended to substitute for the chaotic collection of private houses and temporary hutments, which at present supplement the premises of the University, a range of buildings suitable for university work, and, at the same time, worthy of the dignity of a university.

The meeting in the Majestic Theatre was a memor-

able one. The Vice-Chancellor (Dr. J. B. Baillie), who, in the enforced absence of the Chancellor, the Duke of Devonshire, presided over the great gathering, opened with an eloquent and felicitous speech, and the high note then struck was maintained throughout. He was followed by the Duke of York, who, in the course of an inspiring appeal, said: "You, as Yorkshiremen, will do well to consider how valuable an asset to your county and your commerce, your industries, and your population, is the University of Leeds. The teaching and research work undertaken in all its forty departments contribute directly and indirectly to the services of the community."

The Speaker of the House of Commons, Mr. J. H. Whitley, M.P., in a message of encouragement and hope, incidentally referred to the fact that he was once a teacher himself, and that in his connexion with education in the West Riding he felt there was "an inexhaustible amount of both talent and character in the humbler homes of our people." The influence of impressive buildings was touched upon in characteristic fashion by the Dean of York (Dr. Foxley Norris), now Dean-elect of Westminster. While not quite convinced that the University of the North ought not to have been at York, he was sent to say that York would do its best to help the scheme for Leeds. Mr. Philip Snowden, M.P., who is a native of the West Riding, in a closely reasoned speech, said much to the point upon the functions of a university. He would like to see our universities even more democratic than they are. Without being misunderstood, he would rather see the desired half-million raised by the pound contributions of 500,000 comparatively poor people than by the large and generous gifts of a few wealthy people. He hoped that trade unions, co-operative societies, and other working-class organisations in the West Riding would take up the matter of the appeal and thus show their desire for the extension of democratic education. The Marquis of Hartington, M.P., brought a message of hope and encouragement from his father, the Chancellor of the University. A memorable meeting ended on a note of confidence and optimism, but with the words of the Vice-Chancellor in mind: the first hundred thousand ensures against failure; the last hundred thousand ensures success.

Inheritance and Insanity.

THIS year's Harveian Oration before the Royal College of Physicians of London was delivered by Sir Frederick Mott on heredity in relation to mental disease. A subject of more pressing urgency and general public interest could scarcely have been chosen. The gravest problems of individual ethics and State medicine depend entirely for their solution on the state of our knowledge concerning it; yet precise knowledge is fragmentary and may be misleading.

Sir Frederick Mott cited the inquiries of Miss Agnes Kelley a little more than ten years ago into the pedigrees of three groups of persons: adult patients in the London County asylums, high grade mental defectives, and normal children from the elementary schools of Bethnal Green, London. Insanity was very much more prevalent in the pedigrees of insane persons than in those of mental defectives, being in the proportions of 50 per cent. and 25 per cent. Conversely, mental deficiency was more apparent than insanity in the family histories of the defective children; while the charts of the normal school

showed insanity and mental deficiency only in a very small percentage of cases. Further, Sir Frederick and his co-workers collected information, extending in many instances to four and five generations, concerning 4000 individuals at one time or another in London County asylums, and came to the conclusion that there was a signal tendency to antedating in respect of dementia præcox, manic-depressive insanity and involutional melancholia: that is to say, if a parent suffered from manic-depressive insanity, or a parent or grandparent suffered from involutional melancholia or senile dementia, one or more of the descendants might suffer from dementia præcox during adolescence.

Sir Frederick, however, gave no indication of the effect on these conclusions of the present tendency to broaden the clinical conception of stereotyped, adolescent, dementia præcox which fits so neatly into board of control schedules and asylum administration. A parallel criticism occurs in consideration of his views on the genetic origin of this disease set forth in considerable detail in the course of the oration. He

outlines a correspondence between the activity of the interstitial cells of Leydig in the testis and the inception of the great sexual occurrences in ontogeny, the determination of sex and the acquirement of functional activity. Yet he says that *at birth* there was "plenty of evidence of nuclear mitosis, and I came to the conclusion that numbers of the cells had attained maturity and were on the way to a regressive atrophy." At puberty the cells of Leydig reappear, after "commencing manifestations of nuclear activity and karyokinetic figures" at eleven years. What ontogenic event coincides, then, with the "maturity" of these cells at birth?

It is evident that we know far too little of the histological appearances of the endocrine glands at successive ages in the normal animal, and of their influence upon the body functions at different periods or at any period of life. But Sir Frederick Mott is to be congratulated upon a continuity of effort in the elucidation of a baffling problem. It is to be hoped that his great labours, no less than the eminence of his advocacy, will encourage a more concerted attack upon the manifold problems of mental fitness.

The French Congress of Industrial Chemistry.

THE fifth French Congress of Industrial Chemistry was opened at Paris on October 4, under the auspices of the Société de Chimie Industrielle, and was organised in conjunction with the Exposition Internationale des Arts Décoratifs at the Grand Palais and with the centenary of Chevreul's discoveries of the nature of fats and his manufacture of the stearine candle. The Congress was preceded by a series of non-technical addresses on the applications of chemistry to a number of industries, and by a reception at the Grand Palais. The formal opening of the Congress on October 5 was presided over by Monsieur de Monzie, the Minister of Public Instruction; it included an address by Sir Robert Hadfield on his own recollections of metallurgy in France. The Congress then resolved itself into sixteen sections, in each of which important papers on many branches of chemical industry were read and discussed. The official banquet was held at the Palais d'Orsay, the chair being taken by Monsieur E. Borel, Minister for the Marine, and the formal adjournment of the Congress took place on October 8 under the presidency of Monsieur C. Chaumet, Minister of Commerce. The following two days were spent in visits to works, one group of those present inspecting factories in the neighbourhood of Paris and a second travelling to Grenoble to visit the international exhibition of water-power and works in the vicinity.

The celebration of the discoveries of Chevreul on fats and oils was held at the National Museum of Natural History, in which Chevreul did his work, on Sunday, October 11. The place of honour was taken by the President of the French Republic, Monsieur Doumergue, and, after a number of short speeches, Prof. Henry E. Armstrong delivered an appreciation of the work of Chevreul and its consequences; the silver gilt medal of the Société de Chimie Industrielle was presented to Prof. Le Chatelier and to Prof. Armstrong. The proceedings terminated in a banquet at the Club, which was during the War the Cercle Interallié and is now La Bienvenue Française. The British delegates to the Congress included Prof. Armstrong, Mr. E. C. Evans, Prof. C. S. Gibson, Mr. A. J. Greenaway, Sir Robert Hadfield, Mr. E. A. Hailwood, Sir Frederick Nathan, Sir W. J. Pope, Dr. S. Miall, Mr. A. R. Smith and Mr. E. A. Umney.

One of the most striking features of this very successful Congress, in addition to the admirable manner in which it was organised and fitted in with the exhibition and the Chevreul centenary, was the fact that quite a number of Cabinet ministers took an active and even an enthusiastic part in the proceedings. Each of these gentlemen, when he spoke, showed a clear appreciation of the importance of pure science and of its applications to industry; it is an unfortunate fact that we cannot imagine a number of Cabinet ministers taking an active and appreciative part in a congress of applied chemistry in Great Britain.

W. J. P.

University and Educational Intelligence.

CAMBRIDGE.—Lists of candidates who have passed the recent First and Second Examinations for Medical and Surgical Degrees have appeared. In the First Examination lists the number of those who satisfied the examiners before matriculating—which in most cases means that they received the necessary instruction at school—is large; the percentages of non-matriculated candidates on the several pass lists being: Pt. 1 (Chemistry), 60 per cent.; Pt. 2 (Mechanics), 80 per cent.; Pt. 3 (Physics), 67 per cent.; Pt. 4 (Biology), 40 per cent. More of these candidates take the examinations in October than at any other season of the year, but the figures quoted emphasise the fact that, while most of the public schools make it their business to prepare boys for the chemistry and physics, not a few are now also able to do so in biology.

Authorisation has been granted for the following reappointments: Dr. Duckworth (reader in human anatomy); Prof. W. E. Dixon (reader in pharmacology); Mr. S. W. Cole (lecturer in medical chemistry); Dr. T. S. Hele and Dr. F. J. W. Roughton (lecturers in biochemistry); Dr. Shillington Scales (lecturer in medical radiology and electrology).

The following have been elected to fellowships at Trinity College: Prof. G. E. Moore, Mr. A. S. F. Gow, Mr. R. V. Southwell, Mr. P. W. Duff, Dr. J. A. Chadwick, Mr. H. O. Evennett, Dr. P. Kapitza.

At Corpus Christi College Mr. T. R. B. Sanders has been appointed lecturer in engineering, while Mr. C. H. E. Smyth and Mr. R. A. Butler have been elected fellows.

At Emmanuel College the following have been awarded Research Studentships: Mr. E. G. Lewis (External), Mr. G. E. Hutchinson (Honorary), and Mr. C. Rimington, whilst grants for research have been made to Mr. A. Sopwith, Mr. W. L. Cuttle, and Mr. R. A. R. Hartridge.

The following reappointments have been made: Mr. J. T. Saunders, fellow and tutor of Christ's College, to be demonstrator of animal morphology; Mr. H. H. Brindley to be demonstrator of biology to medical students.

The Lees Knowles Lectures on military science are to be given by Maj.-Gen. Sir Frederick Maurice, K.C.M.G., whose subject will be "Statesmen and Soldiers in the American Civil War."

The degree of Doctor of Science *honoris causa* is to be conferred on Sir Edgeworth David, professor of geology at the University of Sydney. There is a pleasant rumour abroad to the effect that Sir David intends to spend some weeks in Cambridge in the near future.

EDINBURGH.—The following changes in the staff have recently taken place: Prof. J. Shield Nicholson has resigned the chair of political economy, which he has held for forty-five years; Prof. Godfrey H. Thomson has taken up duty as professor of education in succession to the late Prof. A. Darroch; Mr. A. D.

Hobson has been appointed lecturer in experimental zoology, and Mr. S. W. P. Steen and Dr. A. C. Aitken lecturers in mathematics.

LEEDS.—At a meeting on October 21 the Council expressed its thanks for the contribution promised by the Worshipful Company of Clothworkers towards the further development, equipment, and maintenance of the Textile Industries and Dyeing Departments of the University. This increased financial assistance provides for a capital grant of 18,300*l.* on buildings and permanent equipment, and for an additional annual grant of 3000*l.* during the next seven years to ensure the more efficient maintenance of these Departments. The grants made for capital endowment (buildings and equipment) since the institution of the Yorkshire College of Science now amount to 98,488*l.*; the annual grants made from 1874 to the present year amount in the aggregate to 144,804*l.*

An offer by Col. Stephenson Clark, Past-Master of the Clothworkers' Company, of a fund of 1000*l.* for the establishment of a scholarship tenable in the Clothworkers' Departments, was accepted with most grateful appreciation. A fund amounting to 2079*l.* was handed over to the Council for the establishment of a scholarship to be known as the "Arthur Smithells Scholarship." The Exchequer Grant allocated to the University by the University Grants Committee has been increased by 14,000*l.* a year.

On the grounds of intellectual distinction and of long and meritorious service to the University the title of emeritus professor was conferred upon Dr. T. Wardrop Griffith, who recently retired from the chair of medicine.

APPLICATIONS are invited by Guy's Hospital Medical School for the Beane scholarship in materia medica. The scholarship, which is of the annual value of 50*l.* and tenable for three years, is open to candidates who have received part, at least, of their medical education at Guy's Hospital. The latest date for the receipt of applications, which should be sent to the Dean, is December 19.

A COURSE of four "Armourers and Brasiers' Company" lectures on "Metal Crystals," appealing to those engaged in metallurgy, engineering, and allied industries, and to students of chemistry and physics, is to be delivered at the Chelsea Polytechnic, Manresa Road, S.W.3, by Prof. H. C. H. Carpenter, on November 5, 12, 19, and 26. The lecture hour will be 8 o'clock and admission will be free without ticket.

THE new engineering laboratories of the University College of Swansea were to be opened on October 30 by Lord Eustace Percy, president of the Board of Education. The buildings provide a floor area of 16,000 sq. ft., and this development has been made possible by the generosity of local engineering firms and collieries. The nucleus of the fund of 50,000*l.*, which is the sum required for the whole building scheme, was provided by the Welsh Engineers and Founders' Association and some donations from anthracite colliery owners led by Mr. C. F. Cleaves. The value of the plant which has been presented to the Department of Engineering now amounts to 10,000*l.*, and includes an experimental boiler plant obtained by the generosity and exertions of Sir James Kemnal. With the aid of this plant and backed by the local coal and oil industries, it is intended to make combustion engineering a prominent feature in the work of the Department. Organised visits to works are contemplated, while a course in the theory of accounts and works costing is being given voluntarily by Mr. R. A. Wetherall, Borough treasurer to the Corporation of Swansea.

Early Science at Oxford.

November 2, 1683. It was ordered, that a Loadstone should be cut *secundum Axem*, and then one half of it *secundum Aequatorem*; and triall be made, whether ye parts will retain ye same poles, which ye whole had. Mr. Piggot proposed an experiment viz: that ye needle of a compass will change its place at ye approach of ye centre of gravity of a bar of Iron, drawn up perpendicularly, from ye earth, by it. He was desired to try this experiment, before ye company ye week following. Dr. Wallis was then pleased, to shew us a draught of a chimney-peice, in ye Rectory House at Helmsdon, in Northamptonshire, which has ye date of ye Lord 1133 on it, in numeral figures; from whence it seems to appear, that numeral figures were in use amongst us, about 120 years sooner, than is generally supposed.

Dr. Aldrich discoursed of ye necessity of (at least) two drums in ye ear, otherwise in probability, he said, fourths would be agreeable notes. The anatomists are desired, to make use of what opportunity they shall have, for a farther enquiry into this matter.

1686. The Society having adjourned during ye long vacation, this day met again, and design constantly to continue their meeting.

An account was received from Dr. Wallis of a child which had on each hand 6 *fingers*, and on each foot six toes.

A Specimen from Dr. Lane of a strange *earth* which has a strong scent like Oyl of Turpentine, and upon distillation yeilds a good quantity of Chymical Oyl.

November 3, 1685. A letter was read from Mr. Ash concerning a girl in Dublin, who has several horns growing out of her skin.

Dr. Garden of Aberdeen communicated more of his observations concerning weather.

November 4, 1684. Mr. Musgrave communicated an account of a large preternatural Glandulose substance growing between the pericardium and ye heart of an Ox. The weight of ye whole substance, cleared from ye little fat &c: adjoining to it, amounted to 19½ lb. As to its figure it so far resembled a heart, that it was a long time taken for nothing else; but it was something flatter than a heart is naturally, each of ye flat sides making an equilateral triangle. In ye lungs were severall Cystides containing matter more or less fluid: one very large Cystis held some ounces of a matter not unlike that of a Steatoma.

The butcher who killed this Ox, says ye lungs grew fast to ye Pleura on both sides, which he affirms not to have happened once in 40 times in ye Cattle killed by him. He says also that this Ox though not overburdened with fat, complained much in travailing, which is easy to account for, there being not room for ye heart to be distended, as it ought, in its diastole.

Then Dr. Plot shewed some Saffron, which grew in Herefordshire; its taste was tart enough, and it seemed little unlike our best saffron, wanting only its bright or yellow-red colour, and being of a much browner and darker hue, which also by some was supposed chiefly owing to its being very dry.

He shewed us likewise an *Ovum Centennium*, which was given him that week for ye supposed Cocks-egg. It was somewhat bigger than a Pigeon's egg, of a pale box-colour, but opening it we found it nothing nigh full, otherwise not differing from an ordinary egg. So that we suppos'd it might be ye first egg of some young Pullett, one of the Society affirming, that he knew, some years since, a chick, which, wanting a day, or two of three months old, began to lay, and the eggs for some weeks were scarce bigger than this.

Societies and Academies.

LONDON.

Optical Society, October 15.—C. V. Raman and Sushul Krishna Datta: On Brewster's bands. The paper considers the explanation of Brewster's bands and other allied phenomena from the viewpoint proposed by Schuster (*Phil Mag.*, Oct. 1924). When monochromatic light is reflected by or transmitted through two parallel plates in succession, a superposition of the Haidinger ring-systems due to the two plates is obtained. When non-homogeneous light is used, the Haidinger rings disappear and also the superposition pattern, except in the special case of the differential system of the first order for two plates of equal thickness. A simple geometrical explanation is thus forthcoming why Brewster's bands can be observed even in non-homogeneous light with thick plates in this case.—T. Smith: Lagrange's theorem and stationary functions. Lagrange's theorem for several variables is expressed in a concise notation and used to evaluate a function which is stationary for small changes in each of its variables.—W. G. Collins: Some new instruments for recording rapidly varying phenomena. In these instruments a fine stylus terminating in a highly polished spherical surface of small radius rests on a travelling strip of transparent celluloid. A record of the movement of the part of the instrument to which the stylus is fixed is obtained by the permanent deformation of the surface of the celluloid by the stylus. As this deformation is produced by very slight pressure and no material is removed from the celluloid, the energy required to produce the record is very small. Only a comparatively small amount of celluloid film is required, and the record is immediately available for examination by optical methods.

ROME.

Royal Academy of the Lincei: Communications received during the vacation.—U. Cisotti: Properties of functions of complex variables on any surface.—Leonida Tonelli: Convergency of Fourier's series.—Mineo Chini: Determination of the geodetics of certain surfaces.—Luigi Fantappiè: Resolution of a class of integral equations of the first species with constant limits.—Orazio Lazzarino: Conditions of existence of Volterra's reciprocity theorem.—Stefan Mazurkiewicz: Functions satisfying a generalised Lipschitz condition.—Alfredo Sabbatini: Integral quadratic equations with variable limits.—E. Fermi and F. Rasetti: Effect of an alternating magnetic field on the polarisation of resonance light.—Felice Garelli: Contribution to the cryoscopy of solutions of gases in various solvents.—Antonio Pieroni: Certain derivatives of pyridine.—Luigi Rolla and Giorgio Piccardi: Chemical statics of electronic phenomena. The qualitative and quantitative application to ionisation phenomena of the law of mass action and of laws derived therefrom is demonstrated, and a method is developed for the calculation of the potential of ionisation.—Maria De-Angelis: New observations on dachauardite. The results of crystallographic measurements of well-formed crystals are given.—C. Jucci: The third generation of crosses between silkworms of three or of four mutations. Is the "mutation number" a unitary Mendelian character?—G. Bergami: Influence of the embryonal trephones on the cicatrization of wounds.—Vincenzo Rivera: Cure of certain vegetable tumours by means of X-rays. Cultures of *Bacillus tumefaciens* on peptone-agar are not affected by exposure to X-rays, whereas the tumours produced by this organism on *Ricinus*

communis or *Pelargonium zonale* are arrested and destroyed by the rays, the plants afterwards exhibiting normal development.

Diary of Societies.

SATURDAY, OCTOBER 31.

BRITISH ASSOCIATION OF CHEMISTS (Annual General Meeting) (at Midland Hotel, Manchester), at 8.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Associates and Students' Section) (Annual General Meeting) (at Newcastle-upon-Tyne), at 8.—H. P. Mould: Modernisation of Old Collieries.

MONDAY, NOVEMBER 2

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Mr. Shattock: Demonstration of Specimens in the Museum of some Bone Tumours.

ROYAL INSTITUTION, at 8.—General Meeting

SOCIETY OF ENGINEERS (at Geological Society), at 8.30.—G. O. Case: The Influence of Aggregates on the Strength and Properties of Concrete.

INSTITUTE OF ELECTRICAL ENGINEERS (Western Centre) (at Bristol), at 6.—J. W. Beauchamp: Domestic Electrification (Lecture).

INSTITUTE OF ELECTRICAL ENGINEERS (Mersey and North Wales (Liverpool) Centre) (at University, Liverpool), at 7.—A. E. Malpas: Chairman's Address.

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—O. S. Garland: Taking Stock.

TUESDAY, NOVEMBER 3

LEEDS PHILOSOPHICAL AND LITERARY SOCIETY (in Philosophical Hall, Leeds), at 5.—Sectional Scientific Meeting.

MINERALOGICAL SOCIETY (Anniversary Meeting) (at Geological Society), at 8.30.—G. S. Garnett: The Dissociation of Dolomite.—B. J. Tully: A New Refractometer.—G. T. Prior: (a) The Manganese Iron of Vaulbuit Farm, Frieska District, Cape Province; (b) Meteoric Stone of Witkipp, Carolina District, Transvaal.

ZOOLOGICAL SOCIETY OF LONDON, at 8.30.—Dr. H. H. Scott: Some Congenital Malformations of the Kidney in Reptiles, Birds, and Mammals.—Dr. F. P. Stowell: Physical and Chemical Conditions in the Sea Water of the Zoological Society's Aquarium—a Comparison

with the Water of the Open Sea.—A. Loveridge: A Mite Pocket in the Gecko *Gymnodactylus laudaranus* Stoliczka.—H. C. Abraham: A Marine Spider of the Family Attidae.—Major S. S. Flower: Contributions to our Knowledge of the Duration of Life in Vertebrate Animals. IV. Birds.

INSTITUTION OF CIVIL ENGINEERS, at 6.—Sir William Henry Ellis: Address and presentation of Medals.

ROYAL AERONAUTICAL SOCIETY (jointly with the Institution of Automobile Engineers) (at Royal Society of Arts), at 7.—Wing Commr. T. R. Cave-Browne-Cave: The Evaporative Cooling of Aero Engines and Condensation of their Exhaust Gas.

INSTITUTE OF METALS (Birmingham Section) (at Chamber of Commerce, Birmingham), at 7.—W. C. Gray and R. E. Ansell: Some Notes on the Properties of Nickel-Silver.

SOCIETY OF CHEMICAL INDUSTRY (Birmingham and Midland Section) (in Birmingham University), at 7.15.—The Behaviour of Sulphur Dioxide in Acid Solutions.—Dr W. Wardlaw: The Oxidising and Reducing Action of Sulphur Dioxide on Solutions of Metallic Salts.—S. R. Carter: Some Physico-chemical and Electro-chemical Aspects of Sulphur Dioxide as an Oxidising Agent.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (at Technical College, Cardiff), at 7.30.—F. J. Dyer: Vitamins.

INSTITUTE OF CHEMISTRY (Edinburgh and East of Scotland Section) (Annual General Meeting) (at North British Station Hotel, Edinburgh), at 7.30.—At 8 (jointly with Society of Chemical Industry, Edinburgh and East of Scotland Section)—Dr J. P. Tocher: Inaugural Address.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at Midland Hotel, Manchester), at 7.30.—A. G. Ellis: Chairman's Address.

INSTITUTE OF METALS (North-East Coast Local Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—Dr J. A. Smythe: Methods and Uses of Metallography.

RÖNTGEN SOCIETY (at British Institute of Radiology), at 8.15.—Dr. F. W. Aston: Atoms and X-rays (Presidential Address).

WEDNESDAY, NOVEMBER 4.

INSTITUTION OF MINING ENGINEERS (Annual General Meeting) (at Institution of Mechanical Engineers), at 11 A.M.—H. B. Mitton: Sinking of a Colliery in the East Nottinghamshire Coalfield.—Prof. H. Louis: A Novel Point in Mineral Valuation.—A. E. Mavrogordato: Miners' Phthisis, Past and Present, on the Witwatersrand, and Methods of Dust Control.—Dr H. S. Hele-Shaw and T. E. Beacham: A New Form of Air-Compressor.—Dr J. S. Haldane: Thermal Efficiency and Effectiveness of Heat-Engines.

GEOLOGICAL SOCIETY OF LONDON, at 6.30.—N. E. Odell: Preliminary Notes on the Geology of the Eastern Parts of Central Spitzbergen, with special reference to the Problem of the Hecla Hook Formation.—Dr K. S. Sandford: The Geology of North-East Land (Spitzbergen).

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—Major B. Binyon: Chairman's Inaugural Address.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (Newcastle-upon-Tyne), at 7.—H. E. Skinner: The Design of Cable Ships.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at Caxton Hall, Westminster), at 7.—J. J. Lassen: The Modern Development of Combustion Recording.

SOCIETY OF CHEMICAL INDUSTRY (Nottingham Section) (at University College, Nottingham), at 7.15.—S. R. Trotman, Dr E. R. Trotman, and R. W. Sutton: An Investigation of the Nature of Wool Protein.—S. R. Trotman and H. S. Bell: The Sulphur Content of Wool.

ROYAL MICROSCOPICAL SOCIETY (Biological Section), at 7.30.

INSTITUTION OF AUTOMOBILE ENGINEERS (Derby Graduates Section) (at Cavendish Café, Derby), at 7.30.—W. B. Flint: The Motor Omnibus as a Means of Transport.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—G. D. Elsdon and P. Smith: The Determination of Palm Kernel Oil and Butter in Margarine.—Dr C. Newcomb: The Determination of Alcohol and Ethyl Chloride in Chloroform.—H. Atkinson: The Volumetric Determination of Soluble Sulphates by means of Barium Chloride and Potassium Stearate.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

ROYAL SOCIETY OF ARTS, at 8.30.—Sir Thomas H. Holland: The Organisation of Scientific Research throughout the Empire (Inaugural Address).

THURSDAY, NOVEMBER 5.

ROYAL SOCIETY, at 4.30.—L. Ballif, J. F. Fulton, and E. G. T. Liddell: Observations on Spinal and Decerebrate Knee-Jerks with special reference to their Inhibition by Single Break-Shocks.—K. Furusawa: (a) Muscular Exercise, Lactic Acid, and the Supply and Utilisation of Oxygen. Part XIII. The Gaseous Exchanges of Restricted Muscular Exercise in Man; (b) A Spirometer Method of studying continuously the Gaseous Metabolism of Man during and after Exercise.—D. T. Harris: The Effect of Light on the Osculation.—To be read in title only.—Prof. A. V. Hill: The Surface Tension Theory of Muscular Contraction.—J. F. Fulton and E. G. T. Liddell: Electrical Responses of Extensor Muscles during Postural (Myotatic) Contraction.—L. N. Katz: On the supposed Pluri-segmental Innervation of Muscle Fibres.—L. N. Katz and C. N. H. Long: Lactic Acid in Mammalian Cardiac Muscle. Part I. The Stimulation Maximum.—H. J. G. Hines, L. N. Katz, and C. N. H. Long: Lactic Acid in Mammalian Cardiac Muscle. Part II. The Rigor Mortis Maximum and the Normal Glycogen Content.—Phyllis Kerridge, L. N. Katz, and C. N. H. Long: Lactic Acid in Mammalian Cardiac Muscle. Part III. Changes in Hydrogen Ion Concentration.—W. E. Garner: The Mechanism of Muscular Contraction.—R. W. Riding and Prof. E. C. C. Baly: The Occurrence of Helium and Neon in Vacuum Tubes.—Prof. O. W. Richardson: Structure in the Secondary Hydrogen Spectrum. III.—Prof. T. R. Merton and J. G. Pilley: On the Excitation of the Band Spectrum of Helium.—H. Hartley and J. E. Frazer: The Conductivity of Univalent Salts in Methyl Alcohol at 25°C.—C. S. Beals: The Arc Spectrum of Palladium. Its Zeeman Effect and Spectral Type.—N. Ahmad: Further Experiments on the Absorption and Scattering of γ -Rays.—R. A. R. Tricker: A Determination of the Variation of the Mass of the Electron with

Velocity, using Homogeneous β -Rays. Preliminary Results.—E. H. Boomer: Experiments on the Chemical Activity of Helium.—R. M. Wilmotte: On the Construction of a Standard High Frequency Inductive Resistance and its Measurement by a Thermal Method.—R. B. Brode: The Absorption Coefficient for Slow Electrons in the Vapours of Mercury, Cadmium, and Zinc.—P. Kapitza and H. W. B. Skinner: The Zeeman Effect in Strong Magnetic Fields.—F. R. Weston: The Flame Spectra of Carbon Monoxide and Water Gas. Part II.—H. S. Hirst and Dr E. K. Rideal: The Thermal Decomposition of Nitrogen Pentoxide at Low Pressures.—R. W. Gurney: The Number of Particles in the Beta-Ray Spectra of Radium B and Radium C.

LINNEAN SOCIETY OF LONDON, at 5.—M. Maxwell: The Home of the Eastern Gorilla.—Miss E. Bolton: Validity of Certain Species in Neoptera Brongni.—Dr H. S. Holden and S. H. Clarke: On the Seeding Structure of *Tilia europaea* L.

ROYAL SOCIETY OF MEDICINE, at 5.—Dr P. Watson-Williams: The Toll of Chronic Nasal Focal Sepsis on Body and Mind (Semon Lecture).

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr E. Bramwell: The Myopathies (Bradshaw Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS, at 5.—P. Dunsheath: Dielectric Problems in High-Voltage Cables.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir John A. F. Aspinall: Some Railway Notes Old and New (Thomas Hawksley Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (Joint Meeting of Birmingham and Coventry Graduates) (at Broadgate Cafe, Coventry) at 7.15.

CHEMICAL SOCIETY, at 8.—O. Silberad: Further Studies on a New Chlorinating Agent Preparation of Polychlor Derivatives of Tolene.

INSTITUTION OF MECHANICAL ENGINEERS (Glasgow Section).—A. B. Smith: Some Problems on the Application of Lubricating Oils to Machinery.

INSTITUTION OF MECHANICAL ENGINEERS (Manchester Section).—H. N. Gresley: The Three-Cylinder High-Pressure Locomotive.

FRIDAY, NOVEMBER 6.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION (at 11 Chandos Street, W.), at 4.45.—Dr A. I. Simey: The Prophylaxis of Common Colds.

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—Prof. J. Proudman, J. H. Powell, and others: Tides in Narrow Seas (Chairman, Dr H. Lamb).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Exhibition of Microscopical Preparations made from Recent Cases of Intestinal Stasis.

SOCIETY OF CHEMICAL INDUSTRY (Manchester Section) (jointly with the Manchester Sections of the Institute of Chemistry and the Society of Dyers and Colourists, also the Manchester Literary and Philosophical Society) (at 16 St. Mary's Parsonage, Manchester), at 7.—Sir William H. Bragg: Long Chain Molecules.

PHOTOMICROGRAPHIC SOCIETY (at 4 Fetter Lane), at 7.—Demonstration of the Agfa Colour Plate.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—W. H. Simmons: Flow Meters.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Newcastle-upon-Tyne), at 7.30.—F. D. Verrill: Shipyard Pneumatic Plant and Pneumatic Riveting.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—Annual Convocation.

PHILOLOGICAL SOCIETY (at University College)

SATURDAY, NOVEMBER 7.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.), at 3.—G. W. Young: The Yellowstone Park, U.S.A. (Lecture).

PUBLIC LECTURES.

SATURDAY, OCTOBER 31.

HORNIMAN MUSEUM (Forest Hill), at 9.30.—C. D. Forde: Stone-Age Man in Brittany.

MONDAY, NOVEMBER 2.

KING'S COLLEGE, at 5.30.—C. J. Gadd: The Science of Divination.—R. J. Bartlett: Psychology and Advertising.

TUESDAY, NOVEMBER 3.

KING'S COLLEGE, at 5.30.—Miss Hilda D. Oakley: The Philosophy of Aristotle. (Succeeding Lectures on November 10, 17, 24, and December 1.)

UNIVERSITY COLLEGE, at 5.30.—P. Flemming: Bloomsbury and the Bedford Estate: a Study in Street Names.

WEDNESDAY, NOVEMBER 4.

UNIVERSITY COLLEGE, at 5.30.—Prof. W. M. Calder: The Early Christian Inscriptions of Asia Minor. (Succeeding Lectures on November 5 and 6.)

THURSDAY, NOVEMBER 5.

BEDFORD COLLEGE FOR WOMEN, at 5.15.—W. G. Constable: English Medieval Painting.

KING'S COLLEGE, at 5.30.—Prof. Winifred Cullis: The Influence of the Home in Social Hygiene.

CHELSEA POLYTECHNIC, at 8.—Prof. H. C. H. Carpenter: Metal Crystals ("Armourers and Brasiers' Company" Lectures). (Succeeding Lectures on November 12, 19, and 26.)

FRIDAY, NOVEMBER 6.

KING'S COLLEGE, at 5.30.—Prof. J. S. Huxley: Science and Culture.

UNIVERSITY COLLEGE, at 8.—Prof. G. Dawes Hicks: Contemporary English Philosophy. (Succeeding Lectures on November 13, 20, 27, December 4 and 11.)

SATURDAY, NOVEMBER 7.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—R. A. Smith: Aspects of Roman London. I.

SATURDAY, NOVEMBER 7, 1925.

The Coal Crisis.

IT would appear as though the British public had been awakened only quite recently to the fact that the coal industry of Great Britain, upon the well-being of which the very existence of the nation depends, is in a very critical condition; needless to say, those engaged in the industry have long been well aware of it. With the general realisation of the fact by the public at large, has come a flood of suggested remedies of all kinds, most of them from people outside the industry. Thus quite recently the Sociological Society has been discussing the subject in a series of papers, but it cannot be said that anything of value has emerged from that discussion. Most sensible persons are wise enough in cases of serious illness to call in a properly trained medical practitioner, who understands the nature and causes of diseases, rather than trust to the ministrations of laymen, however intelligent or however well meaning. The sociologists have done what people in the latter category are only too apt to do; they have suggested palliatives directed to the symptoms, but not one of them has even recognised the actual cause of the disease.

Something of the same kind may be said of other suggestions that are being persistently obtruded upon the public notice, none of which is being put forward more insistently than low-temperature carbonisation. Unfortunately, in many instances the advice, so far as this process is concerned, is not wholly disinterested; the serious needs of the situation are being exploited for propaganda purposes, particularly by those who have already invested money in one or other of the low-temperature carbonisation processes. Apart, however, from this aspect of the subject, careful consideration will show that this or any other method of utilising the coal when obtained cannot possibly touch the root of the evil. If it were granted that low-temperature carbonisation could do all that its most zealous advocates claim for it—a hypothesis which is unfortunately far enough removed from actual fact—no such process could bring any real help to the coal industry.

It is claimed that by the substitution of low-temperature coke for raw coal in our domestic fireplaces our cities would be clear of smoke, and it is hinted that our domestic coal bill might even be decreased. It seems, however, to be overlooked that it is quite possible to attain these desirable objects by methods which, instead of being as doubtful as those of low-temperature carbonisation are to-day, have stood the test of generations. We have only to turn to Germany, where we can see that these excellent objects are attained by the simple system of substituting the closed stove for the open fireplace. Every one who has been on the continent knows how relatively clear the atmosphere of the large towns is, whilst statistics show that, whereas in

Great Britain we consume 15 cwt. of coal per head of population per annum for domestic purposes, the consumption in Germany is only 5 cwt.

Here, then, is a proved method for attaining what low-temperature carbonisation claims to be able to do, though it has never shown that it can do it. The only difficulty lies in persuading the Englishman to do away with his open fireplace with its no doubt wasteful but certainly cheerful flaming fire! The persistence with which we in Great Britain cling to this method of heating is usually put down to innate conservatism, but it is just possible that there may be a sounder reason. Along with the many advantages of our island home we have to take the corresponding drawback of our insular climate with its mists, grey skies and dull days, and it may quite well be that the desire for light as well as heat in our rooms may be unconsciously based upon a psychological or even upon a physiological need. Apart from this consideration, it is quite clear that the substitution of the stove for the open fireplace would have the same results here as it has in Germany, where the winter climate is more severe than it is with us.

As regards the application of low-temperature carbonisation to industrial uses, we in Great Britain could reap no benefit therefrom; even if it be assumed that by means of this process considerable economies in the utilisation of coal might be effected, this would cause injury rather than an advantage to the coal industry. It is quite impossible under modern conditions that any such improvement in the utilisation of coal can be confined to any one nation, and it is surely clear that a nation which, like our own, depends so largely upon the export of coal, can gain no advantage by any process which makes for a decreased consumption of fuel. Our main source of existence is by the export of coal directly or indirectly; not only do we sell coal abroad, but also, whenever we import Spanish iron ore and export rails, or import raw cotton and export piece goods, we are exporting coal indirectly. If we learn to manufacture these products with a smaller consumption of coal, our competitors abroad will do the same thing, and the more the consumption of coal is decreased per unit of goods produced, the smaller is the advantage which we reap from our coal supplies. It would, therefore, seem tolerably clear that, wherever the remedy for the present critical condition of the coal trade is to be found, it will not be in low-temperature carbonisation or in any similar process having for its object the more economical use of coal for industrial purposes.

Another remedy which is being urged insistently in certain quarters is the nationalisation of the coal industry. A Bill was promoted in Parliament some time ago purporting to nationalise the industry, though its real effect would have been syndicalisation rather than

nationalisation, or, in other words, the handing over of the collieries of the country to the Miners' Federation. We can only guess what the result would be from previous experiments along that line. It is now a good many years ago since the Yorkshire Miners' Federation made such an experiment by the purchase of Shirland Colliery—a colliery which had up to then been a profitable and prosperous concern. It would appear that in the first year after the purchase a small profit was made, in the next year a small loss, and in the third year a loss so considerable that the Federation was glad to dispose of its purchase at a loss.

The nationalisation of a highly speculative industry, as mining always must be, would appear to be foredoomed to failure. There are two examples of the nationalisation of coal-mining on any considerable scale; the first was in the Saar coalfield, the greater portion of which was, before the War, State-owned and State-worked by the Prussian Government, which was probably as well adapted as any Government in the world could be to obtain successful results; yet it was conclusively shown that Government-worked coal cost more to produce and yielded smaller profits than the coal produced by private enterprise in Westphalia. More recently we have the example of Soviet Russia before us, and it is possible to compare the results obtained in the Donetz Coal Basin in 1924 with those of 1913. Before the War the Russian coal-mines were self-supporting; in 1924 they received heavy subsidies from the State; in spite of this, wages were lower by 59.2 per cent. than they were in pre-War times, the output per man was 41.9 per cent. less than in pre-War times, and the total output was just under one-half of what it was in 1913. It would be difficult to show more clearly the disastrous effects of nationalisation upon the coal-mining industry.

It is frequently stated that the great development in the use of water power and of power generated from oil has seriously interfered with the demand for coal. On a subject like this it is impossible to obtain close figures, but approximate estimates would appear to show that the inroads made by these two sources of power have not as yet assumed very serious proportions. It may be roughly reckoned that the world's requirements of power are of the order of 160 million h.p. evolved continuously throughout the year; of this, according to the recent World Power Congress, the amount of the developed water power in the world supplies about 17 million h.p., whilst the power generated from oil is probably about 15 million h.p., so that these two together only produce about one-fifth of the world's power requirements, in addition to which we have the world's requirements of coal for metallurgical purposes, for which it can be replaced neither by oil nor by water power. On the other hand, it must be admitted that

the substitution of oil and water power for coal hits Great Britain particularly hard, because the former replaces the coal which we used to sell for bunkers, whilst the latter has in part replaced the coal which we used to sell to continental railways. In respect of the latter, however, we have ourselves largely to blame. The reason why some continental countries have developed hydro-electric schemes and electrified their railways is not because they hope to effect any very great savings in running costs in this way, but, as one of them put it, because they now have a source of power which will not go on strike.

It can be said with confidence that none of the remedies above mentioned, nor the many others urged upon the public mind, touch the real root of the trouble, but that everybody who has studied the economics of the coal industry would be found to be unanimous as to where the real trouble lies. The injury to our export trade due to continued threats of strikes is a subsidiary cause of our difficulties, but the main cause lies in the fact that our coal costs too much in wages; economies in other departments of the industry can no doubt be effected, but they must necessarily be insignificant compared to economies in wages, seeing that wages form something like three-fourths of the cost of producing coal. This statement does not mean that the wages per day of the coal-miner should be decreased (it may perhaps even mean exactly the opposite), but what it emphatically does mean is that there are more men engaged in the coal industry to-day than that industry is capable of supporting. This statement is particularly true of the off-hand men, the proportion of whom to hewers has increased enormously since pre-War days owing to a variety of causes, mainly perhaps to the seven hours Act.

Whilst the cause of our difficulties in the coal trade is thus tolerably well known, the means of remedying it are by no means so obvious, and it is to be sincerely hoped that the Coal Commission now sitting will find the proper remedy to apply. That there must be a remedy cannot be doubted, and that it could be produced if everybody interested were determined to find and apply it seems more than probable. The British coal industry has been through serious crises before now, and has survived them; the main difference between the present position and previous ones is that on all previous occasions everybody in the coal industry was labouring whole-heartedly towards the restoration of the industry, whereas to-day there is a party within the industry the main object of which appears to be to achieve its destruction. It is this tendency above all others which the Coal Commission will have to find means to combat, if it is to save the coal industry, and with it the nation, from ultimate ruin.

HENRY LOUIS

- (4) *Experiments in Genetics*. By Dr. Charles Chamberlain Hurst. Pp. xxiv+578. (Cambridge: At the University Press, 1925.) 50s. net.

SINCE the rediscovery of Mendel's now famous paper led to the creation of a science of genetics, there has been a steady flow of treatises dealing with this branch of biology, and it is not without interest to mark how the motives that have prompted the study of this science have been reflected in the stream of books that treat of it. The man of science, as was natural, was first in the field, partly in his delight over the workings of a beautiful new tool for the shaping of thought, partly because he was spurred on by the self-imposed duty of co-ordinating the new knowledge, and of suggesting the most promising lines of further advance. It is to impulses of this sort that we owe the existence of such books as those earlier ones of Bateson and of Baur, and the more recent ones of Morgan and his colleagues, fresh with the joy of discovery and recking little of possible applications. Then, as genetics makes good and is pushed into the academic curriculum, comes the demand for the student's text-book, less critical and more dogmatic, generally written by one of greater experience in teaching than in research. Later, as the significance of the science dawns upon the practical breeder and his immediate advisers, comes the output of books in which the dominant motive is the application of genetical discovery for purposes of ultimate commercial gain.

Such books, as might be expected, make their appearance more frequently in the United States than in Great Britain. For the genetical worker over there is generally supported by State funds, and naturally feels called upon to satisfy the clamour of democracy that it is getting its money's worth. Dr. Jones's book (1) on "Genetics in Plant and Animal Improvement" is a very favourable specimen of its class. It is clearly and interestingly written by one who has served a sound apprenticeship in research, and at the same time is

evidently in close touch and sympathy with the practical man. The author has a double qualification for writing the book he set out to write, and he has used those qualifications well. Especially good is his account of hybrid vigour and of the effects of inbreeding, as indeed might have been expected from one who is an acknowledged authority on these matters. Altogether the book should prove of high value to the considerable numbers of those whose teaching or practice concerns the betterment of domesticated animals and plants. At the same time, those whose interest in genetics is purely scientific will appreciate the freshness and sincerity of the author's account, and should gain not a little of value from the volume.

Though Dr. Jones deals ostensibly with the improvement of animals as well as of plants, it is chiefly from the latter that his illustrations are taken. Indeed, when dealing with animals he is apt at times to be misleading. Thus he points out justly that a population of self-fertilised plants, no matter how heterozygous to start with, tends with each generation to become more and more a collection of homozygous individuals—as was argued long ago by Mendel himself. But he then goes on to suggest that if a herd of Shorthorn cattle consisting of reds, whites and roans, were inbred, it would come to consist of reds and whites only (p. 333). The paragraph is puzzling, for surely Dr. Jones cannot believe that Shorthorns are self-fertilised! Possibly he is conscious of limited experience in animal genetics, since in his preface he suggests that his book should be supplemented by Prof. Winters' book (2) on "Animal Breeding," which is published in the same series. This is a pity, because Prof. Winters' book is about as poor a production as Dr. Jones's is excellent.

Prof. Winters has quite failed to grasp the significance of modern genetical discovery. He still talks about three distinct types of inheritance, Mendelian, blending, and prepotent; he refers to Galton's law of ancestral heredity as "one of the greatest, if not the greatest, of the practical contributions of biology to animal breeding"; and he attempts to measure the relationship of animals in terms of "blood," as they used to do before the science of genetics was invented. With these notions as a foundation, it can be understood that when the author comes to discuss such topics as inbreeding, crossbreeding, and selection, he is neither clear nor stimulating. For the rest, the book is of the "scissors and paste" type, lacking that unity of presentation which comes of sound and critical thinking.

(3) It is a relief to turn from it to Dr. Crew's "Animal Genetics." In writing this book Dr. Crew, a scientific worker, has his eye on the practical breeder most of the time. He wishes to enlist his sympathies in the direction of mutual co-operation which shall

be helpful to both. He fully realises the impertinence of suggesting that the breeders of such stock as grace the show-yards of Great Britain do not know their business, and that it is for a geneticist to put them right. Nevertheless, he is aware of the mistakes that do not figure in the show-yard, and he feels that even in the light of present knowledge some of these could be avoided. With fuller knowledge would come greater certainty in getting the right animal; but the acquisition of that knowledge means the co-operation of the breeder, and the first step is to stimulate his interest. So Dr. Crew has written his book "in order to provide the breeder with a brief account of what has been and of what is being done by the geneticist," and it says something for the progress of research in animal breeding that he has been able to give a clear account of the process of heredity in its widest sense without having recourse to illustrations from the plant world.

Dr. Crew's book falls roughly into three parts, dealing respectively with the general mechanism of heredity, with the peculiar problems associated with sex, and with various special topics, such as prepotency, inbreeding, selection, sterility, etc. As might be expected, Dr. Crew is at his best in the part relating to the special problems of sex, such as are conveyed by the terms hermaphroditism, sex-reversal, intersexes, and the like. We do not know of any better general account of these phenomena. The workmanship is sound throughout, the material thoroughly up-to-date, and the book conveys the impression of having been written by a man who knows what he wants to say and goes straight to the point. The author has managed to pack an astonishing amount of stuff into a relatively small space, and this condensation does not always make too easy reading. However, the matter is always clear, though there are places where the reader must be prepared to make an extra effort. It can be safely said that there is no better book on animal genetics, and its excellent bibliography should prove invaluable alike to the student and the teacher. Whether it will greatly influence the present generation of stock-breeders is very doubtful, but if it succeeds in capturing the imagination of the younger generation it will have gone far towards achieving Dr. Crew's primary object.

(4) To pass from Dr. Crew's book to the stately volume wherein Dr. Hurst has enshrined his "Experiments in Genetics" is to pass from the atmosphere of a busy modern city to that of a quiet country town. In it Dr. Hurst has collected together and reprinted a series of papers dating back to the 'nineties of last century. His choice of material for experiment shows remarkable versatility, including, as it does, orchids, rabbits, poultry, peas, horses, pigeons, and snapdragons,

while some of the most interesting papers deal with original data on the inheritance of eye colour, musical ability, and other human characteristics. The reader will find here little or nothing concerning the later developments of Mendelism, whether of linkage, or non-disjunction, or lethal factors, yet those papers which deal with animals will probably appeal much more to the practical breeder than Dr. Crew's more scholarly account. Dr. Hurst makes heredity look very simple, perhaps too simple for the critical mind, and he presents his facts in a manner that can be readily grasped by the average untrained intelligence. Having started, too, as a practical horticulturist, he instinctively keeps the breeder's point of view in mind, and he has an eye for telling examples. In so far as science goes, the breeder must be taught to walk before he can run, and we believe that a stimulating elementary booklet on animal breeding could be culled from the contents of this rather ponderous volume. In any event, Dr. Hurst has conferred a boon on the geneticist who wishes to consult him by bringing together papers scattered in a number of different journals, some of which are not always easy to obtain.

THERE are vogues in scientific literature as in other activities. There is evidence at the moment of an increasing interest both in the scientific past and in speculations as to what the future holds for us. As to the former, the influence of a new spirit of humanism in scientific teaching has brought into being on the theoretical side a History of Science Society in the United States, the membership of which extends to most European countries; and on the applied side we now have in England a flourishing, if young, Newcomen Society with a growing American branch. The movement, too, has spread to the universities. London has its new M.Sc. degree in the history and method of science, whilst many other universities, both in Europe and the United States, include various courses of lectures by eminent scholars upon

different phases of the history of science. Naturally this new spirit has found its expression in literature. For some years now there has appeared a succession of books dealing with special and general historical studies in science. The specialist, the general reader, and the schoolboy are all being catered for.

What is the significance of this new tendency? The War had undoubtedly something to do with it, though it was not responsible for its initiation. The pioneers of the new movement were certainly pleading before 1914 for the breaking down of the barriers between science and the humanities. The intensive part played by applied science in the War has, however, brought widespread attention to many new problems. Whither are we tending? What has the future in store for us? The pace of scientific research is so rapid, inventions carrying with them revolutionary possibilities in our everyday lives crowd in on us with such persistence, that it is but natural to find the intellectual public a little bewildered and vaguely uneasy as to what lies ahead. It is still a vivid memory that eight million lives were lost between 1914 and 1918. Nor can the aftermath of the economical and political upset of values, and the new difficulties of life and livelihood resulting therefrom, do other than accentuate this natural tendency to speculation as to what is to confront civilisation in the years to come. Here again we meet problems that have found an outlet in a flood of literature of which the "To-day and To-morrow" series issued by Messrs. Kegan Paul is an example.

Very properly, the studies of "yesterday" and of "to-morrow" are related. We are past the stage when history was regarded as a mere enumeration of facts and dates. The problems of the future are the better considered in the light of the lessons of the past. This is particularly true of the history of science, in view of the inevitable bearing scientific progress must have, not only upon the methods of mechanical routine of the future as a result of the multiplicity of inventions yet to come, but also upon the more disciplined and ordered ways of thinking out social problems of peace and war on the part of the populace in general.

It is appropriate, therefore, that of the four volumes before us, two deal with the past and two with the future.

(1) Dr. Druce has undertaken a formidable task in essaying even a brief history of science within the limits of 140 pages. Such a work can only be successful if it frankly confines itself to the broader movements of scientific history at the expense of any details that are not relevant to the main purpose. Proportion is everything. From this point of view, Dr. Druce's

book shows many weaknesses. The influence of Greek science for many centuries was essentially due to the teachings of Plato, Aristotle, and Ptolemy, and it would have been better to enlarge upon these influences at the expense of the many other lesser Greek philosophers who in fact find prominence in this book. Ptolemy is dismissed with six lines on page 18, whilst on page 40 his theory is merely referred to as having involved "cumbersome assumptions." The chapter on Roman science is also unsatisfactory. It is largely confined to the Julian Calendar, to Galen, and to the metallurgical sections of Pliny. The wider aspects of contrast between the Greek and Roman attitude towards science are ignored, whilst the influence of Seneca, de Varro, and Vitruvius is not even mentioned. The best portions of the book, probably because the author is a chemist, are those dealing with the growth of chemical science. The book is well indexed and a bibliography is added.

(2) Mr. Cochrane's is a book of an entirely different kind. Its title is somewhat misleading in that it is not so much a connected narrative as a series of biographies of men of science. It is intended for school-boys and girls and is very interestingly written. Part I. deals with the ancients, Part II with physicists, and Part III. with chemists. As a stimulant to more serious study it should serve its purpose well.

(3) Of the remaining books, "Paris" is a thoughtful essay on the future of war. Capt Liddell Hart attacks the current theory (a transmission to modern militarists of the teachings of Napoleon and Clausewitz, and involving in its application the dogma of the "nation in arms") that the national goal in war can be attained only by mass destruction. Such a theory carries its own penalties. "Of what use," asks the author, "is decisive victory in battle if we bleed to death as a result of it?" He states that the true aim of a nation at war is "to subdue the enemy's will to resist with the least possible human and economic loss to itself." From this point of view, Capt Hart surveys the future rôles of air, land, and sea forces in relation to civilian and economic considerations as much as to the enemy's military forces. The author's point of view is well summarised in his closing lines. "Weapons, target, and aim will alike be civil. The future of war lies in the future of peace."

(4) Finally, we have Mr. Low's very interesting vision of the future in the light of scientific progress. It is indeed an encyclopædic vision. Within 200 pages we are hurried breathlessly through the whole gamut of the activities, habits, comforts, practices, and modes of thought of the human being and what is to become of them all. We have referred to the work as an encyclopædic vision; we might almost have called it

a catalogue of future possibilities. Sound and silence, artificial light, planet communication, transport, wireless, sport, clothes, marriage and love, warfare, politics, art, crime, the occult—all these are here, and much more. Mr. Low may or may not be right in many of his forecasts, but neither to the man of science nor to the man in the street is it sufficient to tell the "what" of the future and to omit the "how" and the "why."

I. B. H

Devolution in the Modern State.

A Grammar of Politics. By Harold J. Laski. Pp 672 (London: George Allen and Unwin, Ltd., 1925) 18s. net.

MR. LASKI has produced what is certainly the most comprehensive book on political theory that has appeared since the War. Written with all the knowledge and more than the authority displayed in Mr. Laski's earlier works, it is at once more human and more entertaining. Essentially moderate both in statement and suggestion, it insists on the difficulty of modern politics and scorns short cuts to the millennium as cloaks to disguise poverty of thought and devices to serve the ends of rhetoric; yet it succeeds nevertheless in conveying an urgent sense of the gravity of the situation.

A large part of the book is devoted to showing how political institutions such as the British Parliament are used as the instruments of the classes that have successively dominated them. A hundred years ago in England the landed class was dominant, and legislation reflected its interests; in the middle of the century the new property class, born of the industrial revolution, succeeded to power, and the doctrine of *laissez faire* with its corollary of unrestricted competition in the economic, and refusal of State action in the political field, gave countenance and support to the vast acquisitions of private wealth. Mr. Laski is particularly severe in his criticism of the social effects of the dominance of this class, effects from which we are still suffering:

"The commodities and services necessary to the life of the community are never so distributed as to relate to need or to produce, a result which maximises their social utility. We build picture palaces when we need houses. We spend on battleships what is wanted for schools;" and of the effect upon the governing class itself he writes. "Men may begin to acquire property to safeguard their lives from want, but they continue to acquire it because of the distinction which comes from its possession. . . . It enables them to attune the will of society to their own."

The phase of the propertied interests is, however, in Mr. Laski's view, passing away in its turn, and the

desire of the masses for a better standard of life, better houses and more education, though dimly and intermittently expressed, is beginning increasingly to set the direction of political activity. How far can the State secure the satisfaction of these demands? How far, in other words, is the popular remedy of Socialism adequate to the nation's needs?

Here Mr Laski grows cautious. Like so many modern writers, he has an almost temperamental hostility to the State, and is far from wishing to see men's lives regulated by an increasing measure of public control. Reacting strongly against the Hegelian conception, Mr. Laski regards the modern nation State as by no means a final form of organisation; it is just one of the number of groupings into which mankind happens to have arranged itself, and it is becoming a question how far this particular form of grouping is best adapted to the changing needs of men.

In the last resort Mr. Laski seems to regard the State as an organisation largely federal in character. It is a complex of different organisations formed to carry out special purposes, and whatever authority it possesses must be based upon and drawn from them. Sovereignty in the modern State should be neither absolute nor uniform; it should, on the contrary, be distributed among a number of different bodies, on the principle that the right to make decisions should be vested in the interests chiefly affected. This means

"making the mining industry a unit of administration in the same sense as Lancashire. It means the abandonment of the sovereign State, in the sense which equates the latter with society and gives it thereby the right to dictate to associations within society."

This plea for devolution is all to the good.

The chief defect of the modern State is its size. So vast is the stage upon which the drama of politics proceeds, so interwoven the complex strands which condition events, that the State assumes increasingly the aspect of a mechanism, while the procession of events gives countenance to a determinist attitude, if not to men's lives as individuals, at least to their affairs when taken in the mass. What happens in society seems less the result of human will and foresight, the embodiment of purpose and the effect of guidance, than the mechanical resultant of the interplay of forces the genesis of which escapes detection and the workings of which evade control. In such a society the individual feels helpless, he obtains the impression that he does not count, and that his will cannot be made to matter. From this sense of helplessness springs a political apathy, which tends to regard politics as a professional preserve with which the ordinary man has no concern, because its concern is so obviously not with him.

Hence arises the paradox that amid all the forms of democracy man is as helpless as he ever was; though the battle of freedom has been won in theory, it still remains to give it effect in practice. "We still need to know," as Mr. Laski puts it, "what working hypothesis it involves and what institutions can effectively embody its purpose."

The conclusion at which Mr. Laski arrives is that the way to revive man's interest in politics is by taking a smaller unit for governmental purposes wherever a smaller unit is practicable. Different units are practicable for different purposes. Mr. Laski, cautious as ever, is by no means a wholesale devolutionist. "It is practicable to allow a town to decide for itself whether it wants municipal electricity; it is not practicable to allow it to decide whether it wants an educational system." Subject to provisos of this character, functional devolution and territorial decentralisation are recommended, because they create a corporate sense of responsibility, train men in self-government, and confide "the administration of powers to those who will feel most directly the consequences of those powers."

This book is a profound—in some ways it is a great—work; at times witty, at others learned, at others expository, at others a little dull, it rises to a nobility of outlook and an eloquence in expression which distinguish it as perhaps the finest contribution to the political thought of our times since Mr. Graham Wallas wrote "The Great Society." C. E. M. JOAD.

Our Bookshelf

The Outline of History: a Plain History of Life and Mankind By H. G. Wells. New edition, fully revised (Complete in 24 fortnightly parts) Part 1. Pp. 32 Part 2. Pp. 33-64. (London: Cassell and Co., Ltd., 1925.) 1s 3d. net each part

MR WELLS's world history was first written in 1918-1919 and revised in 1920 and 1923. Even in the short period which has since elapsed, discoveries of new material have been made in almost every part of the world, and, whether by accident or by design, new evidence is being brought to light almost daily which bears upon the early history of man upon this globe. It is, therefore, no matter for surprise that Mr. Wells, in preparing the new edition of his "Outline of History," should have found it necessary not merely to recast, but to rewrite a considerable part of it, especially in the earlier sections. It is inevitable that a work of this kind should be at the mercy of any new discovery which may at any moment throw doubt on a conclusion or necessitate a change in point of view. Mr Wells has done his utmost to protect his readers from this danger by bringing his information fully up-to-date, and even so recent a discovery as that of the Galilean skull receives due mention.

The first two parts which have now been issued afford

an opportunity to test the quality of the work in its new form. They comprise from the beginnings of the earth down to Neolithic man in Europe, ending with an account of primitive trade. This, to many, will be the most interesting section of the whole work, as it deals with the earliest stages in the evolution of animal and human life and embraces so much that is new. It is inevitable that a writer of such strong individuality as Mr. Wells should at times run counter to accepted views; but he is always prepared to argue his case on good grounds. His dates for the late stages of the Palæolithic period on some views may appear too high, but this is of little moment beside the great advantage which his time charts and scales confer on the reader who is not an expert. To such a one they will be invaluable as an indication of perspective.

A special feature of this edition is the illustrations, which have been greatly increased in number and chosen with much discrimination and care.

Der Schadel des eiszeitlichen Menschen von Le Moustier in neuer Zusammensetzung. Von Dr. Hans Weinert. Pp. vi+54. (Berlin: Julius Springer, 1925.) 6-60 gold marks.

IN 1908 the skeleton of a young man of the Mousterian or Neanderthal race was discovered by Otto Hauser in the lower cave of Le Moustier, in the Dordogne, and it was eventually purchased by the Museum für Völkerkunde in Berlin. The specimen seems to have been disinterred without sufficient skill, and the skull was broken into many fragments. It was first studied by the late Prof. H. Klaatsch, who reconstructed the skull without much success. This reconstruction was improved in two later efforts in the Berlin Museum. A final attempt has now been made by Dr. Hans Weinert, in the light of the latest knowledge, and the result is described in detail in a small volume just published in Berlin. The work is beautifully illustrated with both photographs and diagrams, and includes an exhaustive revised table of measurements.

The new reconstruction of the facial bones seems to have been rendered difficult by the breaking of the edges of the fragments during previous efforts. Dr. Weinert, however, with the aid of Prof. W. Dieck, who arranged the dentition, has now produced a face in conformity with other known examples of Mousterian man. The lower jaw is wider than in the previous reconstructions, and all the contours now agree well with those of the other skulls. The Le Moustier individual, if he had survived to maturity, would doubtless have had a skull essentially identical with that of La Chapelle-aux-Saints. Dr. Weinert concludes that he was probably contemporary with the latter, and finds no evidence to support the view of Klaatsch that the one is of greater geological age than the other.

A. S. W.

The Anthocyanin Pigments of Plants. By Muriel Wheldale Onslow. Second edition. Pp. viii+314. (Cambridge: At the University Press, 1925.) 21s. net.

AFTER very favourable comments in these columns (vol. 99, p. 261, 1917), a good reception and nine years of support, the first edition is now replaced by a second containing all the admirable qualities of its

predecessor. The accumulated findings of investigators in this period are incorporated in its text, and its admirable bibliography in consequence includes more than 200 new references, carefully chosen and critically summarised, so as to avoid, on one hand, omitting useful publications, and on the other, to guard against undue increase in size. The general arrangement is unaltered, and the new contributions are mainly to be found in those chapters dealing with the chemistry and biochemistry of the subject and in those on genetics, these latter being extremely numerous, but many of them not of fundamental importance.

The new edition serves to emphasise the fact that, in spite of advances into the chemical constitution of many anthocyanins, we are by no means clear as to the reactions involved in their origin, or as to the relation between their chemistry and their Mendelian factors. If the book were to serve no useful purpose other than this, it would still have done enough to compensate for the labours involved in its preparation.

Brazil after a Century of Independence. By Herman G. James. Pp. xiv+587+8 plates+3 maps. (New York: The Macmillan Co., 1925.) 17s. net.

THERE was room for a comprehensive work on modern Brazil in spite of the many volumes on Latin America which have appeared in recent years. Mr. James has produced a well-balanced volume, appreciative but yet critical, and written from the point of view of the student and not the globe-trotter or financier. It contains much of scientific interest, and has a useful physiological introduction, which books of this nature too often lack. Special attention may be directed to the chapters on natural resources, agriculture, and transportation. In the chapter on population and vital statistics, we miss a discussion of the relative birth and death rates of the various immigrants and the adaptability of various races to the climatic and other conditions. No mention appears to be made of the Japanese, of whom there are now more than 25,000 in Brazil. The three maps are clear and useful, but scarcely adequate to a volume of this scope. The illustrations are few and of little interest.

L'Industrie des cyanures. Par P. Brun. (Encyclopédie scientifique: Bibliothèque des industries chimiques.) Pp. x+469. (Paris: Gaston Doin, 1925.) 20 francs.

THIS volume, which deals very fully with the various industries connected with cyanide production and utilisation, is divided into three sections: theoretical, industrial preparation, and finally, applications of the cyanides to various industries. The main section (2) is devoted to the extraction of the material from industrial residues and synthetic preparation.

A useful feature is the inclusion of lists of the patents and authors quoted in the text; its usefulness would have been still further increased if a reference had been given to the page on which they were described. It is unfortunate that the book is not provided with a suitable index. An interesting chapter is devoted to the toxicological effects of hydrocyanic acid and potassium cyanide and the researches on these poisons.

The volume is a useful addition to the literature of chemical industries.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.

The Production of Oysters (*O. edulis*) on English Beds in Relation to New Observations on Breeding Phenomena.

THE present shortage of oysters (*O. edulis*) on all English, and apparently most European, beds is a suitable occasion to press for improved methods of production. The depleted state of the beds can be ascribed to an unusual mortality in 1920 and 1921

FIG. 1.—Graphs showing the weekly percentages of oysters, with good shell-growth carrying embryos or larvae in relation to the moon's phases from the Truro oyster beds (Fal Estuary) in July-October 1925, indicating an irregular correlation between lunar periodicity and breeding phenomena.

The continuous line graph shows oysters carrying embryos of an age upwards to about two days.
The dotted line graph shows oysters carrying embryos mainly fully shelled or older than about two days.
The continuous curve shows the moon's phases from Admiralty Tide Table data.

and the comparatively low yield of spat since 1921 owing to the poor summers. The spat-fall for 1925 is as yet scarcely determinable in the ordinary course of practical work. It is probably accurate to state that the majority of the oysters living on English beds in 1924 and 1925 were spat (that is, settled from the free-swimming larvae) in 1921.

The chief method of catching—or rather obtaining—oysters in England is that of scattering clean shells

or laying tiles on the oyster beds in the early summer, at the time the earliest batches of larvae are judged ready to settle down from the free-swimming stage; in some localities the beds are also harrowed whereby buried shells may be turned over so that the soil can be washed off the recently embedded shells by the tidal current and a clean surface obtained in that way for the settling larvae. Harrowing is also said to improve the growth of the older oysters. The clean shells, or cultch, are generally put out in mid-June, but may not be put out until a few weeks later if the summer is a late one and the oysters thereby delayed in spawning. The principles on which cultch is laid are that the oyster is an early summer spawner, that early spat grow to a larger size than late ones, that spat settle in numbers only in the warmer weather (when the temperature of the water is about 64° F.), that the surface on which the oyster larvae can settle should be clean.

Some time ago the present writer pointed out that the oyster is a summer breeder (J. M. B. A., 1920) and was shown to breed from June until September on the River Yealm close to Plymouth Sound. In favourable (warm) summers, however, the period may extend from late May until October, during most of which time larvae are constantly present in—or rarely absent from—the sea, being emitted from the parent population in batches. The significance of this fact has not been grasped by oyster-producers. In a favourable summer, oyster larvae may be assumed to be present in the water all through the summer, therefore clean cultch may be expected to catch spat even if laid so late as August, or even in very warm years in September. During the past summer batches of 100 oysters with good shell-growth from the Fal Estuary have been examined weekly for the percentage of breeding individuals—amongst other characters—with the results shown in the accompanying graphs in Fig. 1.

The graph shows at once that the percentage of spawning individuals was almost as high in September as in July. Unfortunately the work this year was not begun in May. The rhythmical character of the breeding is clear from the graph, and there is undoubtedly a closer—but irregular—relation between spawning and the full moon than with the mere tidal influence of the moon, but this aspect of the problem will be treated more fully later.

It is clear, however, that the waters in the Fal Estuary must this year have borne an enormous amount of oyster larvae, since from July 1 until September

23 there was a weekly average of the oyster population with seven per cent. containing mature or nearly mature larvae ready to be shot or being shot into the water. There is every reason to believe that the breeding conditions on other beds were similar to those on the Fal, and yet oyster-producers rely for their catches on cultch laid about June. Indeed, on the public oyster beds in the Fal Estuary, the amount of cultch laid was almost negligible for the fine stretch of ground available, and it is probably true that oysters to the value of thousands of pounds have been lost to

that fishery for the years 1928–30 from this omission. Probably no particular body or individual is responsible for this omission, but there is no reason why it should recur.

During the course of other investigations, the writer has conducted definite experiments on catching late spat, which give point to the remarks made above. On August 4, 1923, clean shells were put into the sea—long after the normal cultch had been put out—and

caught spat which grew to a size of only $\frac{1}{8}$ to $\frac{1}{4}$ inch by October 22, but in July 1924 these tiny spat had grown to well-shaped brood oysters $\frac{3}{4}$ to more than one inch in length and depth, while a few Portuguese oysters were obtained in the same experiment with dimensions $1\frac{3}{4}$ by $1\frac{1}{4}$ inches in a period of eleven months. Definite experiments made in early August 1924 showed that oyster spat were still settling in the sea at that time. In July 1924 fresh clean shells amounting in number to 1373 in various experiments were put in the sea for the purpose of catching spat. Rather more than 50 per cent. of these shells caught one or more spat; one shell caught 10 spat, and shells with 3 to 6 were not uncommon, and it is probable that only a small percentage of these spat would have been caught on cultch laid earlier. In July this year these year-old young had attained a size up to $1\frac{1}{4}$ inches and a beautiful normal shape. Cultch can, therefore, be laid with profit late in the season even in a poor or normal summer, whereas in a long warm summer it is probable that the yield of spat might be increased two- or three-fold over and above the larger increase due to the warmer summer. In the warmer waters of the southern European beds, a late summer laying of cultch might often be as productive as an early summer laying and result in doubling the production of oysters.

In oyster production, as in many other cases, success is accumulative, for the addition of young oysters to the beds soon increases the amount of larvæ set free in the water, as the following observation proves. On July 21 this year, 100 young oysters from the River Blackwater in their third summer (*i.e.* aged mainly about two years), and of an average length and height of only 40 by 42 millimetres (1.57 to 1.65 inches), yielded 10 individuals with embryos or larvæ within the shells, and 10 ripe females ready to spawn. In these spawning young, however, the number of larvæ produced is relatively small compared with the number produced by larger oysters, comparative figures will be given later.

Until the artificial production of oysters is established on an economic basis, and it will be many years before this desirable end is attained—though the proof given above that oysters breed in quantity throughout the summer will enable experiments on spat-catching in tanks to be carried on over a much longer period than at present and perhaps hasten success—it is important that more attention should be paid to improved methods of catching oyster-spat in the sea. The laying of clean shell, shown above to be economically effective even late in the year, may not in itself be the best means of increasing the stock of young oysters, and the problem may easily be one in which the naturalist can be a real help to the oyster-fishery in general.

Acknowledgment is due to the Truro Corporation for supplying the oysters for the observations on spawning, to the Tollesbury and Mersea Native Oyster Co. for the many facilities afforded for experimental work on their excellent grounds, and to Prof. Awati for valuable assistance at Mersea during July.

Marine Biological Laboratory,
Plymouth, October 13.

J. H. ORTON.

Ethics of Birth-Control.

As a constant reader of NATURE I should be very grateful if you will allow me to make public one or two criticisms of the review by Prof. J. S. Huxley of "The Ethics of Birth-Control," published in the issue of September 26.

One of the greatest societies ever known upon our planet, the Catholic Church, has denounced artificial

birth-control as immoral, simply on the ground that it is against the natural law or our "human dignity." This surely is interesting from a purely scientific point of view, since the Catholic Church is composed of men of many nations, and is therefore more representative of human nature than the British "Special Committee of the National Council of Public Morals," the report of which is under discussion. I mention this in passing, in order to show that Canon Lyttelton is really representative of a strong and by no means negligible body of human opinion.

The reviewer objects to the use of the word "unnatural" as applied to birth-control. Moral theologians have adopted the use of the terms natural and unnatural to distinguish two kinds of vices. If an action is performed in the proper or natural way, but contrary to the moral law, as in fornication, it is said to be natural. If it is performed in a manner contrary to nature, as in masturbation or sodomy, it is said to be unnatural. Contraception is rather to be classed among the unnatural vices, because the natural purpose of the marriage act is deliberately frustrated.

The argument based on the use of food is constructed in the defiance of logic. The parallel between eating and the act of generation is perfectly legitimate, but leads logically to precisely the opposite conclusion. Eating is primarily intended to sustain life, and there is a natural pleasure in it, which may be quite legitimately enjoyed. The act of generation is primarily intended to bring forth life, and again there is a natural pleasure attached to it. The decadent Romans, who ate and drank merely for the pleasure of it and deliberately vomited that they might begin all over again, were indulging in an unnatural vice of gluttony; and no sane person would attempt to justify their worse than bestial conduct. How far do those fall short of a similar condemnation, who indulge in the pleasure of the marriage act and yet deliberately frustrate its primary purpose?

Lastly, the reviewer quite gratuitously criticises the Middle Ages. He says "The over-concern of the individual for the salvation of his own soul was a characteristic of the Middle Ages." Someone, a great while before the Middle Ages, had said "What shall it profit a man, if he gain the whole world and suffer the loss of his own soul?" It is interesting to find the Medieval Church so thoroughly Christian!

I apologise, Sir, for the length of this letter. But it seems only fair that so important a question should be seen in more than one light. If the illogical character of the reviewer's reasoning is not at once evident to his readers, his review must give the impression that contraception is necessarily approved by all scientists and reasonable men. This is far from being the case.

GREGORY SWANN, O.S.B.

Ampleforth Abbey, York.

October 16.

FATHER SWANN's letter deserves a reply. (1) The whole of his argument as to whether birth-control is natural or unnatural (I gather it is in either case a vice!) depends on the prior assumption that the *sole* "natural purpose of the marriage act" is procreation. There are, however, a large number of people who would deny this, and say that its natural purpose (or better function) is dual—not only procreation, but also the increase of marital love and joy.

The great point of fact is that there is, *increasingly* with increased infant welfare and increased pressure of population, a large disharmony between the frequency of the nuptial act required for a sufficient family—say three to five children—and that which

is a satisfaction, on the most restrained and moderate scale, of our "natural" normal and healthy instincts. I still maintain that it is impossible to say whether the production of a family or the reasonable satisfaction of the sexual instinct is more "natural," in that this term merely introduces confusion into the question. There still seems to linger in some quarters the idea that the sexual act is *per se* evil.

In any case, it appears to me to be very dangerous ground for a representative of the Catholic Church to denounce contraception as unnatural while the same Church sanctions what the average man would regard as equally or more unnatural, namely, *coitus reservatus*, as a way out of the difficulty. It also sanctions intercourse during the (so-called) "safe period," which also, if I understand Father Swann, he would call unnatural (provided it were really "safe").¹ In any case, as shown clearly by Dr. Stopes ("Wise Parenthood," p. 55; and "Contraception"), union during this period is for most women definitely "unnatural."

(2) I will not waste space with comment on Father Swann's criticism of my analogy from food, save to say that if we only ate in order to sustain life, the most modest dinner-party would be excessive. And that his remarks on the ancient Romans and the *vonitorium* are off the point. The moral need for restraint remains whether one practises artificial birth-control or no, and whether one enjoys one's dinner or no. To assume that contraception must mean excess is a mere insult to those who practise it.

(3) As to the individual's concern for salvation, I was merely attempting to show that it could be pushed to too great lengths, which is undoubted. The same authority quoted by Father Swann also made a remark to the effect that those who lost their life should find it. Those who are over-concerned about their individual souls do not "lose themselves" in this way.

J. S. HUXLEY.

October 21.

The Anti-trade Winds.

IN the article published in NATURE of July 18, p. 115, I am glad to see that Mr. L. C. W. Bonacina is in conformity—at least in a general sense—with my views upon the question of the anti-trades. I do not know the opinion of European meteorologists exactly in regard to the *fixity* of these currents; but if we examine books as those of Ferrel, Dove, Angot, etc., it seems that the existence of the anti-trades is a well-recognised fact. The evidence, however, is not clear; on the contrary, the facts seem to be against that theory. I find very much justified the remark of Sir Napier Shaw (Quarterly Journal of the Meteorological Society, January 1925) that he had "never been really able to prove the existence of an anti-trade over the region between anti-cyclones and the equator."

Do the south-west or westerly winds extend over the limits of the equator? I think they do not. Besides the observations of Bogota, those of Pasto in South Colombia (Lat. $1^{\circ} 31' N.$), at the height of 2595 metres, show that the high winds blow from east and south-east.

The directions of the dust of volcanoes are frequently said to prove the existence of the anti-trades. As I wrote in the U.S. *Monthly Weather Review*, December 1923, the volcanoes Cotopaxi at Quito and Colima in Mexico do not prove the existence of such winds.

I know that Mr. Bonacina refers to mean condi-

tions in the use of the terms *trade* and *anti-trade*. I do not see any objection in the use of the *trades*. They blow in the Atlantic quite constantly, but not so the anti-trades. My opinion is that the atmospheric circulation, as developed by Thompson, Ferrel, etc., is not in accord with observed conditions in tropical and equatorial countries.

S. SARASOLA, S.J.

Observatorio Nacional de San Bartolomé,
Bogotá, September 11.

FATHER SARASOLA's observations are certainly out of harmony with the older ideas about the general circulation of the atmosphere as due to Ferrel, Dove, and others, but these are not nowadays accepted as anything more than a rough approximation, and the observations, in fact, lend most valuable local support to more recent views, according to which over the equatorial limits of the north-east and south-east trades the average direction of the wind is respectively south-east and north-east, becoming south-west and north-west respectively above the polar margins of the trades. A scheme involving this disposition of the anti-trades was, as I indicated in the article in NATURE of July 18, put forth by Blair (*Monthly Weather Review*, 1916), and various upper air observations in different localities certainly support it. In the vicinity of the Cape Verde Islands, lat $16^{\circ} N.$, the "anti-trade" is, I believe, south-east, in conformity with the observations in Colombia, whereas in the vicinity of the Canary Islands in lat $28^{\circ} N.$ it becomes south-west. In a report of upper air observations at the Apia Observatory, Samoa ($14^{\circ} S.$), during 1923-24, the anti- or counter-trade is very definitely established above the south-east trade, its base being between the altitudes of three to five miles according to season, the direction being north-east below and changing through north to north-west above.

It may, therefore, be suggested that, corresponding to what happens over the south-east trade in Samoa, the south-westerly wind may yet, with further observations, be found in Colombia above the southeasterly wind found by Father Sarasola overlying the north-east trade—which south-westerly wind would gradually descend with increasing latitude towards the polar margin of the north-east trade. It must, further, not be forgotten that the northern trade system is much upset by the monsoons, being locally subverted in summer, and reinforced in winter, and if the north-east trade is variable locally as regards regularity and other features, it were only to be expected that the counter-trade would be so too. But I fail to see that there is any evidence for doubting the existence of the "anti-trades," at all events, in a statistical sense, and theory surely necessitates some kind of average counter-flow *away* from the equator to balance the statistical "trades" *towards* the equator.

Much of the difficulty which appears to exist about "trades," "anti-trades," "westerlies," and other *stereotyped* winds, as items in the general circulation of the atmosphere, undoubtedly turns upon the matter of definition. Any one who tries to frame an exact definition of a "trade," etc., to be applied to the actual currents of the atmosphere will soon discover that "trades," "anti-trades," and so forth, are really statistical abstractions, artificial categories, indispensable in enabling us to form a mental picture of the mean or average structure of the circulation, but a fatal snare the moment we lose sight of the fact that this statistical picture of the circulation represents not a fixed static system, but one in a perpetual state of perturbation—of distortion and subversion

¹ I quote from "The Morality of Birth Control," by 'A Priest of the Church of England,' London, 1924.

of the average structure so depicted. It is not so much meteorologists dealing with day-to-day weather as geographers approaching meteorology through climatological normals that are liable to fall into the trap, but in any case it is time that the subject of "trades," etc., in text-books both of meteorology and physical geography, were presented in a manner more calculated to make the student think in terms of the *perturbability* rather than the *fixity* of the great wind-belts of the globe. Suppose the actual daily circulation, the interchange of air between the equator and the poles, did conform to anything resembling the cast-iron statistical model, what would be the result? All weather changes, as we know them, would cease, some regions would absolutely never see rain at all, others would literally never be dry, whilst in England, to judge from conditions when the actual distribution of wind and pressure *does* momentarily coincide with the statistical picture, we should have almost constant cloud and drizzle.

This is no doubtful inference; it is in absolute accord, not merely with common experience of daily weather sequences, but also with the principles of the modern theory of the Polar Front. Sometimes when a great wall of high pressure westward of Ireland interrupts our "westerlies" there occurs something which any one whose mind was fettered by the statistical picture would never allow for, namely, the passage of a northerly current all the way from the Arctic to the tropics, and current in sub-tropical latitudes has, so far as I can see, as much right to be called a "trade" as the shorter equatorward current prevailing when the controlling anticyclone takes up its more usual position about 35° N. The number of distortions, minor and major, of the mean or average statistical picture is such that there is no criterion for deciding in all cases whether a particular current of air is, or is not, a "trade," or "anti-trade," as the case may be.

Weather Prediction from Observations of Cloudlets.

THE simplicity of the following method of weather prediction is liable to excite incredulity. Nevertheless, our climate is so changeable that the method can be crucially tested on most days within five minutes by any one. I have used it during many years and on hundreds of occasions, and have found it at least as reliable as the, necessarily, belated weather reports given in newspapers. It is so simple that, as it seems to me, every one must know it; but, apparently, that is not so. In any case, I write only for the man who, perhaps knowing nothing about scientific meteorology, desires to ascertain for himself the kind of weather he is likely to experience during the next few hours.

Though clouds often condense during heavy downpours, they are popularly said to "dissolve in rain." Actually they disappear through evaporation. They "dry up," vanishing like steam out of a kettle, or like ground mist on the morning of a fine summer day. They climb from the horizon, but wax or wane on the way, condensing or thinning. If then the behaviour of the smallest and thinnest fragment of cloud that can be clearly isolated be watched, it is usually possible to predict very quickly and with fair confidence the state of the weather for the next few hours. If the cloudlet waxes visibly, rain is almost certain, if it wanes, fine weather is equally probable; if it neither waxes nor wanes, existing conditions are likely to continue. It is often much easier to be sure of the waning than of the waxing; for the total dis-

appearance of the cloudlet eliminates the possibility of observational error.

This method is inapplicable only when the sky is cloudless, or when it is of a uniform grey. It is uncertain when a high wind prevails; for then continents of cloud, dissolving perhaps but still dropping rain, may drift up from below the horizon. Of course the nearer the cloudlet (the lower it is) the more closely do the conditions in which it floats approximate to those on the ground, and the more easily may it be observed, and, therefore, the more confident may be the prediction. I have often watched a cloudlet diminishing under a grey and dripping blanket of cloud, and made plans for fine weather. It is said that a lenticular cloud may, at the same time, wax at one end and wane at the other. This implies that unlike weather conditions prevail at the two ends—possibly the meeting of a warm with a cold current, or a heating by the sun of one end, but not the other. Personally, I have observed it only when a cold mountain peak causes to windward the formation of a cloud which drifts along its sides, and dissolves to leeward—a pretty phenomenon which, as in some human affairs, gives an appearance of bustle without real progression.

Linked with this matter is the truth that red in the morning usually presages rain, and red in the evening fine weather. It is common knowledge that our prevailing wind is from the west, that only a low sun paints the clouds, that, speaking generally, it paints only those which are somewhat between it and the observer; and only those on which it shines directly. Thus a cloud that lies in the shadow of another which is nearer the sun is not coloured. Given a westerly wind, then, it follows that red in the morning implies that the sun is shining from a wide clear area in the east on clouds that have drifted overhead from the west. That is, it probably means that clouds are gathering. A glance to the west should settle the matter. On the other hand, when the western clouds are painted, that implies that the sun is shining, and the wind blowing, from a clear area beyond, and, therefore, that the clouds are breaking. It follows again that, if the wind be in the east, red in the morning should indicate bright weather and red in the evening rain.

But no matter what the cloud colours, the surest quick weather test is that furnished by the behaviour of a cloudlet, which, very often, may be seen to wax or wane with surprising swiftness.

Alleged Rhætic Crane Flies.

IN NATURE of March 7 last, p. 351, reference is made to the discovery of two species of Rhætic crane flies, described by Dr. G. R. Wieland, palæobotanist, in the January number of the *American Journal of Science*. Copies of Dr. Wieland's paper have only recently reached me, and I was astonished to find, from the very clear photographs and diagrams published therein, that these wings are not dipterous at all. Apart from beetle elytra, the most abundant wings found in the Upper Triassic beds of Ipswich, Queensland (age, Rhætic or a little older), are Homopterous tegmina, most of which belong to the extinct family Scytinopteridæ, ancestral to the Cercopidæ. These tough tegmina have the peculiarity of usually splitting, when fossilised, along the *vena dividens*,

which is a deeply impressed concave vein (Cu_2) separating the anal area or clavus from the rest of the wing (Fig. 1). When the wedge-shaped clavus has become separated, the remainder of the wing appears to be very narrow at the base, and this would suggest a resemblance to dipterous wings, though the thick and strongly arched costa is quite unlike that of any Diptera.

Another point of resemblance between the two, which evidently deceived the author, is the frequent presence of a closed median cell (discal or discoidal cell, mc); but such a cell is found in many orders. All primitive Diptera have the radial sector with four or three branches, and all Diptera, without exception, like their allies the Mecoptera, have the first cubitus unbranched. The Rhætic wings have a simple radial sector and a forked first cubitus, and in these and all other characters agree with the Upper Triassic Scytinopteridæ.

The problem of the ancestry of the Diptera is one of the greatest interest, and it is important that no inaccurate determinations of fossil wings should confuse our view of it. The oldest known fossil Diptera at present are those from the Upper Lias of Europe.

FIG. 1.—*Tipuloidea rhatica* (Tillyard) Wieland. Wing, with missing clavus restored by broken lines.

No Diptera are yet known from the Lower Lias. In the Upper Triassic beds of Ipswich, Queensland, the age of which is either Rhætic or a little older, the Diptera are replaced by their ancestral order Paratrachoptera, which had four wings and a venational scheme very much like that of the caddis-flies or Trichoptera, but with a simple instead of a forked first cubitus. I do not assert that true Diptera might not have existed in the Rhætic, but it is certainly highly improbable. The fossil record shows that the rest of the world in the Upper Permian.

Root-cap Development in *Calluna vulgaris*.

ONE of the characteristic differences between root-apex and stem-apex in a plant is that the meristem of the former produces a tissue in front of the apex known as the root-cap. In my experience this root-cap remains small even in roots

FIG. 1.—Root-cap development in *Calluna vulgaris*.

growing in water, owing to the disintegration of cells on the outside.

It is thought that the accompanying photograph (Fig. 1) of a root of *Calluna vulgaris*, grown for some months under controlled conditions as described in a recent paper (Rayner, *Brit. Journ. Exper. Biol.* vol. 2, 1925, p. 265) and showing the development of a root-cap of considerable length, may be of interest to botanists owing to its unusual character.

Rabbits in Africa.

THE common rabbit, I understand, is not indigenous to that part of Africa forming the Ethiopian zoological region, although it occurs in the Palæarctic part of the continent bordering on the Mediterranean. It is interesting, therefore, to note the occurrence of a well-established colony at Masindi, which has been there for so long that its origin is unknown to the natives, who give the rabbits the same name as the indigenous hare. For a long while I thought they

The London Skull.

By Prof. G. ELLIOT SMITH, F.R.S.

THE merit belongs to Mr. Warren R. Dawson of having recognised the importance of the fossilised fragment of a human cranium found during the excavation for Lloyd's new building in the City of London. I have to thank him for the opportunity of studying so interesting a specimen. Both of us wish to express our appreciation of the ready manner in which the members of the Committee of Lloyd's have placed the specimen at our disposal for scientific examination, and of their generosity in presenting it to the Anatomical Museum of University College, London.

Mr. Dawson has written the following account of the circumstances in which the fossil was discovered :

"During 1924 and 1925 the site bounded by Leadenhall Street, Lime Street, and Leadenhall Place in the City of London, upon which the historic East India House originally stood, has been excavated for the erection of a new building for the Corporation of Lloyd's. Before the erection of the steel-work began, the central part of the site was cleared by means of mechanical excavators; but as the stanchions and girders rendered the available space more and more restricted, part of the digging had to be done by manual labour. The chance of finding fossil bones was slight in that part of the area in which the steam excavator was used; for this apparatus raises large masses of earth at each plunge and deposits its burden bodily into iron skips, which are in turn hoisted by cranes and emptied into lorries. On such parts of the site as were dug out by manual labour, however, fossil bones have from time to time come to light.

"By the kind permission of the Committee of Lloyd's, facilities have been given for a scientific examination of these bones, and the clerk of the works, Mr. G. T. Murton, has in all cases carefully noted the exact depths and the nature of the soil in which the finds were made. In March 1925 I exhibited the specimens at a meeting of the Zoological Society. These comprised the head of a femur and some teeth of the mammoth found in the river

portion of the site. The fragment of skull was broken into four pieces by a blow from the excavator's pick; but one of the pieces (a small triangular splinter from A in Fig. 1) was not recovered. The other three pieces were fitted together and exhibited at a meeting of the Zoological Society of London on October 20. On that occasion the erroneous statement was made that the skull was found at a depth of 26 feet from the surface; but a few days later the clerk of the works directed my attention to the error and informed me that the human fossil came from the blue clay in the 42 feet level.

"The misunderstanding arose from the fact that our inquiries concerning the 'skull' were believed to refer to the remains of the ox found at a depth of 26 feet, and not to the flattened plates of bone, which were not recognised as parts of a skull."

This correction eliminates the difficulty that presented itself in attempting to associate a mineralised human skull revealing interesting primitive traits with

The London skull.

area T represents the situation (on the endocranial cast) of the temporal boss, and P the singularly ill-developed parietal area.

The bones are completely mineralised and of a reddish-brown colour. The condition of the cranial

FIG. 2.—The inner surface of the cranium viewed from the front.

F, fossa areæ striatæ (with a ridge concentric with the crista lunata).
S, diminutive fossa areæ striatæ on left side.

sutures (lambdoid and sagittal) suggests an age of more than forty, but probably less than fifty years. The smoothness of the contour of the skull, and especially the faintness of the muscular impressions (Fig. 4), make it highly probable that the sex is female. The distinctness of the large lunate crest (Fig. 2, L), and the deep fossa striatæ (F) on the right side of the occipital bone—a reversal of the normal asymmetry—affords, as I pointed out in 1908 (*Brit. Med. Journ.*, Aug. 29, 1908, p. 597), clear proof of left-handedness.

The special interest of the relic arises from the fact that a skull which, from the circumstances of its deposition, is probably more recent than the known occurrence of the Neanderthal species, should reveal features so closely simulating those of the female crania of the Neanderthal type (those of Gibraltar and La Quina), and differ so profoundly from those of her (presumed) contemporaries of the Upper Palæolithic period. The height of the cranium is no greater than that of the La Quina woman (and the restored Gibraltar woman's skull); and the maximum breadth of the cranium is intermediate between the measurements in these two members of the Neanderthal species. The greatest breadth of the endocranial cast of the London skull

is 136 mm., that of the La Quina cast being 130 mm., and of the Gibraltar cast 140 mm.

The resemblances in the brain cases are indicated, however, not merely by the measurements of height and breadth, but also by the form of the endocranial casts, both their profile (Fig. 3) and the modelling of their surfaces (Fig. 5). The astonishing similarity of the size and shape in the profiles of the casts of the brain cases in the London, La Quina, and the Gibraltar skulls is brought out in Fig. 3. When one recalls that the London cast reveals a form suggestive of the short brain of the Gibraltar type rather than the long brain of the La Quina type (Fig. 3), and that the Gibraltar brain was wider than the Londoner's, it seems probable that the volume of the latter cannot have been much, if any, more than 1200 c.c.

In his memoir on the Neanderthal race (*Roy. Soc. Phil. Trans.*, 1907) Prof. Sollas describes the skull of an aboriginal Australian that was no higher than the Gibraltar skull. On comparing a replica of the endocranial cast of this skull (S.A. in Fig. 3), which Prof. Sollas gave me some years ago, it is found to agree even more nearly in profile with the La Quina cast, the only significant difference being a greater fulness in the parietal area. The Australian skull is usually as lofty as that of the modern British woman, the outline of whose endocranial cast is represented in Fig. 3.

This serves by contrast to emphasise the remarkable similarity of the London skull with those of the Neanderthal group and the exceptional Australian (S.A.). The cerebellum alone reveals any marked contrast. The fulness of this part of the brain in the London skull differs from the flattened form (cerebell.) of the Neanderthal and closely conforms to the type found in *Homo*

FIG. 3.—The outline of the endocranial cast of the London skull seen in profile from the left (thick line), compared with the Gibraltar and La Quina women and Prof. Sollas's Australian (S.A.), described in the *Roy. Soc. Phil. Trans.*, 1907, p. 325, as well as those of Pithecanthropus, Eoanthropus, and a random sample of a modern woman.

sapiens, as well as, curiously enough, in the Piltdown cast (Eoanthropus).

The modelling of the surface of the cerebral hemisphere in the endocranial cast (Fig. 5) reveals features of special interest. The localised swelling in the posterior

part of the temporal area (the temporal boss marked T in Fig. 5) is clearly defined, as it is in casts obtained from the La Quina, Piltdown, and Java (*Pithecanthropus*) crania, in all of which its distinctness is due partly to the lack of fulness in the parietal area (P). Even in the flat endocranial cast of Prof. Sollas's Australian skull the parietal area is prominent and no localised temporal boss is apparent. Though the parietal area is

FIG. 4.—Back view of the London skull. The prominent boss on the right side at F is associated with the deep fossa striatæ (Fig. 2).

fuller in the London cast than in that of the La Quina skull, it resembles the latter more nearly than it does the Australian. The contour of the latter in Fig. 3 (S.A.) is merely one of the expressions of this increased parietal development. In this, and in fact in most other respects, however, the London skull differs profoundly from the condition usually found in *Homo sapiens*, even in such early examples as the Cromagnon and Combe Capelle crania, the brain cavities of which would, if the contours were shown in Fig. 3, much more nearly resemble the modern than the ancient London woman.

Several of the skulls of the Upper Palæolithic are remarkable for their flatness; but none of them approaches so nearly as the London skull does (Fig. 4) the shape distinctive of the Neanderthal species.

The Solutrean skull found in 1891 at Brünn (Moravia)—embedded in loess in association with the woolly rhinoceros and mammoth—was claimed by Makowsky to belong to a type intermediate between *Homo neanderthalensis* and *H. sapiens*. In 1906, Schwalbe argued that it conformed to a primitive type of the species *sapiens*, because the cranium was much higher than the Neanderthal form and lacked the distinctive type of eyebrow ridges. In spite of this, several anthropologists (see, for example, Stolyhwo in *Globus*, December 17, 1908, p. 363) refused to accept Schwalbe's view. The London skull affords much more definite evidence in support of these claims for the existence of an intermediate species than any of the Moravian specimens or Stolyhwo's Novosiolka skull reveals. In fact, the London endocranial cast (Fig. 5) reproduces the form of the Neanderthal type so nearly that the question of the possibility of the survival into Aurignacian times (in Britain) of a stray representative

of the species *neanderthalensis* is forced upon our consideration.

In spite of these considerations, however, one is not justified in claiming, on the evidence of data derived solely from the posterior part of the skull, that the London skull belongs to the Neanderthal species or to an intermediate type. The front end of the cranium or the face would have provided decisive evidence for the determination of the species; but unfortunately these parts of the skull are missing. Hence, as the fossil was found in a deposit definitely later than that in which Neanderthal man is known, and taking into consideration the range of variation in modern man, as displayed in the Australian skull (S.A. in Fig. 3), it would not be justifiable to claim this fragment of a skull as conclusive evidence of the survival of a member of the Neanderthal species into Upper Palæolithic times.

The thinness of the cranium is not a certain criterion of identity with the species *sapiens*, for the London skull is quite as thick as that of the La Quina woman.

In support of these tentative suggestions, the size and fulness of the cerebellum must be given some weight as an indication of affinity or identity with the species *sapiens*. The filling out of the parietal area, slight though it be, may possibly be indicative of a rank above that attained by the Neanderthal brain.

As to the date of the London skull, perhaps the most relevant facts are provided by the excavations in 1892 for the New Admiralty Buildings in London (Lewis Abbott, *Proc. Geol. Assoc.*, 1892, vol. 12, p. 346). The lowest terrace of the Thames provided evidence

FIG. 5.—Left side of endocranial cast of the London skull.

of the association of the Pleistocene mammals with a Solutrean implement.

Whatever the fuller study of this remarkable skull may reveal, the fossil is certainly by far the oldest human relic yet found in the City of London and presents probably the nearest resemblance to the Neanderthal type ever found in a member of the species *sapiens*.

In the task of investigating this fossil I have had the benefit of the valuable advice of Profs. D. M. S. Watson and J. H. McGregor (of Columbia University).

Science in Russia.

By W. BATESON, F.R.S.

IN consultation with Sir Henry Miers and Prof. D'Arcy Thompson, who were among the British delegates, I have prepared the following account of our recent visit to Russia to the celebrations of the two-hundredth anniversary of the Russian Academy of Science. The celebrations began on September 5. We were to have six days in Leningrad, full of every kind of function both solemn and festive, to be followed by four more, similarly crowded with events, in Moscow. We came determined to see and hear all that we possibly could in the time; and aware that the gathering had been organised largely with an eye to its propaganda-value, I suppose that most of us with our curiosity combined a considerable measure of scepticism as to the real value of anything we might be shown.

Nothing could exceed the courtesy and hospitality with which we were received. Railway travelling in Russia was to be entirely free, and those who cared to do so were invited to visit any place in the country, Kieff, Odessa, etc., that could be seen before the end of September. At the frontier our baggage was passed in (and on the return journey passed out) unexamined, and we were authorised to send cables gratis. New motor omnibuses, specially sent from Moscow, met us at the station, and after we had been duly filmed, conveyed us to our hotel—a fine and well-appointed house. Rumour alleged that no other hotel could provide even reasonable comfort, but that may have been untrue. Of the ordinary charges we paid about half, but at Moscow, where we were distributed among several hotels, no charge at all was made.

If these preliminary symptoms inclined us to complacency we soon saw others of a different character. In the long drive through the streets of Leningrad the evidence of the empty and half-ruined buildings, the peeling walls, the dishevelled pavements, and the broken roadways—full of dangerous and neglected pits, above all the clothes of the population, with rarest exceptions, dingy and often improvised of coarse and unusual materials, were indications of troubles which no camouflage could conceal. Wherever we went in Leningrad, though in a slightly less degree perhaps in Moscow, we had the experience—to scientific persons novel and rather disconcerting—of finding ourselves conspicuously well dressed. It was indeed a little embarrassing to meet men of refinement and learning whose trousers were eked out with large and unrelated fragments, though almost worse to pass groups of artisans going home from work in rags which suggested the casual ward of a workhouse rather than decent employment. Readers of *NATURE* will not expect a report on social conditions, but some hint of the setting in which we saw what we did see can scarcely be omitted.

In preliminary announcements the numbers of foreign visitors expected had been given as about a hundred and fifty. We were not furnished with any list of those who did attend, but the highest estimate of our actual numbers which I heard was ninety-six. Of these perhaps half were representatives of mathematics and natural sciences in the stricter sense, the remainder being economists, historians, orientalists, and especially students of Slav languages, etc.

The proceedings opened with an evening reception in the rooms of the Academy. On this and on most other formal occasions our arrival was attended by a guard of honour with bayonets fixed, and we marched in under the lime-light of the ubiquitous cinema men. Here we found ourselves in an immense gathering assembled from all parts of Russia, representative of every kind of learning, and if several of the eminent foreigners whose presence had been promised failed to appear, there were no defects on the part of our hosts, for practically every one with whom we had acquaintance, direct or indirect, was there.

On the following Sunday we assembled for the first of several public seances, which both in Leningrad and Moscow constituted the formal business of the congress. Proceedings began—as always—with the singing of the International, which was followed by discourses of various kinds. After an introduction from the president, Karpinski, the secretary of the Academy, Oldenburg, gave an interesting history of its origin and activities, reminding us of the many distinguished men who had worked under its auspices. Other members of the Academy, especially Steklov and Lazarev, followed him, but alternating with them were speeches by members of the Government, giving their views on what science had done and might do for the people. At various times we were thus addressed by Kalinin, president of the Soviet, Krassin, Kameneff, Lunacharsky, minister of education—on several occasions—and other well-known leaders. At one of these seances Zinovieff, president of the Leningrad Soviet, gave a long and rhetorical address, developing an analogy between the aims of science and those of the revolutionists, which was afterwards printed.

Among much in all these speeches which of course escaped us, one conclusion very plainly emerged, that the revolutionary government is perfectly sincere in its determination to promote and foster science on a very large scale. Signs were not wanting that science, especially perhaps in its applications, is regarded by the present governors of Russia as the best of all propaganda. It was interesting to hear the faith that the advancement of science is a first duty of the State proclaimed by professional politicians. We ought perhaps not to inquire too closely whether they and we mean the same thing by the term science. Zinovieff, for example, speaks in the same breath of the "discovery" of Karl Marx and the "discovery" of Charles Darwin. Each of these men valued the work of the other, he told us, in a very high degree, and in evidence of Darwin's admiration of Marx he spoke of a letter, sent in acknowledgment of the book on capital, which was to be published. In an impassioned passage, which was enthusiastically applauded, he drew a parallel—derived from Lenin—between what science had done for the abolition of syphilis, patiently trying and discarding 605 reagents before 606 was reached, with what revolutionists were attempting for the abolition of capitalism. Capitalism was a scourge worse than syphilis, and if need be, not 606 but 6006 remedies must be tried so that the planet may be delivered once for all from its "yoke." Judging, however, from the

proportion of the population lost in the first experiments,¹ those who survive to benefit by the ultimate deliverance will be few.

Whether science will soon fulfil the many promises made in its name must be doubtful, yet not merely from what we heard, but also from what we saw, the failure we may be sure will not be for want of genuine effort. Next in importance after communism, the tenets of Leninism assert the doctrine that science is the basis of happiness. Religion is to be eradicated as a vice; science and the arts are to be promoted in its place. Those who regard this fervour for science as mere affectation for propaganda purposes miss an essential fact, and in our visits to laboratories and institutions, as related below, we found abundant and imposing evidence of the expression of this faith in material works. Of these new institutions we saw a great many, and though of course none of us could personally visit more than a part, we found on comparing notes that certain features were common to most of them. Palaces and great houses from which the owners have been dispossessed have been hastily adapted for the purposes of science. The effect was often incongruous. Though objects of value had been removed, we saw laboratory benches improvised among the remains of Empire furniture and statuary, and under Boucher ceilings representing nymphs sporting with amorini. Formerly each institution would have the Tsar's portrait and probably an occasional ikon. The modern analogue of these is the "red room," arranged as a sort of shrine of communism with the bust of Lenin, surrounded with copious literature of propaganda. Signs also there were that, in other and less innocent ways, not only the universities but also the various scientific institutions were utilised as agencies for the dissemination of communistic ideas.

Doubts might be entertained as to whether the best atmosphere for research has been created in the institutions, but no praise is too high for the zeal and vigour with which work is being conducted in the new circumstances. As typical of them may be mentioned the Institute of Zoological and Botanical Research under Prof. Philpitschenko and Prof. Dogiel, which has been set up in the house and parks of the Leuchtenberg family at Peterhof. Besides the permanent staff, many hundreds of students are there accommodated in the summer months, partly for instruction and in part co-operating in the experiments we saw in progress. The whole gave the impression of a very active and well-organised school, which has already done excellent work both in fundamental and applied biology. At Moscow Prof. Nawaschin and a band of cytologists trained by him are housed in a fine building and equipped with good instruments. His researches are of course classical, and we saw with satisfaction that in this case at least, one of the "purest" of biological sciences was not suffering through the competition of the applied branches.

Another very large house, also in Moscow, has been assigned to Prof. Koltsov as an Institute of Experi-

mental Biology. This includes numerous departments, especially a genetical station under Prof. Serebrovsky, work in experimental morphology, hydrobiology, etc. At the old Agricultural School at Petrovsky-Razumovsky, we saw more genetical work in application to agriculture and the long-established researches of Prof. Prianschnikov on agricultural chemistry. The Darwin Museum, created by Prof. Coats and his wife in illustration of the theory of evolution, was a remarkable and I believe unique curiosity. It contains a quantity of valuable and largely unpublished material bearing on the incidence of variation and a great number of other novelties. We were invited to inspect many more institutions, especially various establishments connected with public health, but all these I had to forgo.

Among the new organisations of a biological character the most extensive is the Institute of Applied Botany and Plant Breeding. The immediate object is to provide breeds of cereals and other agricultural plants for the various parts of Russia. The work is in the hands of Prof. Vavilov, who has already built up a great establishment for this purpose, employing 350 people, of whom some 200 are trained workers. In his travels through Turkestan, Afghanistan, and neighbouring countries, and by a vast correspondence, collections of seeds of wheat, barley, rye, millet, flax, etc., have been brought together on a great scale. The central office is in Leningrad and occupies a very large building, which is in great measure a living museum of economic plants as represented by their seeds. Of wheat alone some 13,000 forms are here collected. In various parts of the country are twelve subordinate stations, and by sowings made once in about three years it is proposed to perpetuate most of the collection alive. Besides a cytological department under Prof. Levitzky, there are special sections for meteorology, statistics, etc. Exceptional opportunities have been provided for investigating the geographical distribution of cultivated plants, especially in its bearing on problems of origin, which have resulted in several novel suggestions. At Dyetskoe (formerly Tsarskoe) Seló is the home breeding-station of this Institute. The chief building on it is a pleasant house, originally intended as a villa for Queen Victoria, and adjacent to this a number of laboratories and additional accommodation have been provided.

Sir Henry Miers contributes the following notes on three great Institutes, indicating the scale on which scientific work is contemplated in Russia, and its concentration in Moscow and Leningrad.

"*The Geological Commission*, recently installed in a vast new building in the Vassili Ostrov, contains numerous rooms for the geologists who take expeditions to all parts of the country and generally work up their material in the winter months. There are no less than 200 geologists and a total staff of 400. All results are classified and co-ordinated in a central bureau; the relative abundance and distribution of minerals of economic importance are collected in a graphic form on special maps. The whole top floor is being utilised as a museum.

"*The Aero-hydro-dynamical Institute* at Moscow, approaching completion, at an estimated cost of three million roubles. A new wind channel, 52 metres in length, built in two sections, 3 metres in diameter at

¹ Though accurate figures are wanting, some estimates may be formed from the "Report on Epidemics in Russia since 1914," 2 Parts, by Prof. L. Tarassévitch, published at Geneva, 1922, for the League of Nations. On the basis of the statistics provided he estimated that "Russia may consider herself fortunate if she emerges from the present crisis with the loss of 20-25 per cent. of her population." Pt. 2, p. 44.

one end, 6 metres at the other, is nearly finished. An experimental tank, like the Froude tank at the National Physical Laboratory, 225 metres long, 12 metres broad, and 6 metres in depth, is being constructed. A large experimental tower for wind experiments has been erected.

"The Institute of Applied Mineralogy in Moscow is being built on a grandiose scale at an estimated cost of 1,800,000 roubles, with an area from 9 to 12 thousand sq. metres and cubic content of about 60,000 cubic metres. It will be equipped for research work on a vast mass of material from all parts of the country.

"Typical of the organisation of research in special directions is the *Institute of Biological Physics*, in Moscow, directed by Prof. P. Lazarev; the whole interior of a large building has been rearranged for work on many branches of applied physics, and includes investigations on such subjects as the ionic theory of nervous excitation, with a geophysical laboratory in which researches on the remarkable magnetic anomaly of Kursk have been conducted.

"As an example of the growth and reorganisation of scientific collections:

"The *Mineralogical Museum* of the Academy has been quadrupled in extent during the last twenty years and has just been established as a national public mineralogical museum, distinct from that of geology, and fully equipped with laboratories.

"A visit to any school would show how important and overwhelming a part is played by nature study and elementary science in the education of children, especially in reference to all the affairs of life under the Soviet system."

Of the old-established scientific institutions, the Museums of Zoology and of Palæontology and the Botanic Garden were the only ones which I managed to visit. The fine and largely unique contents of the two museums are of course familiarly known. One recent acquisition I saw with mixed feelings—the almost complete skeleton of the giant *Indricotherium*, a rhinoceros-like creature, standing about twelve feet high at the shoulder. These bones, the collection of which has taken three years, were found exposed at Chalkar Tengiz, a remote and little known locality, but from the photograph of the site I saw that in 1886 I must have passed within a few yards of the very spot. The Botanic Garden alone still showed signs of the hardships through which it had come.

Great provisions are being also made for the development of art, archæology, and ethnology. Though unable to visit the *Musée Russe*, in which the collections illustrative of the history of the races included in the Soviet are preserved, I heard continually of its extraordinary excellence. Though it is the work of several decades, its recent extension has been much assisted under the new regime. Of the new developments at the Hermitage, Sir Martin Conway lately published an account. Among later novelties I was shown the astonishing collections brought from East Turkestan by M. Kozlov's recent expeditions. From tombs originally constructed at a depth of twelve metres below the surface and permanently immersed in water, have been brought a vast series of textiles, both woollen quilts and silks in admirable preservation,

together with ornaments of various kinds and domestic objects, the whole belonging to a civilisation previously unknown. The decorations representing stylised animals, especially reindeer (possibly elk) and oxen, are evidently Sassanian in affinity, as M. Orbeli demonstrated. Some of the designs in the silk fabrics are of incomparable beauty, and very striking also are fragments of a curious red and black lacquer showing the utmost delicacy of taste and workmanship. These remains have not as yet been dated with certainty, but are presumed to cover a long period belonging chiefly to the sixth-seventh century A.D., but in part probably to a much earlier epoch.

Of all the things seen I suppose the interior of the *Usspensky Sobor*, the great Cathedral of the Coronations, exhibited the greatest break with past traditions. Until lately the whole was plastered with gold leaf and paintings rising little above the *objêt de pitié* type of art, giving an effect certainly solemn and gorgeous but tasteless and oppressive. The archæologists have declared the whole of this display of orthodoxy to be modern and debased. The process of stripping has been begun and is steadily proceeding under scholarly and skilful guidance. The ancient pictures are being slowly recovered and will be seen before long as they were intended to be seen upon the original white of the walls. The most famous and venerable of all ikons, the *Korsun Madonna*, traditionally ascribed to St. Luke, has already been cleared. I remember it looking like a piece of black leather. Seven layers of paint have been removed and a most remarkable original picture has been displayed in its entirety. Terrible judgments were expected by the common people to follow these impieties and the opening of the reliquaries by which they were accompanied. Time alone can show whether their anticipations will be justified, but meanwhile there is no gainsaying the fact that in the restorations which are to be extended throughout the Kremlin churches, and carried out upon every ikon of importance, the history of religious art in Russia will be revealed.

Of the banquets, lordly, if indeed the term princely were not more appropriate, graced, as that in Moscow at least was, with Imperial porcelain and madeira; of the operas, of the ballets and the sumptuous production at the Arts Theatre, where several of the courtly costumes were real brocades—lately somebody's "properties" in the fullest sense—one I verily believe lent from the Kremlin collection itself—this is not the place to speak at length.

We left with no clear conception of the principles or practice of communism; and in particular as we looked round at the 1200 persons assembled for the Moscow banquet, in a city teeming with beggars, we tried in vain to conjecture any system by which admission to the table, or exclusion from it, may have been determined. Of liberty we saw no sign. We here are accustomed to think of science and learning as flourishing best in quiet places, where they may come to slow perfection, under systems providing a reasonable measure of personal independence and security. Present conditions in Russia have brought about the very contrary, and among the grave indications of disharmony, which every visitor observes, the want of freedom is by far the most serious.

Obituary.

MR. J. S. GAMBLE, C.I.E., F.R.S.

A FEW weeks ago the Indian Forest Service and British forestry had to deplore the loss of Sir William Schlich, who may be said to have been the doyen of British Empire forestry. Following shortly on the death of his friend, the Indian Service has now lost another great forester in the person of James Sykes Gamble, who, on his departure from India in 1899, left a great reputation behind him both as a scientific forester of the first calibre, an educationist, and a great botanist. Gamble went out to India when the botany of the forest was imperfectly known for the practical forester's purpose and the Indian timbers were quite unknown. Before he left the country he placed in the hands of the Indian forester a manual the value of which received immediate recognition.

Gamble was the second son of Dr Harpur Gamble, R.N., and was born in London on July 2, 1847. He was educated at the Royal Navy School, New Cross, and at Magdalen College, Oxford, where he took firsts in Mathematical Moderations and in the Final School of Mathematics. The following year, 1869, he was selected by the Secretary of State for India to undergo training on the Continent for the Indian Forest Service. This scheme had been recently inaugurated by Sir Dietrich Brandis, at that time the first Inspector-General of Forests in India. Out of the seven selected in that year, Gamble and three others were deputed to the Nancy Forest School, the rest going to Germany. Gamble had many stories of the interesting life he led at Nancy, where he was trained under some of the greatest foresters of the day. He was under M. Clément de Grandprey in the fine forest of Haguenau before he went to the School. At the latter place at the time there were some of the best known names in French forestry, Nanquette being director. In the jubilee number of the *Indian Forester* (July 1925) Gamble wrote: "Personally, I can testify to having started my interest in wood-structure under the auspices of Professor Mathieu and with the help of the well-arranged collection in the wood-chalet in the School Garden." The Franco-Prussian War interfered with the English students' studies at Nancy and they were transferred to Scotland under Dr. Cleghorn, who had made a great name in Indian forestry annals and had been associated with Brandis in the first organisation of the Forest Service (1863-64). In the spring of 1871 Gamble returned to Nancy, and in November he sailed for Calcutta, taking out with him some Wardian cases of *Ipecacuanha* for the Botanic Gardens. It was this commission, received from the India Office, which took Gamble to Kew, where, under the guidance of Sir Joseph Hooker, he paid his first visit to the Gardens and Herbarium, thus starting an association with the Gardens which was to continue in later years and to last until his death. With these cases in his charge he landed at the privateghat (landing stage) of the Calcutta Gardens on the Hoogly River, and it was from the same ghat that he took his departure from India twenty-eight years later.

Gamble was posted to Burma and, like every man who goes first to that fascinating country, fell in love with it and with the forests. His stay in Burma was

short, for in August 1872 he received orders to report in Bengal, orders he was very reluctant to comply with. In those days forest organisation in Bengal did not exist. Towards the end of the year Schlich was sent to Bengal as Conservator, and the friendship which was to last through life commenced between these two men. Before Schlich left Bengal he had placed forest administration on a firm basis, and Gamble afterwards carried on the work, as also the editorship of the *Indian Forester*, which Schlich founded in 1875. For a time Gamble was Conservator in Madras, and in 1890 he was transferred to the North-West Provinces (now United Provinces) as Director of the Imperial Forest School at Dehra Dun and Conservator of the School Circle, comprising an area of forests in the lovely Dun and Siwaliks and neighbouring Jaunsar Himalaya. Gamble proved himself one of the best directors the School has ever had. In connexion with the School he planted a small arboretum, which the writer had the good fortune to visit for the first time in his company, and saw once again in April last during a visit to India.

The Indian forest officer owes a great debt to Gamble on the score of the valuable botanical work he accomplished; but it should be recorded that the latter was a thoroughly efficient forest officer and in his day carried out some remarkably fine work. He was an indefatigable research worker and a patient cataloguer. In his early days in Bengal he prepared a list of the trees, shrubs, and climbers of the Darjiling district, a second edition of which was published in 1895. As an outcome of his work in Madras he compiled a flora of that Presidency. He drew up a list of the *Bambuseæ* of British India, published in the *Annals of the Royal Botanic Garden, Calcutta*.

It was while he was associated with Brandis as Assistant Inspector-General of Forests that he commenced the research work on Indian timbers, which resulted in the publication of his great work "A Manual of Indian Timbers," for which generations of Indian forest officers have blessed the name of Gamble. This first appeared in 1881, was soon out of print, and for a decade the young Indian forest recruit was almost helpless in the forest in the absence of such an essential handbook. A second edition, much amplified, appeared in 1902, and a third three years ago, the latter an improvement even on the second.

In the year of his retirement Gamble was made a C.I.E., and in the same year was elected a fellow of the Royal Society. In 1900 he was put in charge of the organisation of the forestry exhibit at the Paris Exposition of that year. The whole of the objects were assembled and arranged and tabulated in Calcutta by Mr. F. Manson, to whom the writer acted as assistant on what proved an extremely interesting piece of work. Gamble was awarded the Jury Medal and Diploma of the Exposition for this work; he also received the Barclay Medal of the Royal Asiatic Society of Bengal. He was elected to the Athenæum in 1902.

Gamble collaborated with the late Sir George King in materials for a flora of the Malay Peninsula, work which he afterwards carried on by himself. He was also associated with Schlich at Oxford in the training of Indian forest probationers and lectured on Indian

forest botany. He settled at Highfield, Liss, in Hampshire, and married, in 1911, Gertrude, daughter of the Rev. A. S. Latter.

To the Indian Forest Department and his many old friends Gamble's death will come as a great blow. He has left behind him an enduring memorial by which many a young forest officer who never met him will revere his name. E. P. STEBBING.

PROF. W. WRIGHT SMITH has sent us the following brief notes on Mr. J. S. Gamble's botanical work:

Gamble was associated with the late Sir George King on a very extensive publication entitled "Materials for a Flora of the Malayan Peninsula." This was started by Sir George King, who was responsible for Nos. 1-13; then King and Gamble appear as the authors for Nos. 14-21. These papers appeared in the Journal of the Asiatic Society of Bengal for the years 1903-1909, and the last numbers contain chiefly the Gamopetalæ. On the death of King, Gamble completed the work to the end of the dicotyledons. This constituted Nos. 22-25—published 1912-1915—and represented the orders Nyctagineæ up to Salicaceæ. One or two of the families were done by other authors.

On the completion of this very large work—I should perhaps have noted that Ridley had already done the monocotyledons of the area—Gamble turned his attention to the flora of Madras, and during the years 1915-1924 he published six parts of the "Flora of the Presidency of Madras," from Ranunculaceæ down to Plantagineæ. At the time of his death he was busily engaged on the Urticaceæ and had hopes of bringing out another part at an early date.

The very many new species which came to light during the work on the flora of the Malayan Peninsula, and also on the flora of Madras, appeared in numerous short papers scattered throughout the *Kew Bulletin* during the last twenty years.

PROF. E. H. BARTON, F.R.S.

THE scientific world has lost a very able and steadfast worker in the person of Prof. Edwin Henry Barton, professor of physics in University College, Nottingham, who died suddenly on Wednesday, September 23, when starting, in apparently perfect health, for a day's walk. He leaves a widow and two sons.

Prof. Barton was born in Nottingham in 1859, and lived there all his life except for two years spent in study, the first under Sir Arthur Rucker in the Imperial College of Science, London; the second under Hertz at the University of Bonn. The recognition of his talent, or perhaps the opportunity to develop it, came to him comparatively late in life, for he was a trained engineering draftsman when, at the opening of the University College, Nottingham, he commenced a course of study, and at the age of thirty-one years passed the London matriculation. His career as a student was brilliant, and he was awarded an 1851 Exhibition Research Scholarship. On returning to Nottingham in 1893 after his training in London and Bonn, he became lecturer in physics, and in 1906 professor and head of his department. His published scientific work was recognised in 1916 by election into the Royal Society.

Prof. Barton was the author of some very useful books for students; the best known being his "Text-book on Sound." This book from its scope and careful treatment may be held to complete a trilogy with Preston's "Light" and "Heat," so well known to advanced students. Prof. Barton's other works were "Analytical Mechanics" and "Introduction to the Mechanics of Fluids." At the time of his death he was well on the way with an advanced treatise on "Properties of Matter." To Glazebrook's "Dictionary of Applied Physics" he contributed the article on "Sound." His published papers, about sixty, were mostly in the *Philosophical Magazine*. When with Hertz, he commenced research on electric vibrations, and his earlier papers dealt with the transmission, damping, and reflection of waves along wires. In later years he turned rather to acoustic and other mechanical vibrations. In the sound experiments he adopted optical levers attached to the various parts of the moving wire or plate to amplify the vibrations, which he then recorded photographically.

As most of Prof. Barton's papers were collaborations, a great number of students and colleagues had the benefit of his inspiration in these researches. In particular, in the last eight years he published a series of no less than fourteen papers with Dr. H. Mary Browning, who was first his student and later his colleague. In this series the author used coupled and triple pendulums to illustrate the close analogy existing between electrical, optical, and mechanical vibrations, in all cases bringing the mathematical theory into relation with the physical action.

We have good authority for saying that the best early training for a would-be physicist is either mathematics or engineering. Prof. Barton, as we have seen, began life as engineer, and in his student career showed great mathematical ability, so he may be said to have happily combined both the desiderata specified. By nature a student, he was conversant with most branches of his very progressive subject with its voluminous recent addition of the "new" physics, relativity and quantum. When lecturing he handled his subject with a thoroughness which carried conviction and with a wealth of illustration which sustained the attention of his audience.

Prof. Barton was well known as an expert in sound, and as such was consulted by musicians and experimentalists in sound in various parts of the world. As regards the practice of music he was a *virtuoso* and could perform on many instruments. This faculty served him for demonstration in lectures and for his researches; so that the physics wing at Nottingham often resounded to the merry strains of cornet, trumpet, harmonicon, or other kinds of music. He was a very popular head of his department at Nottingham, where his great ability and invariable courtesy will not soon be forgotten.

His special talent may be held to pass on to the next generation, as his two sons both had brilliant careers in physics at Cambridge.

DR. GEORG SCHWEINFURTH.

GEORG AUGUST SCHWEINFURTH, who was born at Riga, of German parents, on December 29, 1836, and died in Berlin on September 20 last, was a naturalist

who gained great distinction by his travels and discoveries in East Central Africa. A trained botanist, he was chosen at the age of twenty-seven to classify and arrange the Barim and Hartmann collections brought from the Sudan. In 1863-66 he studied on the spot the flora of Egypt and adjacent regions from the Delta to Khartum and from the Red Sea along the slopes of the Abyssinian highlands to the Blue Nile. In 1866, with funds provided by the Humboldt-Stiftung, he set out for the Bahr-el-Ghazel province of the Sudan.

Schweinfurth's journey, which lasted three years, was one of the most fruitful ever carried out by a traveller in Africa. Undertaken primarily for the purpose of botanical investigation, it took on a much wider scope. Schweinfurth studied not only the flora but also the fauna and the orography of the country. He did a great deal to elucidate its puzzling hydrography. Crossing the Nile watershed he discovered the Welle. This great river, one of the chief tributaries of the Congo, he believed at the time to belong to the Lake Chad basin. This detracted little from the value of his discovery, which won for him the award, in 1874, of the Founder's Medal of the Royal Geographical Society. Above all, however, Schweinfurth studied the people, and to him we owe almost the first accurate account of the Diur, Dinka, Bongo, and the cannibal Azandeh (or Niam-Niam) and Mangbettu. His discovery of the Akka pygmies settled conclusively the then vexed question as to the existence of dwarf races in Central Africa.

In regard to fauna, Schweinfurth's most notable discovery was that of an aberrant type of chimpanzee (*A. troglodytes schweinfurthi*) in the Azandeh country. The existence of the chimpanzee in the Nile basin was previously unknown; Schweinfurth also found the grey parrot and other West African types in the Nile regions. His botanical work was extensive; he revealed the eastward extension of the great equatorial forest and vividly described the remarkable "gallery" formations it contains; avenues of gigantic trees "like the colonnade of an Egyptian temple," and "aisles and corridors" in the innermost recesses of apparently impenetrable woods. (This formation, as Schweinfurth carefully acknowledged, had been previously reported by Carlo Piaggia.) The account of his journey, "The Heart of Africa," first published in 1873, abounds in passages in which the character of the scenery is clearly depicted, and the description is aided by reproductions of his own drawings—for to the gift of careful observation Schweinfurth added that of a capable artist. Taken in all, with its attractive style, its fullness of information concerning the people, the country, and its flora and fauna, and remembering that the period dealt with was one when slave-raiding and ivory hunting were the chief industries, "The Heart of Africa" is scarcely exceeded in interest by any other work on African travel.

Schweinfurth never returned to Central Africa, but made many other shorter expeditions. In 1873-74 he was in the Libyan Desert with Gerhard Rohlfs, and between 1876 and 1888 he visited south-west Arabia several times, adding considerably to the knowledge of that region. In the intervals he lived at Cairo, where, in 1875, he founded, under Ismail Pasha's auspices, the Société Khédiviale de Géographie. He also continued

his botanical and geological investigation of the lower Nile valley. In 1889 he took up his residence in Berlin, where, save for visits to Eritrea (1891-94), he remained. His interest in Africa never ceased, and a new edition of "The Heart of Africa," with much new material, appeared in 1918. His botanical and geological collections are now exhibited in the Berlin Museum.

MR. WILLIAM WELSH.

MR. WILLIAM WELSH, whose death occurred on September 12, was born at Edinburgh in 1859. After being educated at George Watson's College he went, at fifteen years of age, to the University of Edinburgh, where he worked under Tait and Blackie. From there he proceeded to Jesus College, Cambridge, where, under the guidance of Routh, he secured the senior position in the Mathematical Tripos of 1882 and in the Smith's Prize examination in the following year. Elected to a fellowship in 1883, he remained on the active staff of his college until his death.

By the death of Welsh, Cambridge has lost one of the best of her mathematical teachers. The ability he possessed for getting at the essence of a subject, and in reducing its analytical cloak to a minimum, always enabled him to present it in a form which for lucidity, elegance and thoroughness could scarcely be equalled. He treated his subjects as such, and not as a means to solving a large number of tricky problems—an art in which he himself specially excelled—and he was a strong advocate of that part of the reform incorporated in the new Tripos in 1910 which forced a more uniform adoption of the practice of subject-lecturing.

Welsh was a member of the small Cambridge board which drew up one of the first syllabuses of reformed geometrical teaching for schools. But, like so many of the prime movers in this matter, he afterwards regretted his part in the work, on account of the rapid decline of geometrical teaching which resulted from it. Not that he ever felt that the reform was not an improvement, but because events proved the impropriety of making it without a great deal of previous preparation.

Welsh was a man of an extraordinarily retiring nature, always anxious to avoid publicity in any form. He was, however, possessed of a singular charm of character, and he will be greatly missed in a small circle of intimate friends and in the larger sphere of mathematical teachers at Cambridge. The spirit of his genius will live for a long time in the generations of younger mathematicians who had the good fortune to come under his influence.

G. H. L.

WE regret to announce the following deaths:

Mr. Francis Jones, senior chemistry master of Manchester Grammar School from 1872 until 1919, and the author of numerous text-books on chemistry, on October 22, aged eighty years.

Prof. W. Kilian, professor of geology and mineralogy in the University of Grenoble and member of the Paris Academy of Sciences, aged sixty-three years.

Sir John Struthers, K.C.B., formerly Secretary of the Scottish Board of Education and a trustee and sometime vice-chairman of the Carnegie Trust, on October 25, aged sixty-eight years.

Current Topics and Events.

At the annual statutory meeting of the Royal Society of Edinburgh held on October 26, the president, Sir Alfred Ewing, delivered an address on some of the modern aspects of physical research. He said that the functions of a scientific society are to provide (1) facilities for intercourse, formal and informal; (2) a library of reference; and (3) a means of publication. The records of scientific research are not a readily marketable commodity and would fare badly if they were left to depend on the laws of supply and demand. Looking back through the old publications of the Royal Society of Edinburgh would disclose many papers by Kelvin and others which may without exaggeration be described as marking epochs in the history of discovery. The urge towards scientific research is not mainly utilitarian, but arises from a special type of intellectual curiosity. A scientific society is, consciously or not, propagandist in that it extends an interest in science beyond the bounds of the scientific workers. There is, in fact, a greatly changed attitude now towards science and the scientific method. Research has now found a place not only in manufacture and in industry, but even in the budgets of the politician. The foundations of the older physics have been rudely shaken, with a notable effect on the mental attitude of the scientific expert. The old positiveness is gone. We are faced with dilemmas from which there is apparently no way out. For example, how to reconcile the facts of interference and diffraction with the equally well-established facts of absorption and photo-electricity, we simply do not know. Hence, along with the pride of achievement in all this notable progress, there is mingled a consciousness of mystery and humility. The widening of the circle of light has made wider the circumference of darkness which, for the moment at least, seems curiously impenetrable.

THE Therapeutic Substances Act which was recently passed provides for the regulation of the manufacture, sale, and importation of vaccines, sera, and other therapeutic substances, and requires that these substances shall comply with standards to be prescribed for their strength, quality, and purity. In order to provide facilities for carrying out the necessary tests, the Pharmaceutical Society of Great Britain decided to establish and equip laboratories for that purpose, and has appointed Dr. J. H. Burn as the Director. Dr. Burn was educated at Barnard Castle School, and gained an open scholarship in natural science at Emanuel College, Cambridge, afterwards obtaining a first class in the Natural Science Tripos. With the exception of two and a half years' war service, Dr. Burn has devoted himself mainly to research work in physiology carried out under Prof. Joseph Barcroft, Sir F. G. Hopkins, and, at the National Institute of Medical Research, under Dr. H. H. Dale. In this Institute he directed his attention chiefly to the examination of the methods for testing biological products the activity of which cannot be determined by chemical assay. Dr. Burn has published, chiefly in the *Journal of Physiology*,

numerous papers on the testing of pituitary extract, neo-salvarsan, etc. It is intended that the new laboratories shall be used not only for routine testing by biological methods, but also for carrying out researches in pharmacology, and it may be confidently expected that, under Dr. Burn's expert guidance, they will play an important part in the scientific development of organotherapy, to which increasing attention is now being devoted.

In an address given on October 21 before the British Commercial Gas Association meeting at Plymouth, on the "Conservation of the Nation's Store of Solar Energy," Prof. J. W. Cobb dealt with the relative economy of alternative methods of utilising our coal supplies. Our requirements of artificial heat exceed what can be obtained directly from the sun or indirectly from the growth of "fuel crops" from year to year, or even from century to century. We depend on an accumulated store of fossilised fuel. In the use of coal we are actually drawing on a wasting store. The conversion of coal into electricity involves a loss of 80-90 per cent. in the power station itself, and this loss must be regarded as an extravagance where the distribution of heat for most purposes is concerned. The loss is much reduced when the coal is first carbonised and the gaseous and solid carbonisation products are used as fuel. The initial loss is then some 20 per cent. only, and this loss is compensated by the increased value and efficiency in use of the products. The carbonisation of coal at lower temperatures than customary now, is beset with difficulties both technical and commercial, the nature of which was indicated, but it seems probable that the gas and coke industries will adapt themselves to supply the smokeless fuel which public opinion is demanding ever more insistently.

THE first annual report to the Court of Governors and the report on the work of the Tropical Division for the year ended July 31, 1925, of the London School of Hygiene and Tropical Medicine, describe the progress made under the directorship of Dr. Andrew Balfour in the foundation of this new school. On August 1, 1924, the London School of Tropical Medicine became an integral part of the new school and its first working division. Mr. Morley Horder has been appointed architect, and it is expected that the foundation stone of the School will be laid on the site in Gower Street during the session 1925-1926. The Trustees of the Rockefeller Foundation have generously agreed that the promise of two million dollars made in February 1922 shall be interpreted as 460,830*l.*, the value in sterling of the sum promised at the time of the original undertaking. Of this, 52,610*l.* has been expended by the Ministry of Health on the purchase of the site. Concurrently with the preparation of plans for the new building, the Education Committee and the Director have drawn up a provisional scheme of studies. The Board has recognised the necessity for taking early steps to secure the services of the prospective heads of Divisions,

and to this end, and in order to supplement the teaching for the Diploma of Public Health, the University Grants Committee has made provision for a grant of 5000*l.* for the year ending July 31, 1926, supplemental to the grant of 2300*l.* made in the past to the London School of Tropical Medicine. This sum of 7200*l.* is available for the work as a whole, apart from the sum of 4000*l.* provided annually by the Rockefeller Trust for the general work of administration. The steps taken by the Board as a result of the Treasury grant of 5000*l.* will include application to the Senate of the University of London to set up Boards of Advisers for the appointment of professors, and in the meantime the securing of advice and assistance from competent authorities in regard to planning, equipment, and organisation. Arrangements will also be made for lectures in physiology as applied to hygiene, and in bio-chemistry, and for progress in the equipment and organisation of the Museum.

THE Director's report on the work of the Tropical Division of the London School of Tropical Hygiene and Medicine sets forth the activities of the various departments and the extent of the research work undertaken. Arrangements have been made with the Government of Southern Rhodesia for the prosecution of medical research in that colony. A Research Fellowship in Comparative Pathology has been established, and the holder has assumed the duties of pathologist to the Zoological Society. A Research Fellowship in Spirochaetosis has also been founded, while there are hopes that an Entomological Field Station will be set up at the Air Ministry's Camp at Halton, Bucks. In regard to the instructional courses given in this Division a notable change has been made. Owing to the increasing congestion of the courses of study it has been decided to conduct only two courses each year in place of the three previously held. It is anticipated that this change will increase the educational value of the teaching, and enable more attention to be paid to the subject of tropical hygiene.

In the *World's Health* for October an interesting account is given by Captain Reuterskiold of the aerial ambulance in Sweden. There are vast districts with comparatively large populations which are totally deprived of means of locomotion during part of the year. In winter the roads are obstructed by snow-drifts, and in summer many villages may be isolated by floods caused by the melting snows. In these circumstances it was decided to make a trial of aerial transport, and the Government in 1923 agreed to share the expense of purchase of an aeroplane with the Swedish Red Cross. A Bréguet biplane was chosen, with a 300 H.P. 12-cylinder water-cooled Renault engine, capable of carrying two stretcher cases with one attendant. Wheels were impracticable and were replaced by skis, and a pair of floats were added to facilitate landing on water. Military airmen piloted the machine, and the service began in December 1924. During the winter eleven patients were transported. One patient, suffering from hæmorrhage and living in a very isolated district,

was transported to Boden in an hour and a half, whereas the journey by sledge would have taken twenty hours, thus gaining eighteen and a half valuable hours.

THE first article in the Journal of the Franklin Institute for September, entitled "The Way of the Wind," is contributed by Dr. W. J. Humphreys, of the United States Weather Bureau. In it he discusses, mathematically and physically, the main factors that cause the wind to blow apparently "where it listeth," the mathematical treatment dealing with what must happen, if the initial assumptions made are both accurate and complete, and the physical considerations seeking to elucidate what actually does happen. Recent advances in the theory and practice of wireless propagation are ably summarised by Dr. A. S. Eve, and a technical paper on the action of hydrogen peroxide on photographic plates containing a single layer of silver halide is communicated by Dr. C. E. K. Mees, of the Eastman Kodak Company. Such plates are only very slightly attacked by hydrogen peroxide, and the investigation tends to uphold the view that the action of this reagent on ordinary plates is due to chemiluminescence. Irregularities in the variation of certain properties of zinc with the temperature are frequently ascribed to the existence of allotropic modifications of the metal, and this hypothesis has been studied in the research laboratory of the New Jersey Zinc Company by means of X-ray analysis and re-determination of the lattice structure of pure zinc. As no change was observed in the X-ray spectrograph at atmospheric pressure and between 20° and 400° C, it is concluded that no allotropic transformations occur within this range of temperature. As usual, the Journal also contains a number of excellent abstracts of publications issued by the Bureau of Standards and other government departments, and reviews of recent scientific publications.

DR. C. G. ABBOT, director of the Astrophysical Observatory, Washington, and secretary of the Smithsonian Institution, will deliver a popular lecture before the Royal Meteorological Society on November 11. The title of the lecture will be "Measuring the Sun's Rays."

THE Huxley Memorial Lecture of the Royal Anthropological Institute will be delivered on Tuesday, November 24, at 8.30, at the Royal Society, by Sir Arthur Evans, who will speak on "Early Nilotic, Libyan, and Egyptian Relations with Minoan Crete."

A CONFERENCE on recent developments in the manuring of potatoes will be held at the Rothamsted Experimental Station on Friday, November 20, at 11.30 A.M. The speakers will include: Sir John Russell, Mr. J. C. Wallace, Mr. R. W. Wheldon, and Mr. T. Eden. Those intending to be present are requested to communicate with the Secretary, Rothamsted Experimental Station, Harpenden.

WE are officially informed that in view of the large number of overseas exhibits which are to be trans-

ferred to the Imperial Institute from Wembley, and of the extensive reorganisation which this will involve, it has been decided to close the Institute Galleries entirely from November 1 for three months. The lectures to the public and to school parties, usually given in the galleries, will also be suspended for that period. While the temporary closing of these important galleries—the permanent exhibition of Empire resources—and the interruption of their educational work are to be regretted, we are sure that the decision will be amply justified in the greatly enhanced interest and attractiveness of the collections.

A NEARLY complete skeleton of a new species of the Iguanodont Dinosaur *Trachodon* has just been mounted in the museum of the Geological Committee at Leningrad. The specimen was found in an Upper Cretaceous conglomerate on the Amour river, a little below the mouth of the Ayan, and is now being studied by Dr. A. Riabinin, who has published a preliminary note on it, with a photograph, in the Committee's Proceedings. The backbone measures nearly 8 metres in length, and when walking the reptile would be about $4\frac{1}{2}$ metres high. The species seems to be closely related to the *Trachodon* (*Claosaurus*) *annectens* described by Marsh from a corresponding geological formation in Wyoming, U.S.A.

APPLICATIONS are invited from natural-born British subjects of either sex of not more than 30 years of age for the Harrison Memorial Prize, the value of which is about 150*l.* The prize if awarded will be to the candidate who, in the opinion of the selection committee, during the previous five years has conducted the most meritorious and promising original investigations in any branch of pure or applied chemistry and published the results of those investigations in a scientific periodical or periodicals. Applications should be made by, at latest, December 1 to the President, The Chemical Society, Burlington House, Piccadilly, W.1.

NOTICE is given by the Chemical Society that a meeting of the research fund committee will be held in December. Applications for grants must be made on or before Tuesday, December 1, on forms obtainable from the Assistant Secretary, Chemical Society, Burlington House, Piccadilly, W.1. The income arising from the donation of the Goldsmiths' Company is more or less especially devoted to the encouragement of research in inorganic and metallurgical chemistry, and the income from the Perkin Memorial Fund is applied to investigations relating to the problems connected with the coal-tar and allied industries.

THE following officers have been elected for two years by the Australian National Research Council: *President*, Sir David Orme Masson; *Vice-Presidents*, Sir Edgeworth David, Sir Baldwin Spencer, Sir George Knibbs, Mr. J. H. Maiden; *Hon. Secretary-Treasurer*, Mr. R. H. Cambage; *Joint Hon. Secretary*, Prof. A. C. D. Rivett. At the annual meeting held in Sydney in August it was decided to endeavour this year to obtain from private sources a sub-

stantial permanent endowment in order to place the Research Council on a firm and independent financial footing. It was resolved also to retain membership of all the International Unions. In the case of the Union of Pure and Applied Chemistry, the Australian Chemical Institute will co-operate with the Research Council in conducting all local activities of the Union.

THE Leeds Philosophical and Literary Society is one of the oldest institutions of its kind in Great Britain, having recently celebrated its centenary. The Society helped effectively to bring the University of Leeds into existence, and is now in close association with the University. It is appropriate, therefore, that opportunities should be provided for the communication and publication of original papers, and arrangements have been made for these purposes. There is now a section for mathematics and the various natural sciences, and its programme, as well as the issue of a revived "Proceedings," are in the hands of a special committee, consisting this session of Prof. P. F. Kendall, Dr. Harold Wager, and Prof. R. Whiddington. The 106th session of the Society was opened on October 20 with a presidential address by Prof. W. Garstang on "Wordsworth Interpretation of Nature." There was a meeting of the scientific section on November 3, and there will be another on January 27. On February 10 next, Prof. D'Arcy W. Thompson will lecture on "The Labours of Hercules and their Astronomical Significance."

ELECTROPLATERS and electrodepositors have long felt the need for a society in London in which they could discuss problems arising from their work and could come into contact with scientific electrochemists, particularly those engaged in research work on electrodeposition. At the suggestion of the Council of the Faraday Society, a small provisional committee was recently formed to take steps to found an Electroplaters' and Depositors' Technical Society, and a meeting to inaugurate this Society will be held on Wednesday, November 11, at 8.15 P.M., at the Northampton Polytechnic Institute, Clerkenwell, London, E.C.1. All actively engaged in some responsible position in electroplating, or in the art of electrodeposition, are to be eligible for membership, and it is suggested that there should be two types of meeting: (1) Meetings at which lectures will be given, or papers read, followed by discussion. The papers presented would be offered for publication to some suitable technical journal. (2) Informal discussions opened by a short paper. The latter meetings would be attended by members only and no report would be published. In view of the desire of the electroplating trade to have a link with a scientific body and to be associated with the name of Faraday, the Council of the Faraday Society has agreed that the new Society be described as "Associated with the Faraday Society," provided that it has representation on the committee. The acting honorary secretary of the provisional committee is Mr. F. S. Spiers, secretary and editor of the Faraday Society, 90 Great Russell Street, London, W.C.2

IN the issue of NATURE of October 17, p. 574, Fig. 4 of Major Burnett's letter on "Bordered Squares of Fifth Order and their Magic Derivatives" was erroneously not magic in one of its diagonals. The square should be

24	14	18	1	8
(17)	(6)	(15)	20	7
(16)	(10)	(12)	23	4
(5)	(25)	(11)	2	25
3	13	9	19	21

APPLICATIONS are invited for the following appointments, on or before the dates mentioned: An experimental officer in the Acoustical Experimental Section of the War Office—The Secretary, Royal Engineer Board, 16 Grosvenor Gardens, S.W. 1 (November 8). A travelling lecturer in electrical

engineering under the Glamorgan Education Committee—The Chief Education Officer, County Hall, Cardiff (November 10). A lecturer in the department of mathematics and mechanics of the Technical College, Sunderland—Chief Education Officer, 15 John Street, Sunderland (November 17). A lecturer in the department of education of King's College, London—The Secretary, King's College, Strand, W.C. 2 (November 18). A senior and a junior investigator in the department of metallurgy of the University of Sheffield for work on the electrodeposition of metals—The Registrar, University, Sheffield. A lecturer and demonstrator in the mechanical engineering department of the Borough Polytechnic Institute—The Principal, Borough Road, S.E. 1. A commercial assistant to the director of the Electrical Research Association—The Director, B.E. & A.I. Research Association, 19 Tothill Street, S.W. 1.

Our Astronomical Column.

COMET 1925a (SCHAIN, COMAS SOLA)—Prof. J. Comas Sola, of Barcelona, one of the discoverers of this remarkable comet, has now succeeded in detecting it in the morning sky on its emergence from the sun's rays, which have concealed it for several months.

The position is as follows

	UT	RA 1925.0	S Decl	Mag
Oct 18 ^d	4 ^h 38 ^m 25 ^s	10 ^h 22 ^m 10 ^s .6	5° 48' 22"	12.5

The correction to his ephemeris is -20^s , $-4'$ 6", which is satisfactorily small. This has been applied to the following ephemeris (for 0^h)

	RA	S Decl	log r	log Δ
Nov 9	10 ^h 17 ^m 33 ^s	8° 17'	0.6288	0.6560
17	10 13 59	9 13	0.6299	0.6428
25	10 9 4	10 10	0.6312	0.6286

The comet, which has the largest perihelion distance known, is now slowly receding from the sun, but approaching the earth fairly rapidly. There is reason to hope that it will be followed for another year, perhaps longer, which should permit accurate determination of the departure of the orbit from a parabola.

LARGE DETONATING FIREBALL.—Mr. W. F. Denning writes: "On October 22 at 10 h. 44 m. P.M. a brilliant fireball was observed at many places in Ireland. As observed from Co. Waterford, its path was from west to east from a few degrees below Polaris towards a point a few degrees below Castor and Pollux. The nucleus at first displayed an intense electric-blue colour and then burst into a strong, red, egg-shaped mass. As seen from Antrim, the meteor with its glare lit up the whole country and apparently had a disc as big as the full moon. Six and a quarter minutes after the object had disappeared, the observers distinctly heard two heavy thuds like the distant report of heavy artillery, followed by a prolonged rumble akin to thunder. The duration of flight was about five seconds, but the observer at Waterford did not listen for any sound, while at Antrim it was specially awaited so that the time interval given (6½ minutes) may be depended upon as being correct. This estimate corresponds to a distance of about 75 miles. It is hoped that further observations will come to hand so that the real path of this fine object may be computed."

WOLF'S NOVA IN AQUILA.—Dr. W. H. Steavenson gave an account of this remarkable object at the

October meeting of the British Astronomical Association. A slide was shown from a plate of the region taken at Königstuhl about a year ago. This showed stars as faint as mag. 16.5, but there was no trace of the supposed Nova, which is not found on any plates taken there until September 1925. It is possible, however, that study of the Harvard plates may reveal more about the circumstances of its rise. It has been well observed in England by the B.A.A. Variable Star Section. Since discovery, its magnitude has fluctuated between 8.6 and 9. There seemed to be a tendency to decline, but this was followed by a slight recovery.

The spectrum has been studied with an objective prism at Babelsberg Observatory, Berlin. It was continuous, apparently without visible lines, bright or dark, from the distribution of intensity of light, its spectral type was concluded to be approximately G. The star is outside the main stream of the Milky Way, but in one of its faint extensions.

THE TURKISH CALENDAR.—The Turkish Calendar has hitherto been a very singular one. It simply consists of 12 lurations, or 354½ days. There is no intercalary month, such as was inserted (seven times in nineteen years) by most of the ancient nations which used lunar months, consequently the beginning of the year travels right round the solar year in about thirty-three years.

The following data are quoted from the Nautical Almanac

Year	Turkish Year begins	Ramadan begins
1922	Aug 24	Apr 28
1923	" 14	" 17
1924	" 2	" 6
1925	July 22	Mar 26

These are not the dates of new moon, but about two days later, since they await the visible crescent.

The Times of October 26 contains the welcome announcement that a bill for the adoption of the Gregorian Calendar will shortly be laid before the Grand National Assembly. Its adoption would render the use of the Gregorian Calendar general through Europe. It will be remembered that Greece recently adopted a calendar practically identical with it, though it was decided to use the true moon instead of the ecclesiastical moon in computing Easter.

Research Items.

JAPANESE BATTLEDORE AND SHUTTLECOCK.—Mr. Stewart Culin, in the *Brooklyn Museum Quarterly* for September, illustrates and describes a number of Japanese battledores and shuttlecocks, which are used in the shuttlecock play of girls in the streets on New Year's Day, according to an old custom universal among high and low all over Japan. The battledore (*hagonta*) is a flat wooden bat brilliantly painted, or covered with crape pictures in relief. Those much sought by collectors are old ones used by girls of rich families, and they are covered with conventional pictures on a plaster ground and bear family crests. The pictures on many of these of archaic design are conventionalised and broken down court scenes which are connected with the Sagicho ceremony. This was one of the most important annual celebrations in the Japanese Court, occurring on the 14th, 15th, or 18th day of the first month, when the New Year decorations were burned. Comparison of a number of designs shows that the battledore as it now exists was derived from similar objects used in court ceremonial. The shuttlecock is now a seed with feathers attached to a bamboo splint stuck in the seed or with the feathers stuck directly into the seed itself. It clearly suggests a plum blossom. In a catechism published in 1544 the shuttlecock is said to be a charm against mosquito bites, and it is compared in its flight and appearance to the dragon fly, which catches and eats the mosquito.

A GEBER DISCOVERY.—In the *Archiv für Geschichte der Medizin* (Bd 17, Heft 4, 1925) Dr. Ernst Darmstaedter announces an extremely interesting and important discovery in connexion with what has come to be known as the "Geber problem." The identity of Geber with Abū Mūsā Jābir ibn Ḥayyān (about A.D. 750–800) has already been sufficiently proved; the outstanding question is whether the Latin works of Geber are translations from Arabic works of Jābir. Arabic influence in the *Summa perfectionis* and in the other books is very obvious, but no Arabic originals have hitherto been discovered. In a thirteenth-century manuscript at Florence, however (Cod. Riccardianus 933, Lii 9), Dr. Darmstaedter has been fortunate enough to find a Latin translation of the Book of Mercy (*Kitāb al-Rahma*), which is an expansion of one of Jābir's books by a follower of his, and of which the Arabic text has been published, with a French translation, by Berthelot (*La Chimie au moyen âge*, tome 3, Paris, 1893). The importance of this discovery lies in the fact that the manuscript contains also, and in the same hand, the *Summa perfectionis* of "Geber" and the *Liber Geberis de investigatione perfectionis magisterii*. It is thus clear that the celebrated *Kitāb al-Rahma* existed in a Latin form more than 600 years ago, and the association of it with the *Summa* and *De investigatione* in the same manuscript is at least strong presumptive evidence that these too may well be, in the main, authentic translations from the Arabic, as they were for so long considered to be. Dr. Darmstaedter's discovery raises even higher the hope that a diligent search may yet bring to light the Arabic texts of the Latin treatises.

PRESERVATIVES FOR NATURAL HISTORY SPECIMENS.—Prof Gordon E. Gates, professor of biology in the University of Rangoon (Judson College), asks for information on the use of a tincture of calabar bean as a preservative for natural history specimens, referred to by a correspondent in *NATURE* so long ago as October 20, 1881 (vol 24, p. 583). Major E. E. Austen, Natural History Museum, South Kensington, has been good enough to favour us with the follow-

ing information upon the subject: "The use of a tincture of calabar bean as a preservative for entomological and other natural history specimens, although strongly urged by the writer of the note to which Prof Gates refers, would seem to be nowadays practically, if not entirely unknown. The seeds of the calabar bean (*Physostigma venenosum*, Balf.) are highly poisonous, the alkaloid physostigmine, which constitutes the active principle, having a depressant action on the spinal cord. As a preservative from the attacks of destructive insects, for use in museums and entomological cabinets, the strength of the tincture was given as 'one part of the bean to eight of (rectified?) spirit,' the mode of employment being, in the case of Lepidoptera, to place a drop of the fluid on the body of the specimen. As regards entomological collections in the tropics, especially during the rainy season, mould is often a more formidable foe than even ants, book-lice (Psocidæ) or certain beetles. The risk of mould as well as damage by insects may, however, be entirely prevented by thoroughly rubbing the inside of the box into which the specimens are pinned with a piece of sponge, or swab of cotton-wool, soaked in a saturated solution of naphthalene in chloroform, mixed with an equal quantity of ordinary medical (beechwood) creosote. The inside of the box should be rubbed with the mixture until the cork-lining shows through the paper, but the fluid must not be allowed to touch the specimens, or they will be injured."

HERMAPHRODITISM IN DECAPOD CRUSTACEA.—Until recently it was believed that all decapod Crustacea were of separate sexes. Wollebaek described the occurrence of normal functional hermaphroditism in the deep-sea thalassinid *Calocaris* in 1909 and Spitschakoff in the prawn *Lysmata* in 1920. Sven Runnstrom (Beitrag zur Kenntnis einiger hermaphroditischen Dekapoden Crustaceen. Bergens Mus. Skr., ny Raekke, Bd 3, No. 2) has now made a detailed study of *Calocaris*, and describes the histology and cytology of the gonads in all the phases of development. At first no difference can be observed between the germinal cells, but at an early stage the anterior and posterior ends of the gonad begin to show the development of oocytes while the middle part assumes the character of a testis. The development of the ovarian regions lags behind that of the testicular portion, which grows out into numerous follicles within which spermatozoa are produced. When the male phase has been passed through the follicles dwindle and oocytes begin to appear in the middle part of the gonad, the whole of which in the final phase functions as an ovary. It is noted that, in the middle part, oocytes are produced from germinal cells which have lain dormant while neighbouring cells, at first indistinguishable from them, have gone through the stages of spermatogenesis. The author has also investigated certain other decapods, especially the crayfish *Parastacus*, in which rudimentary non-functional hermaphroditism occurs constantly. The general structure of *Calocaris* shows no preponderance of the characters of either sex. It is a true hermaphrodite, a mosaic of the two sexes. Many interesting details are given of the habits of the animal as observed in an aquarium. *Calocaris* appears to feed exclusively on the mud in which it burrows. It was found to seize fragments of mussel offered to it, but, instead of eating them, it buried them inside its burrow, where their decay speedily enriched the surrounding mud with swarms of Infusoria. No doubt the culture so manured served later as food for the crustacean.

BACTERIOPHAGE AND PLANT DISEASE ORGANISMS.—According to a recent paper by G. H. Coons and J. E. Kotila, plant bacteriologists have also to take into account the d'Herelle phenomenon, and lytic principles may be demonstrated which have an inhibiting effect upon the growth in pure culture of organisms responsible for various plant diseases (*Phytopathology*, July 1925). These lytic principles may be increased in effectiveness by "growth" upon the cultures they destroy, the filtered extract of these cultures, sterile as regards contained organisms, proving more efficient as a lytic agent than the original extract used to inoculate the culture. The authors suggest that such lytic principles may be widespread in Nature and may account for the disappearance of a pathogen from a heavily infected soil. By smearing such a lytic principle over sterile slices of carrot they protected these slices against the rotting effects of the well-known *Bacillus carotovorus*. Such organisms are so readily experimented with in culture that if further work should confirm these results, we may anticipate a considerable study of the d'Herelle phenomenon by experimental investigation with the organisms causing "soft-rots" in vegetables.

CROWN GALL IN PLANTS AND CANCER.—It will be recalled that Erwin F. Smith has directed attention to the secondary gall-like growths sometimes formed in plants after infection by *Bacillus tumefaciens*, and suggested that they owe their origin to the permeation of the normal tissue by "tumor strands," growing from the original gall in an analogous manner to that in which human cancer may spread. Furthermore, E. F. Smith, in an account of his recent tour round European centres of cancer research (*Science*, April 17 and June 12, 1925), has briefly indicated that German workers upon cancer are now obtaining very interesting results in work upon animals inoculated with an organism which is said to be indistinguishable from that found in the crown gall of the plant. The Manchester workers Robinson and Walkden (*Nature*, June 23, 1923, p. 858) were unable to confirm Smith's account of the origin of these secondary tumours in the case of crown gall on plants, and now Michael Levine publishes (in *Phytopathology*, August 1925) the results of extensive studies of crown gall, in which he finds that secondary tumours and strands are only formed in very young tissues and result from the growth and elongation of these immature tissues. They begin to form simultaneously with the crown gall at the seat of inoculation, and are in no sense the result of the permeation of normal tissues by subsequent strands of "malignant" tissue.

THE SYSTEMATIC POSITIONS OF THE PTERODACTYLA AND CHELONIA.—In the *Bulletin of the Geological Institution of the University of Upsala*, Vol. 19, 1925, appear three papers of great interest, two by Prof. Wiman on the Pterodactyla and one by Dr. Zdansky on the Chelonia. Prof. Wiman, writing on Dorygnathus and other pterodactyles, gives a full description of the skeleton together with illustrations. In discussing the systematic position of the group he is unable to accept its usual derivation from some form in the neighbourhood of the Pseudosuchia and considers that the Pterodactyla, although having two temporal vacuities, are not really diapsid in skull structure since the arrangement of the bones surrounding the vacuities is not strictly comparable. As to the real ancestry of the group, apart from a mention of Araeoscelus, the author prefers to take a non-committal and waiting attitude. Prof. Wiman's second paper deals with the probable life habits of the pterodactyles. Dr. Otto Zdansky's paper, also with numerous figures, deals with the temporal region

of the skull of the Chelonia in support of his thesis that the skull structure of the Chelonidea is a secondary condition.

VARIATIONS OF SEA TEMPERATURE AND SALINITY.—In the *Bulletin Hydrographique* for 1924, recently issued by the Conseil Permanent pour l'Exploration de la Mer at Copenhagen, there are published tables showing variation in salinity and temperature of the sea with position, season, and depth, being the data collected by the participating countries in the Atlantic, North Sea, and Baltic. The region between North Ireland and the African coast, including the English Channel, is dealt with in the *Rapport Atlantique*. The degree of saturation with oxygen and the hydrogen ion concentration of the water is given for a number of positions. The lowering of the hydrogen ion concentration in the upper layers to which light penetrates, owing to the utilisation of carbon dioxide by diatoms, is very clearly shown. No deductions, drawn from the collected data, are published in the *Bulletin* concerning the flow of the ocean currents, their seasonal variations or fluctuation year by year. Such fluctuations are of particular interest in fishery research. A bibliography of the year's publications by workers in the different countries is included, and of these a fair share now comes from Great Britain.

PRODUCTION OF LOW FREQUENCY OSCILLATIONS.—We recently published in *Nature* (vol. 116, p. 244) a letter from Mr. C. Constançon describing a device for obtaining low frequency oscillations. He used a three-terminal thermionic valve and instead of varying the inductance in the ordinary way by altering the position of the iron core, he varied it by means of direct current excitation. One obvious advantage of this method is that we maintain the symmetry of the inductance of the circuit. In connexion with this method we have received a letter from Prof. D. Mazzotto, of Modena University (Italy), in which he describes an invention which he calls "le triode melodique." This device, which was described in *Scienza per tutti* for May 1, 1924 (p. 134), and March 1, 1925 (p. 76), enables us to get variable low frequency oscillations even more simply. He uses the same kind of valve and a low frequency transformer with an iron core. By touching the plate wire to the various terminals of the high-tension battery, various notes are heard in the telephones. Instead of using the terminals of the battery it is better to make a potentiometer arrangement, so that the sound can be continuously altered. By using a suitable key any piece of music can be produced in this way. The principle of the method seems to be the same as that described by Constançon.

ELASTIC HYSTERESIS IN ROCK SALT.—Experiments have been recently carried out by Messrs. M. Polanyi and G. Sachs on rods of rock salt supported at the ends and weighted at the centre (*Zeitschrift für Physik*, August 22). The load was applied by means of a float in a vessel from which the water could be allowed to run off slowly, and simple polished rods of rock salt and others which had been heated to 600° C. were employed. With the polished rods the first observable permanent deformation took place with less than 500 gm. per sq. mm., and the rods broke with more than 1000 gm. per sq. mm. With the heated rods the deformations were larger, and the elastic limit was certainly below 200 gm. per sq. mm., but in both cases it was found that the more accurate were the methods of measurement the lower were the loads with which permanent alterations of form could be shown to exist. When the load on either kind of rod is slowly removed, and then slowly reimposed,

the load deformation curve does not repeat itself, and if this process is repeated several times between the same load limits, the curve forms a hysteresis loop somewhat similar to that observed in magnetisation, but with the difference that the "elastic" alterations of form on loading are proportional to the tension, but not when the load is reduced step by step. It is also shown that, when the surface layers of the plastically bent crystals are dissolved in water, movements result which show the existence of internal stresses.

THE DEBYE-SCHERRER RINGS OF DEVELOPED PHOTOGRAPHIC PLATES.—Messrs. R. Blunck and P. P. Koch, in the *Annalen der Physik* for September, describe a series of measurements of the Debye-Scherrer rings produced by a practically monochromatic beam of X-rays, using a preparation formed by exposing a photographic dry plate in strong daylight and developing it. The film was separated from the glass and fifteen discs were cut from it and superposed so as to form a little plate about 0.23 mm. thick. This was placed at the centre of the camera in the path of the X-ray beam, and a well-defined ring system was obtained indicating a face centred cubic lattice, with 0.403 Å.U. for the edge of the elementary cube, in good agreement with Vegard's value for silver. An inner ring was shown to be due to gelatin. Measurements of the broadening of the rings due to the fineness of the particles showed that the silver crystals were not smaller than 2.4 Å.U. It was possible to calculate the amount of silver in a single layer from the absorption of the X-rays, it amounted to 0.00065 gm. per sq. cm. The value obtained from the blackening, using the formula of Hurter and Driffield, was 0.00080 gm per sq cm.

UTILISATION OF FISH REFUSE.—An account of the uses of fish by-products in industry is given by A. C. Hopper in the *Chemical Trade Journal* of October 2. Fish meal which has been freed from oil is used for feeding live-stock, as a fertiliser, and as the basis of a plastic for making small moulded articles. Fish glue is widely used on account of its heat-resisting qualities, but freedom from chlorides and protein matter is essential for a good quality glue. Fish oils are used in tanning and in medicine. Oil tanning of skins requires an oil which is easily oxidised, having a high fatty-acid content. Fish oil yields excellent heat-resisting paints when used with tungate driers; drying is rapid if the oil is properly treated and has a low fatty-acid content. Fish oil free from sulphur can be hardened by hydrogenation, giving fats for soaps, candles, and margarine. Fish skins are used in the manufacture of a high quality leather. Further uses for fish products are the manufacture of printers' ink, enamels, lubricants, tool-hardening oils, and tarpaulins.

THE TRANSMUTATION OF METALS.—In *NATURE* last year (vol. 113, p. 459), Prof. Nagaoka, of Tokyo, gave his reasons for believing it possible by subjecting mercury to an intense electrostatic field to drive off from the nucleus of the atom a hydrogen nucleus and to add an electron and in this way produce gold. Since then (*NATURE*, July 18, 1925, p. 95) he has outlined his preliminary results. In the July issue of the *Journal de Physique* he describes his experiments in more detail. The mercury purified in the usual way was distilled two or three times in vacuo at 200° C. before use. It formed the lower electrode in a porcelain flask containing paraffin oil into which the upper electrode of iron dipped. The discharge was obtained from an induction coil giving a spark of

120 cm., and the author estimates the field above the mercury as of the order of 150,000 volts per cm. The discharge was maintained for 4 hours, and the black paste produced in the flask analysed for gold, which was found in minute particles. On heating small pieces of glass in the paste, they became ruby glass identical under the microscope with the ruby glass obtained from gold in industry.

PLATINUM.—A survey of the platinum metal industry by G. Malcolm Dyer appears in the *Chemical Age* of October 3. Most of the commercial platinum is obtained by careful washing of alluvial deposits; the material obtained in this way contains in addition, palladium, osmium, iridium, rhodium, and ruthenium. Tasmanian ore consists almost wholly of the alloy osmiridium. The anode slime from copper refining is another source of the platinum metals. The method of cupellation is no longer used in their separation, but the ore is treated with aqua regia, when platinum, palladium, rhodium, and some ruthenium and iridium dissolve, leaving the osmiridium. The osmiridium is alloyed with zinc and the product dissolved in aqua regia. Osmic acid is distilled off in superheated steam and the remaining acid liquor treated with ammonium chloride, and on standing, ammonium chloroiridate is precipitated, leaving ruthenium. The platinum liquor is treated with ammonium chloride, the chloroplatinate filtered off, and on standing the chloroiridate is precipitated. These salts yield the metals on heating. The remaining liquor is treated with zinc, the black mud filtered off and treated with dilute acid. On treatment with dilute aqua regia, only palladium dissolves, leaving rhodium with a trace of ruthenium. The residue is fused with barium peroxide, treated with aqua regia, and separated by means of the ammonium salts. The fusion of the metals is carried out in a furnace of lime in the oxyhydrogen blowpipe flame.

CONSTITUTION OF BINARY ALLOYS.—In a recent paper by K. Honda and T. Ishigaki (*Science Report of the Tohoku University*, vol. 14, No. 3, p. 219), on the depression of the freezing point of a metal by the addition of a second, an attempt has been made to extend the pioneer work of Heycock and Neville. The present research appears to have been very carefully carried out and affords valuable information in two directions. In the first place the authors offer good reason for the belief that, at any rate in the binary systems which they have studied, the solute metal is always in the monatomic state both where a eutectic and also where a solid solution is formed. In the iron-carbon system it is not clear whether the authors are correct in believing that the same state of affairs holds, since an unassociated iron-carbide, such as Fe₃C, would not be excluded by the results given. The second portion of the work deals with an investigation of the agreement of observed depressions of the solidification point with Planck's formula. The lowering of the freezing points of pure metals is shown to be proportional to the concentration of the added metal, so long as the solution is dilute. The atomic depression is independent of the nature of the solute, and of whether it forms a solid solution or not, and Planck's equation is shown to hold. The latter expression is used to obtain values for the latent heat of fusion of the solvent metal, and results are obtained in good agreement with those of direct observation. Since the latter are not always easily measured, it is possible that the new values are more reliable than older ones. The means of all the results recorded are:

Ag	Al	Bi	Cd	Cu	Pb	Pt	Sb	Ni	Sn	Zn	Au
24.0	81.3	12.5	12.2	41.7	5.85	26.7	38.7	51.9	14.3	26.0	15.3

The New Statutes of the University of Cambridge.

THE statutes of the University of Cambridge proposed by the University Commissioners were made public about a week ago. They occupy no less than sixty-nine pages of the *University Reporter*. Throughout they afford ample evidence of careful drafting, the final result of much deliberation and discussion.

We are not here concerned with such changes as the institution of a house of residents, or with the fact that in future the vice-chancellor is to be elected for a period of two years in the first instance, but rather with such proposals as will affect the various departments of science in the University. In many ways the proposed organisation will change scientific faculties far less than others. Each science school has been a financial unit for a long time; it has in practice organised all formal teaching in its own subject, and the more junior appointments (that is, demonstratorships) have been made by the professor. In most other branches of study, however, much has in the past been done by the colleges. They have financed and appointed their own lecturers, professors having no direct control in the matter. Until recent years many courses of college lectures were not immediately available to members of all colleges. Under the new scheme all formal teaching will be directly controlled by the University.

In the past the General Board of Studies was the co-ordinating body, and it worked through a system of special boards. Membership of the latter might be *ex officio* as in the case of professors, readers, and examiners, or upon nomination by the Council of the Senate, or by grouped junior members of departments. In the future there is to be a general board of the faculties with the powers of the old board, and in addition (presumably subject to the approval of the financial board) control of the salaries of the junior appointments. Eight of its thirteen members are to be elected by the faculty boards. Special boards are to be replaced by faculty boards, membership of which, *ex officio*, is limited to professors or heads of departments. Elected members are to be chosen by ballot at a general meeting of the faculty concerned.

These changes are important, because the powers of the new bodies are considerably greater than those of their predecessors. In addition to routine work, they will elect members of the new appointments committees which will appoint lecturers and demonstrators; they will have the power to institute and appoint to probationary lectureships, and to make recommendations to the general board on the subject of the salaries of the junior members of the staffs. From this system an increased uniformity in the scientific departments should result. In the past, the larger and less embarrassed departments have often been able to grant their staffs higher emoluments than have some of those the finances of which were more straitened. There is a prospect that the co-ordinating general board will now be in a position to ensure for equal work a reasonably uniform standard of remuneration in all faculties and departments.

It is difficult to forecast future events, but the intention of the Commissioners has evidently been to frame a constitution by which the junior members of a faculty can have the opportunity of securing reasonable representation on their board. Past experience has shown that, in the matter of nominating members of special boards, the junior staffs are often as apathetic as is the ordinary man in electing guardians of the poor. The Commissioners propose to

ensure that the machinery shall be there. They can do no more.

It may appear that undue stress has been laid on the financial powers of various bodies, but the strength of the University largely depends on its retaining the younger men most fitted for its purposes and in the past this has sometimes, for financial reasons, been difficult. The stipends of junior members of staffs are usually small, and unless accompanied by fellowship dividends are scarcely sufficient to allow a man to marry unless he happens to have private means. Outside work of some kind or other is usually obtainable, but frequently so much of it has to be done that there is little time left for the all-important research. The Commissioners are endeavouring to avoid this evil by making colleges reserve a proportion of fellowships for University officials, and further by permitting extra remuneration to be made to non-fellows. Time will show whether there is enough money available to implement these policies.

If the necessary funds are lacking, some non-fellows will be in a difficult position, as the University Commissioners, in their endeavour to avoid "sweating," have laid down a maximum number of hours of private teaching which may not be exceeded by university officers. A probationary lecturer giving one course of lectures, for which he will be entitled to draw a "basic" salary of about 160*l.*, will, if he is not a fellow of a college, find little by way of gilt on his gingerbread. The whole financial situation is obscure, faculties controlling few students will presumably have to be subsidised from the University exchequer, as are some scientific departments at the present time. It will be interesting to observe if any faculty can provide a surplus. Expected surpluses have a way of failing to materialise.

The conditions of tenure of various offices are to be changed. Professors are to retire at the age of sixty-five. This decision has been arrived at after several changes of policy. The original commission advocated it. The present one, after publishing an interim account of its intentions, in which it stated that it would increase the retiring age to seventy in certain circumstances, has now reverted to the first proposal. This change of plan threatens to do an injustice to any recently appointed professors who, assuming that seventy was the final decision, on accepting their new posts agreed to come under the provisions of the new statutes. Presumably adjustments will have to be made in such cases.

Lectureships are to be tenable for three years in the first instance, but on reappointment they are in general to continue until the retiring age. There are some who consider that this security of tenure may lead to doubtful efficiency, but as a lecturer's stipend will in the future depend chiefly on the amount of work he does in the department, their fears are probably groundless.

Demonstrators are to be appointed for three years, and are in no case to hold office for more than eight years. The underlying idea is that at the end of the latter period the faculty board will have to face the necessity of creating a new lectureship for a man if it wishes to retain his services. This will mean that each case will be carefully scrutinised, men of uncertain value will be sorted out on the one hand, and on the other, those of ripe middle age and undoubted distinction will no longer have to carry the somewhat juvenile title of demonstrator. On paper it seems as

if the whole scheme should work satisfactorily provided that it is not beyond the limits of the University chest

A change is contemplated in the organisation of biological faculties. The old special board of biology and geology consisted of twenty-eight members. Under the new scheme there will be two faculties, namely, Biology "A," including anatomy, botany, genetics, geology, parasitology, and zoology, and Biology "B," comprising biochemistry, pathology, physiology, with experimental psychology added. For certain purposes a "School of Biological Sciences" will be formed. It seems a little doubtful if any good result will be achieved by this splitting of what was a fairly natural grouping, if a large one.

The primary duty of the Commission was to adjust the relations of the University and the colleges, this has been done not only in the provision of reserved fellowships and in the centralisation of teaching activities, but also in the matter of contributions from the colleges to the University chest. In the

past, the colleges together have had to pay such a percentage of their combined incomes as provided the sum of 30,000*l.* per annum. In the future, definite rates of taxation are proposed by which the poorer colleges will pay less and the larger ones will pay more than heretofore. On the other side, the colleges are relieved from paying contributions on income derived from students. There are adjustments to be made during the transition period, and a rough calculation suggests that at first the sum due from collegiate sources will not greatly exceed the 30,000*l.* As the new order comes in, there should be an increasing sum available, and further, as colleges become more wealthy owing to benefactions or husbanded resources, the University will in its turn be able to expand its activities. It is too much to hope that the University will ever cease to be an active beggar, but the anomaly of the underpaid university officer serving through a university organisation the requirements of colleges, some outstandingly wealthy, should be removed.

International Meteorological Research.

THE Meteorological Section of the International Union of Geodesy and Geophysics met at Madrid at the beginning of October 1924, and the proceedings of the Section edited by the secretary, Prof Eredia, have now been published. Some doubt had been felt by those familiar with international meteorological organisation as to whether the Meteorological Section of the Geophysical Union could find a broad enough field of operations without encroaching upon the proper domain of the International Meteorological Committee. The report of the work of the Section at Madrid which is contained in the present volume ought to remove any doubt of this kind. There are points where the work of the Section touches the work of the International Meteorological Committee, and under the guidance of a president less familiar than Sir Napier Shaw with international meteorological organisation, the Section might have wasted a certain amount of time in the unprofitable discussion of questions belonging to the field of official administration. The minutes of the five meetings, one of which was held conjointly with the Sections of Hydrology, Oceanography and Terrestrial Magnetism, show that the Commission confined itself to the encouragement and development of experimental and exploratory work in meteorology.

One of the most important decisions, afterwards confirmed by the Union in general session, was to provide for the issue of a specimen volume of the observations of the upper atmosphere for a single year, collected from all the world. It is understood that this volume is now in course of preparation, and will represent a great advance not only in regard to the number of observations included but also more especially in regard to their presentation for scientific discussion.

Another important decision arose out of a discussion on the question of the establishment of an International Bureau. It was decided to make a subvention to an existing meteorological service for the execution of a piece of work of the kind that an International Bureau might be expected to undertake. Mr. la Cour, director of the Danish Meteorological Institute, was entrusted with the work selected, which consists in the preparation of an atlas of daily or twice daily synoptic charts for as large a portion as possible of the Northern Hemisphere for the third quarter of the year 1923.

The appendices to the proceedings contain some interesting proposals and some valuable data. The American delegates presented, among other things, a proposal to adopt Dr Marvin's suggestion for improving the Gregorian calendar. The suggestion is, briefly, to have a year of 13 months and a quarter of 13 weeks. There would be an odd day to dispose of in ordinary years and 2 days in leap years. The Commission approved of having 52 weeks in the year, one of the weeks being a week of 8 days, and decided to recommend the Advisory and Technical Committee on Communications and Transit of the League of Nations to take into consideration as soon as possible the simplification of the Gregorian calendar. In a matter of this kind there does not appear to be special need for urgency, the need appears to be rather for discussion and deliberation. A change in the calendar is, and ought to be, an infrequent event, but when a change is made it ought to be as much of an advance as humanity can stand. It seems a pity that the Commission did not tackle the question of the length of the week, it is fundamental. There appears to be no reason why the 7-day arrangement which commended itself to pastoral oriental people 3000 years ago should be suited to western urban civilisation of to-day. Many facts indicate that it is not. A break at the end of 6 days is too soon for the man who has a piece of work in which he is really interested, it is too late for the man who is not specially interested in his work. Consequently the latter, nowadays, usually has a mid-week half-holiday. A 10-day week with a secular mid-week holiday might be better for all concerned. It would save us from the numerical inconvenience and the ill omen of 13 months in the year.

Another appendix deals with the subject of radiation in relation to meteorology. A table giving the radiation of black earth at various temperatures will prove most useful for reference by all students of meteorology and ought to find its way into all standard collections of meteorological tables. The tabulated values of actual radiation recorded at various places, given on pp 94-121, provide the first systematic collection of observations of radiation, and their issue should lead to the adoption of an international form for the publication of such records in future. The variety of forms and units now in use is an obstacle to research which might well be removed.

E. GOLD.

Suggestion and Personality.

A PAPER with the above title was read by Dr William Brown before the Psychological Section of the British Association at the recent meeting at Southampton. Dr. Brown holds that the two forms of theory and practice in the field of psycho-therapy, namely, suggestion and auto-suggestion on one hand, and mental analysis (including the special Freudian system of psycho-analysis) on the other, can be harmonised, and that a sound system of psycho-therapy should satisfy the more moderate claims of both.

Different views are held by psychologists as to the relationship of suggestion to hypnosis. According to the Salpêtrière School (Charcot, Janet), hypnosis is an artificial hysteria or mental dissociation. According to the Nancy School (Bernheim, Coué, Baudouin), hypnosis is a state of artificially increased suggestibility. According to the Freudian School, suggestion is explained in terms of "transference," and when symptoms are removed by suggestion treatment, no real cure has been produced, but the symptoms have merely been replaced by another symptom, namely, psycho-sexual dependence of the patient upon the physician.

Dr. Brown, as a result of his experiences with hundreds of shell-shock cases, agrees with the definition of the Salpêtrière School, as he found that his patients were readily hypnotisable and in direct proportion to the degree of their mental dissociation. Further, the suggestibility, though certainly increased in milder degrees of dissociation, was often conspicuous by its absence in more pronounced degrees of dissociation. Dr. Brown also holds the view that the Freudian theory is refuted by the facts of auto-suggestion as well as by the working of suggestion in very early life, before the fact of transference could have any validity. It was admitted, however, that the question of whether suggestion is always a libidinal relationship is not entirely free from doubt, especially in view of an original and important theory by Dr. Ernest Jones, who explains all suggestion in terms of narcissism.

In conclusion, the relation of suggestion and auto-suggestion to the will was considered. It has been noted that in the attempt to recall a forgotten name, anxious effort to remember generally brings failure. Coué would explain this by his so-called Law of Reversed Effort. "When the will and the imagination are in conflict the imagination always wins." Dr. Brown's view is that such a formulation is only true of states of incomplete will where fear of failure has prevented the full development of volition. Most cases of successful auto-suggestion are characterised by avoidance of thoughts and fears of failure, and may therefore be considered as instances of supplementation and completion of the volitional process by means of adequate control of the imagination.

Finally, auto-suggestion must be supplemented extensively by what Dr. Brown terms "autognosis." In the course of mental analysis the patient obtains a more and more objective view of the past course of his mental life. He understands more clearly in what respects he has failed in the past to adjust himself adequately to the demands of life and to the peculiarities of his own nature. This process of intellectualisation of the mind is one of the most important factors of cure in the course of mental analysis. By such a course the patient is rid of complexes and other dissociations and is thus enabled to face the world with a unified personality.

University and Educational Intelligence.

CAMBRIDGE.—Mr. A. B. Ramsay, lower master of Eton, has been appointed master of Magdalene College in succession to the late Dr. A. C. Benson.

The General Board of Studies has approved that the degree of doctor of science shall be conferred on Mr. H. Hamshaw Thomas, lecturer in botany, who has for some years been engaged in investigating fossil angiosperm plants of Jurassic age from the Yorkshire coast.

Prof. V. H. Blackman, of the Imperial College of Science and Technology, has been appointed an elector to the chair of botany in succession to the late Sir Francis Darwin.

Permission has been given for the sealing of the conveyance of the site for the new University Library. Plans for the proposed building have been exhibited for some time past, but very generous benefactions will have to be forthcoming before they can be carried out.

EDINBURGH.—Prof. J. A. S. Watson has intimated his desire to resign from the chair of agriculture and rural economy at the end of the autumn term, as he has been appointed to the Sibthorpe chair of rural economy in the University of Oxford.

LONDON.—By the will of the late Sir Rickman Godlee, Bart., after the death of his wife, one moiety of his residuary estate is given to University College, and the other moiety of his residuary estate to University College Hospital. By a bequest from the late Miss L. S. Gibbs, 150*l.* per annum is to be devoted to the establishment of a studentship in memory of her mother, to be called "The Laura de Saliceto Studentship," for the advancement of cancer research either on the physiological or the chemical side.

The following doctorates have been conferred:—D.Sc. (*Chemistry*), Mrs. E. H. Ingold (Imperial College—Royal College of Science and the Royal Holloway College) for a thesis entitled "Tautomerism"; D.Sc. (*Geology*), Mr. A. K. Wells, for a thesis entitled "The Geology of the Rhobell Fawr District (Merionethshire)," and other papers.

MANCHESTER.—Through the generosity of Mr. Ernest A. Knight, honorary treasurer of the University, a selected medical graduate will be enabled, this winter, to visit the United States, where he will study and, eventually, report upon the methods used in approved institutions, and investigate the part played by mental factors in the development, treatment, and cure of mental disorders. The competition was open to those who had obtained or had entered upon a course for the Diploma in Psychological Medicine of the University. The purpose of the fellowship is that of the Knight Prize, which is offered annually in the University, to encourage the study of psychological factors in the causation and cure of mental disturbances.

The following appointments have been made: Mr. F. G. G. A. Marraine to be assistant-lecturer in mathematics; Mr. R. J. Cornish to be assistant-lecturer in engineering; Mr. C. J. Polson to be demonstrator in pathology.

THE new buildings of the Swansea University College, which include the engineering laboratories referred to in these columns last week (October 31, p. 662) were opened by Lord Eustace Percy, president of the Board of Education, on October 31. The principal of the College, Dr. T. Franklin Sibly, referred in his opening remarks to the fact that all the students are now concentrated at Singleton, whereas previously many had to work at the Technical College, Mount Pleasant. Lord Eustace Percy said the opening of the new buildings marked "an attempt by the

university colleges to see that the system of higher education served the great industries of the country, so that skilled recruits could be drawn from the whole-time system of higher education, rather than that the industries should have to fall back on part-time technical training." The new engineering laboratories are provided with up-to-date electrical equipment including compound motors, alternators, rotary converters, an oscillograph outfit, certified standards of electromotive force and resistance, and so on. The courses in electrical engineering aim at giving a good general knowledge of the subject with a bias towards power generation, transmission and distribution.

New engineering laboratories at the Derby Technical College were opened on Friday, October 30, by the Hon Sir Charles A. Parsons. For many years past the work of the College has been hampered by the inadequacy of its building. As an extension on the original site is not feasible, new buildings have been provided a short distance away. They include laboratories for mechanics and heat, for more advanced work in applied mechanics and for heat engines respectively, as well as an engineering workshop. The rooms vacated in the main building enable additional provision to be made for physics, electrical engineering and metallurgy. Valuable gifts of plant have been received from local manufacturers, and local firms have assisted in the erection of the machines. In particular, Messrs. Rolls-Royce, Ltd., have presented and fitted up completely a motor-car engine with a Heenan and Froud brake, while the Derby Gas Co. have presented a Crossley gas engine coupled to a dynamo. Sir Charles Parsons referred to the remarkable progress of engineering during the last half-century, and to the consequent change which had taken place in the education necessary for engineering students. He emphasised the importance of practical as well as theoretical training, and offered his congratulations on the completion of the new laboratories.

UNIVERSITY COLLEGE, London, has issued an appeal for 500,000*l.* in order to mark the centenary, in 1927, of the laying of the foundation stone of what was then known as the University of London. The name was changed later to University College, and the College was incorporated in the University of London in 1907, so the celebrations will be of unusual interest as marking the beginning of the second century of university education in London. The activities of University College have increased widely, particularly during the past twenty-five years, and the appeal now sent out is for funds for building developments, equipment and endowment. Among the items set out are a Great Hall, completion of the Gower Street front, electrical equipment for the new chemical laboratories, new buildings for the Departments of Zoology and Comparative Anatomy and Chemical Engineering, the reconstruction of the Departments of Applied Mathematics, Physics, Engineering, and of the General Library, while the Science Library is not yet completed. With regard to the endowment of teaching, the aim is to establish funds which will enable the College to offer the remuneration necessary to attract and retain a teaching and research staff of the highest rank. At present, the chairs of geography and engineering (civil and mechanical), among others, are without endowment, while the chairs of applied mathematics and mechanics, mathematics, botany, geology, physics and zoology are not in receipt of adequate support. Half the sum which it is hoped to raise will be devoted to endowment, thereby releasing general funds for other purposes. The appeal is under the patronage of Prince Arthur of Connaught; the treasurer is Sir Robert Kindersley, to whom donations should be sent, at University College, and the secretary is Dr. W. Seton.

Early Science at Oxford.

November 8, 1687. Mr. President shewed the Society the edition of *Aristarchus de magnitudinibus & distantijs Solis & Lunæ*, in Greek and Latin, the care of which he had taken at the desire of this Society. Then Dr. Smith gave an account of what mathematical manuscripts were in Magdalen College Library.

November 9, 1683. Dr. Plot was pleased to shew some leaves, acorns, and a large branch, of an English Cork-tree, which grows at Abingdon in Cambridgeshire, after which, ye Doctor showed a peice of white marble, which he had stained to a dusky black; ye colour entering $\frac{1}{4}$ of an inch or more. He then acquainted ye Company, with ye severall methods, ye smiths use at Wolverhampton, in Staffordshire, in hardening, and softening, their Iron.

They harden Iron with burnt hoofs, horn, fountain salt, bay-salt, sublimat, urine, and old burnt leather, and tartar, all mix't together, and reduced into a powder, in which they roll ye Iron red hot, to which it will stick, and so put it into ye fire again to harden; which it does only on ye outside to ye thickness of a shilling. They have two sorts of hardening in this town, tough-hardening, and brittle-hardening, which they use according as ye Instruments they make, require. Dr. Plot was told by another, as a secret, that ye toughest hardening was made by ye juice of nettles, mans urin, and linseed oyl, and ye highest by quenching Iron red hot in ye juice of mous eare.

Dr. Smith has undertaken to procure a new Chart, made by a gentleman, (whom ye Doctor knew at Constantinople,) who has lately travelled from Muscovy to China; by this chart it appears, that those two countries are not so far distant from one another, as our maps commonly make them.

November 10, 1685. A Caconut was presented ye Society by Dr. Plot, which, being opened, yielded ye milk, ye white kernell encompassed by a hard shell, (of which drinking cups are frequently made) and a loose cortex over that an inch and $\frac{1}{2}$ thick, of which linen is frequently made.

Mr. Bobart shewed a very curious collection of leaves and seeds of plants lately brought from St. Christopher's, of which he promises a more full account in writing.

November 11, 1684. An account of the preparation of Tartarum Vitriolatum was communicated by Dr. Plot, and also an account of ye weather here at Oxford the last moneth.

A letter from Mr. Cole, dated from Minehead, October ult: 1684, was read; it contain'd more of his observations concerning ye dying shellfish.

Mr. Charles Leigh communicated severall curiosities observ'd by him in Lancashire; particularly of Barnacles, which he takes to be a Shellfish, not a bird; of Caterpillars, concerning which he is of opinion, that ye old ones are killed by the younger; of worms in apple-kernells almost as large as ye kernells, which he urges as an argument against *omnia ex ovo*; unless perhaps ye egg rises with ye juice of ye tree; of a peice of chalk of ye shape and bigness of a muscleshell, taken out of ye bladder of a hog. Of waters impregnated with Latrôn. Of a Water in that Countrey, which, by falling on wood, turns into a substance which rings like a bell. Of a water from a white marl 2 ounces in a quart lighter then common water usually is.

Mr. Vice Chancellor communicated to ye Society severall stones, all of a cubical form, but of several sizes; all *pyrites aurei* found plentifully at St. Davids in Pembroke-shire: whereof Dr. Plot said that they were the true *Ludus* of Paracelsus.

Societies and Academies.

MANCHESTER.

Literary and Philosophical Society, October 13.—W. W. Haldane Gee: (1) John Dalton's spectacles. The vision of John Dalton was very abnormal. He was colour-blind and also short-sighted. We have now definite knowledge of the extent of this defect, for the Misses Taylor of Manchester have given the Society a pair of Dalton's spectacles. The frames are of blued-steel, hand-made, and were originally furnished with swinging arms to fit round the ears, as seen in the portraits of Dalton. The lenses are of the periscopic concave type with a power of 5 diopters. The use of such strong lenses proves that Dalton was very short-sighted, and he would be obliged to wear his spectacles to see objects at a distance, though it is very possible he would be able to read the smallest print at a distance of 8 or 9 inches without any glasses. (2) John Dalton's pupil's note-book. The Misses Taylor of Manchester have also presented on loan to the Society a note-book used by a relative, who was a pupil of John Dalton. It contains notes relating to mathematics, natural philosophy, and meteorology. Two of the entries under the last-named head are of general interest in connexion with the weather. It is noted that "the mean annual temperature at Manchester for 47 years is 48.8," also that the "rain in the first six months of the year is to that of the last six months as 2 to 3." The Stonyhurst College Observatory records give for the mean annual temperature for the last 77 years 47° Fahrenheit, which does not differ much from that noted by Dalton's pupil, for Manchester. The rainfall there for the last six months of the year divided by that for the first six months gives the number 1.491, a most remarkable verification of Dalton's corresponding number of 1.50.—W. L. Bragg: The sizes of atoms. The atoms cannot be regarded as incompressible bodies occupying a definite volume. The limit to the approach of two atoms appears to be set by the action of a repulsion between them, which rapidly increases as the distance between the atomic centres lessens. This field sets in so rapidly, however, that we may form a picture of the packing together of atoms by supposing them to be spheres nearly constant in size, but slightly elastic and compressible. This picture helps to explain the form of many compounds, though it breaks down entirely in other cases and its limitations must be carefully considered. A chief constituent of many inorganic compounds is oxygen. The repulsive force between oxygen atoms assumes a large value when their centres are 2.7 Å. (2.7×10^{-8} cm.) apart. The size of other atoms is in general much less, so that in many inorganic crystals the scale and shape of the whole structure are determined chiefly by the oxygens. A number of models may be made to illustrate this peculiar importance of oxygen. In some of them the structure may be regarded as a closely packed assemblage of oxygen atoms with other atoms in the chinks between them acting as a cement to bind the whole together.—J. M. Nuttall and E. J. Williams: β -rays associated with X-rays. The β -rays associated with homogeneous X-rays have been studied by the Wilson cloud expansion method, the required wave-length being sorted out by reflection from a crystal. The relative numbers of recoil and photo-electron tracks (in various gases) have been determined for a series of wave-lengths of primary X-rays. Several hundred

tracks have been counted and the numbers are in general agreement with the quantum theory of X-ray scattering as advanced by Compton. The results show that the fraction of scattered X-ray quanta which give sufficient energy to the recoil electron to enable it to leave the atom and produce a track, increases with decreasing wave-length of primary X-rays and approaches unity.

PARIS.

Academy of Sciences, September 7.—Jacques Chokhatte: A general formula in the theory of polynomials of Tchebycheff and its applications.—F. Baldet: The presence of the red cyanogen spectrum in Daniel's comet (1907d). A photograph of the spectrum of Daniel's comet, taken in August 1908, shows a red band not previously noted by any observers of this comet. By comparison with the carbon arc spectrum, taken with the same prism objective, it has been found that the comet band coincides with a band in the carbon spectrum, not only in position, but also in the relative intensities of corresponding points. These bands have been identified by Fowler and Shaw with the red spectrum of cyanogen.—V. Nechville: A relation between the mean proper motion and stellar magnitude from the first negatives of Henry.—A. Duboin: The application to chromium of a general method of synthesis of fluorides and silicates. The oxide or fluoride of chromium is added to fused acid potassium fluoride, the mass raised to a red heat and silica added. After slow cooling and extraction with water, the silica is found well crystallised as tridymite, the chromium as the crystallised double fluoride, $3\text{KF} \cdot \text{CrF}_3$.—Viret: The rodent fauna of Saint-Gérard-le-Puy (Allier).—C. T. Popeso: Comparative sleep and awakening of the primordial leaves in grafted and non-grafted beans.—E. Ducloux and Mlle. G. Cordier: The pancreatic extract of *Acanthias vulgaris*; its action compared with that of ox insulin.

September 14.—André Blondel: A modulometer arrangement for the control of radiotelegraphic emissions.—Alfred Rosenblatt: Algebraic varieties of three dimensions of which the types satisfy the inequality $P_3 \leq 3(p_3 - p_4 - 3)$.—Rolf Nevanlinna: Some properties of meromorphic functions in a given angle.—Michel Samsoen: An anomaly of the expansion of glass. The case of boric anhydride. At about 250° C., the coefficient of expansion of boric acid undergoes a sudden increase, from 15×10^{-6} to 200×10^{-6} . This result was obtained by two different experimental methods.—L. Daniel and E. Potel: Grafts of the sweet almond on roots of belladonna. In the graft there is a reduction in the amounts of cellulose and of atropine.—Alfred Labriet and Raoul Husson: The principles of vocal education by the realisation of vocal agreement.

September 21.—P. J. Myrberg: The simultaneous reduction of two quadratic forms.—A. Kovanko: A class of points of non-uniform convergence of series of functions.—Mandelbrojt: The best approximation of analytical functions and their singular points.—B. Galerkin: A plate, in the form of a rectangular isosceles triangle, placed on its contour, submitted to the action of forces acting normally to its surface on the axis of symmetry.—R. de Malle-mann: The diffusion of light by active and inactive molecules. A criticism of some conclusions of Gans relative to the diffusion of light by active molecules.—René Wurmser: The activity of various radiations in photosynthesis.—Const. A. Kténas: The eruption of the volcano of Santorin.—A. Poli-

card and A. Paillot. Study of silk secretion with the aid of filtered ultra-violet rays (Wood's light). Examined in Wood's light, certain parts of the silk-worm, especially the blood, show a brilliant yellow fluorescence. The method is of some practical interest, as the appearance of the silk-worm in filtered ultra-violet light is modified by bad nutrition or by disease.—R. Legendre: A tortoise (*Sphargis coriacea*) caught in the bay of Concarneau.—J. Roger d'Ansan. Ocular gymnastics applied to the treatment of amblyopia ex-anopsia and the strabism derived from it.—Charles Lebailly. The reappearance of foci of foot and mouth disease and the continuity of the virus in Nature. Experiments on six farms were carried out with the view of testing the theory that the virus was carried in cavities in the hoofs of cattle recovered from the disease. Sixty-two cured cattle in all were placed in contact with 450 fresh beasts, but the results were all negative, no return of the disease taking place. The author considers that these experiments definitely disprove the theory of virus latent in the feet of cattle after recovery from foot and mouth disease.

ROME.

Royal Academy of the Lincei: Communications received during the vacation.—Leonida Tonelli: The absolute convergence of Fourier's series.—F. Zambonini and R. G. Levi. Investigations on the isomorphism of molybdates of the rare earth metals with those of calcium, strontium, barium and lead. In view of the fact that a compound such as CaMoO_4 forms mixed crystals with $\text{Ce}_2(\text{MoO}_4)_3$, it is proposed to examine by roentgenographic means the structure of such crystals.—F. Zambonini and V. Caglioti. Neodymium thallous sulphates. The double sulphates having the formulae $\text{Nd}_2(\text{SO}_4)_3 \cdot 4 \cdot 5 \text{Ti}_2\text{SO}_4 \cdot \text{Nd}_2(\text{SO}_4)_3 \cdot \text{Ti}_2\text{SO}_4 \cdot 8\text{H}_2\text{O}$ and $\text{Nd}_2(\text{SO}_4)_3 \cdot \text{Ti}_2\text{SO}_4 \cdot 3\text{H}_2\text{O}$ are described.—L. A. Herrera. Additional figures illustrating various communications. The figures deal with the blastomere of the trout, the imitation of cell-division by means of collodion and ultramarine, and karyokinesis figures in crystals of metaformaldehyde.—Giuseppe Levi. Autonomous growth, by amoeboid movement, of fragments of neurites separated from the trophic centre.—Gabriele Mammanna. A new method of studying linear differential equations.—B. Marzetti. A deviation from Poiseuille's law. The non-linear relationship between the velocity of flow of rubber from a tube or orifice and the pressure to which it is subjected is considered.—Luigi Rolla and Giorgio Piccardi. Chemical statics of electronic phenomena.—G. Bargellini. α -Diphenylcoumarins.—Lorenzo Fernandes. Isomorphism between quadrivalent uranium and zirconium.—A. Ferrari. The crystal structure of lead dioxide examined by means of X-rays. Crystalline lead dioxide has a tetragonal structure of the rutile type, the elementary cell containing two molecules of the dioxide.—G. Scagliarini and G. Tartarini. Products of the oxidation of complex sulphites of trivalent cobalt.—Adriana Stolfi. The behaviour of lead containing RaG in the formation of formaldehyde according to Thunberg's theory.—Francesco Vercelli. Theory of the propagation of radiant energy through water.—E. Onorato. The epsomite of the north-west mine of Idria.—G. Checchia-Rispoli. Cainozoic echinoids of Cirenaiica collected by Camillo Crema.—G. Campanile. Contribution to the study of the systematics of the genus *Cuscuta* (section "Cistogrammica" Englm.).—Alberto Piróvano. Observations on electric mutations and on the process of ionolysis in gametes.

Diary of Societies.

SATURDAY, NOVEMBER 7

- ROYAL SOCIETY OF MEDICINE (Otolary Section), at 11.30 a.m.—A. R. Thesdale. The Otolith Reaction.
GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.), at 3.—G. W. Young. The Yellow-stone Park, U.S.A. (Lecture).

MONDAY, NOVEMBER 9

- ROYAL IRISH ACADEMY, at 4.15.
ROYAL SOCIETY OF EDINBURGH, at 4.30.—Prof. J. W. Gregory. (a) Scottish Drumlins, (b) The Scottish Kames and their Evidence on the Glaciation of Scotland.—J. M. Wordsie. Notes on the Geology of Jan Mayen.—Dr. G. W. Tyrrell. The Petrography of Jan Mayen.—Dr. M. A. Peacock. The Geology of Videy, S.W. Iceland. A Record of Igneous Action in Glacial Times.
INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section), at 8.—E. B. Ball. Some Engineering Features in connection with Irrigation in South Africa (Lecture).
INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—E. S. Rutter and others. Discussion on Modern Developments of Telephones Cables.
INSTITUTION OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—P. Donath. Dielectric Problems in High-Voltage Cables.
INSTITUTE OF METALS (Scottish Local Section) (at Institution of Engineers and Shipbuilders in Scotland, 40 Elmbank Crescent, Glasgow), at 7.30.—Dr. J. A. Cranston. Binding Forces between Atoms.

SURVEYORS INSTITUTION, at 5—J. D. Wallis. Presidential Address
MEDICAL SOCIETY OF LONDON, at 8.30—Dr. R. Hutchison and others.
 Discussion on *Obscure Pyrexia in Childhood*
ROYAL GEOGRAPHICAL SOCIETY (at Eolian Hall), at 8.30—Dr. Knud Rasmussen. From Greenland to the Pacific.
CAMBRIDGE PHILOSOPHICAL SOCIETY (in Botany School, Cambridge), at 8.45—Prof. B. M. Jones. Wings.
BIOCHEMICAL SOCIETY (at King's College)—J. A. Hewitt and H. G. Reeves. (a) Trimerism of Glyceric Aldehyde. (b) Constitution of Glyceric Aldehyde.—Prof. C. Loati Evans. Lactic Acid Formation in Plain Muscle.—Dr. Elizabeth S. Semmens. The Hydrolysis of Starch in the Guard Cells of the Stomata of a Monocotyledon.—J. Gordon, J. W. McLeod, and H. Wheatley. The Importance for the Bacteriologist of Differentiating between the Amino-acids which Favour and those which Inhibit Bacterial Growth.—J. R. Marrack and G. D. Thacker. The Influence of Ionic Strength on the Equilibrium of Calcium Ion in Bicarbonate Solutions.

TUESDAY, NOVEMBER 10.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Shadwell. Medicine in Ancient Egypt, Assyria, and Palestine (FitzPatrick Lectures, I).
INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 8.30—Ing. L. Steinschneider. The Principles of the High Vacuum Distillation of Mineral Oils.—Dr. W. R. Ormandy and E. C. Craven. (a) The Determination of Unsaturation in Petroleum Spirit; (b) The Determination of Molecular Weight of Petrol.
INSTITUTION OF AERONAUTICAL ENGINEERS (at Junior Institution of Engineers), at 8.30—M. L. Brannon. Practical Flying.
INSTITUTE OF MARINE ENGINEERS, at 8.30.—E. F. Spanner. Construction of Ship. A Proposed Method of Minimizing Risk due to Collision.
INSTITUTE OF TRANSPORT (Midland Graduate Centre) (at Imperial Hotel, Birmingham), at 8.30.—A. Jackson. Passenger Fare Charges on Urban Tramway Services.
INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—S. D. Jones. Chairman's Address.
ROYAL PHOTOGRAPHIC SOCIETY (Scientific and Technical Group), at 7.—T. Thorne Baker and G. E. Pearce. Modern X-Ray Installations and their Work.
INSTITUTION OF ELECTRICAL ENGINEERS (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30.—Prof. M. Maclean. Chairman's Address.
PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, at 8.—Lt.-Col. Sir David Prain. Some Useful Plants of India (Lecture).
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—J. P. T. Burchell. The "Skull Mound" Industry of Denmark as represented at Lower Haldston, Kent.

WEDNESDAY, NOVEMBER 11.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Dr. H. Gilford. The Prevention of Cancer and Allie Neoplasms.
ROYAL METEOROLOGICAL SOCIETY, at 5.—Dr. C. G. Abbot. Measuring the Sun's Rays (Lecture).
ROYAL COLLEGE OF HUMANS OF ENGLAND, at 5.—J. Sheiien. Gastrojejunostomy (Bradshaw Lecture).
INSTITUTION OF CIVIL ENGINEERS (Informal Meeting), at 6.—Sir E. Owen Williams. The Relative Economy of Different Classes of Reinforced Concrete Work.
INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at University, Birmingham), at 7.—W. R. Barclay. The Development of Alloy of Nickel and Chromium for High Temperature Work and Electrical Resistance Heating.
ROYAL SOCIETY OF ARTS, at 8.30.—Sir Cecil Harcourt-Smith. The Modern Note in Industrial Art (Trevelyan Wood Lecture).
ECONOMICS EDUCATION SOCIETY (at Royal Society), at 8.30.—Rev. J. C. Pingle. The Nervous Labour Colony in Belgium.
INSTITUTION OF CIVIL ENGINEERS.

THURSDAY, NOVEMBER 12

ROYAL SOCIETY, at 4.30.—Sir William Bragg and R. E. Gibbs. The Structure of a and β Quartz.—Lord Raveleigh. The Light of the Night Sky: its Intensity Variations when analysed by Colour Filters.—Prof. W. A. Bone and G. W. Andrews. Studies upon Catalytic Combustion: Part I.—Prof. O. W. Richardson and F. C. Chalklin. The Exentation of Soft X-Rays.—R. Campbell Thompson. On the Chemistry of the Ancient Assyrians.—J. E. Lennard-Jones. On the Forces between Atoms and Ions.—To be read in title only.—F. G. Mann and Sir William Pope. β β β Triaminotriethylamine and its Complex Metallic Derivatives.—K. R. Ramanathan. The Structure of Molecules in relation to their Optical Anisotropy. Part II.—Dr. E. V. Appleton and M. A. F. Barnett. On some Direct Evidence for Downward Atmospheric Reflection of Electric Rays.
LONDON MATHEMATICAL SOCIETY (at Royal Astronomical Society), at 5.—Annual General Meeting.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Shadwell. Medicine in Ancient Egypt, Assyria, and Palestine (FitzPatrick Lectures, II).
ROYAL AERONAUTICAL SOCIETY, at 5.30.—H. B. Howard. Some Problems in Aeroplane Structural Design.
CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—M. Yearsley. The Development of Speech in the Normal Child.
SOCIETY OF CHEMICAL INDUSTRY (Bristol Section) (at Bristol University), at 7.30.—Dr. E. Vanstone. The Role of Phosphorus in Agriculture.
INSTITUTION OF ELECTRICAL ENGINEERS (Dundee Sub-Centre) (at University College, Dundee), at 7.30.—I. Selar. A Comparison of Electrical Wiring Installations and Analysis of their Costs.
INSTITUTE OF METALS (London Local Section) (at Royal School of Mines), at 7.30.—Dr. R. S. Hutton and Dr. O. F. Hulson. Science and Industry: Some Impressions from the Early Experiences of the British Non-Ferrous Metals Association.
OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—S. A. Emerson. Some Recent Improvements in Modern Ophthalmic Lenses.—W. Swaine. Relation of Visual Acuity and Accommodation to Ametropia.

—Irregular Astigmatism of the Eye.—E. F. Fincham. Effect of Size of Pupil, H. H. Emsley. Effect of Corroding Lenses.—Exhibition and Description of the Zeiss Refraction Meter by J. W. Atha and Co.
INSTITUTION OF ELECTRICAL ENGINEERS (Irish Centre) (at Trinity College, Dublin), at 7.45.—G. G. Sutcliffe. Underground Telephone Construction.
INSTITUTION OF CHEMICAL ENGINEERS (at Institution of Mechanical Engineers), at 8.—Hon. H. Fletcher Moulton and others. Discussion on Scientific Research Workers and Industry.
INSTITUTION OF MECHANICAL ENGINEERS (South Wales Branch)—Eng. Lieut.-Colonel W. H. Reynolds. Chairman's Address.
OIL AND COLOUR CHEMISTS' ASSOCIATION.
INSTITUTION OF THE RUBBER INDUSTRY (Manchester Section)—Short Papers.

FRIDAY, NOVEMBER 13

ROYAL ASTRONOMICAL SOCIETY, at 5.—
PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—T. G. Hodgkinson. Valve Maintained Tuning Forks without Condensers.—R. G. Edwards and B. Worwick. The Viscosity of Ammonia Gas.—Dr. C. Chree. The Times of Sudden Commencements (S.C.'s) of Magnetic Storms: Observations and Theory.—Demonstration of the Kinetic Properties of a Gas Jet by Dr. J. S. G. Thomas.
MALACOLOGICAL SOCIETY OF LONDON (at Luncheon Society), at 6.—W. A. Lindholm. On a Neglected Work containing Typifications of Molluscan and Brachiopod Genera.—E. Ashby. The Aranthoid Chitons of New Zealand with Descriptions and Figures, including several New Species and Photographs of Previously Unfigured Types.—A. W. B. Powell. Description of Two New Gastropods from Whangaroa, New Zealand.—A. S. Kennard and B. B. Woodward. Nomenclatorial Notes relative to British Non-Marine Mollusca. IV.—Rev. E. G. Alderson. The *Amphidaria swainsoni* of Philipp, Hanley and Reeve.—Exhibition of Illustrations and Photographs, taken from the Type Specimen in the Senckenberg Museum, of *Palaemon mirabilis* Milne, by B. B. Woodward, and Specimens of Shells and Radula illustrating a New Molluscan Family, and Genera, by J. R. Le B. Tomlin and Lt.-Col. A. J. Pele.
INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 6.15.—Lt.-Col. K. Edgcombe. Some Controversial Problems.
JUNIOR INSTITUTION OF ENGINEERS, at 7.—Annual General Meeting.
INSTITUTE OF METALS (Swansea Local Section) (at University College, Swansea), at 7.15.—L. B. Pfeil. Effect of Crystal Size on the Mechanical Properties of Metals.
INSTITUTION OF ENGINEERS (Infection) (at Royal Society of Arts), at 7.30.—Dr. W. H. Hatfield. Modern Developments in Steels resistant to Corrosion.
INSTITUTE OF METALS (Sheffield Local Section) (at Sheffield University), at 7.30.—S. Field. Recent Advances in Electro-Deposition.
NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch, Graduate Section), at 7.30.—A. T. Abernethy. Wireless Transmission and Reception.
ROYAL SOCIETY OF MEDICINE (Ophthalmology and Surgery Sections), at 8.30.—Joint Discussion on Plastic Operations on the Face in the Region of the Eye.
INSTITUTION OF MECHANICAL ENGINEERS (Leeds Branch)—Sir John A. F. Apinall. Some Railway Notes Old and New (Thomas Hawkey Lecture).

SATURDAY, NOVEMBER 14

ASSOCIATION OF MINING ELECTRICAL ENGINEERS (North of England Branch) (at Newcastle-upon-Tyne), at 5.—J. A. B. Horsley. The Selection, Lay-out, and Maintenance of Electrical Equipments at Collieries.
INSTITUTE OF TRANSPORT (North-East Centre) (at Newcastle-upon-Tyne), at 5.—C. J. Allen. British Main Line Passenger Train Services.
PHYSIOLOGICAL SOCIETY (at Cardiff).

PUBLIC LECTURES.

SATURDAY, NOVEMBER 7

HORNIMAN MUSEUM (Forest Hill), at 8.30.—R. A. Smith. Aspects of Roman London. I.

MONDAY, NOVEMBER 9.

KING'S COLLEGE, at 5.30.—Dr. W. T. Gordon. Geology and Civilisation (Swiney Lectures). (Succeeding Lectures on November 13, 14, 20, 28, 27, 30, Dec. 4, 7, 11, 14, and 18.)

TUESDAY, NOVEMBER 10.

KING'S COLLEGE, at 5.30.—Miss Hilma D. Oakeley. The Philosophy of Aristotle. Theory of Mind and Soul.
SURVEYORS' INSTITUTION, at 5.45.—E. H. Shaughnessy. Post Office Wireless Stations.
GREENHALL COLLEGE (Bavinghall Street), at 6.—W. H. Wagstaff (Geometry). (Succeeding Lectures on November 11, 12, and 13.)

WEDNESDAY, NOVEMBER 11.

UNIVERSITY COLLEGE, at 5.30.—Prof. G. Elliot Smith and the late Dr. O. F. Sonntag. The Evolution of Man. (Succeeding Lectures on November 18, 25, December 2, 9, and 16.)

THURSDAY, NOVEMBER 12

BEDFORD COLLEGE FOR WOMEN, at 5.15.—C. C. Baker. Italian Painting: its Place in Art.
KING'S COLLEGE, at 5.30.—Sir Arthur Newsholme. The Community and Social Hygiene.
UNIVERSITY OF LEEDS, at 8.—Lt.-Col. W. R. Mansfield. New Light on Christopher Columbus.

SATURDAY, NOVEMBER 14

HORNIMAN MUSEUM (Forest Hill), at 3.30.—R. A. Smith. Aspects of Roman London. II.

SATURDAY, NOVEMBER 14, 1925.

Technical Libraries.

THE formation of the Association of Special Libraries and Information Bureaux, which held its second annual Conference at Balliol College, Oxford, in September, is a welcome sign not only that the librarians of technical and other specialist libraries are realising the need of co-ordination and co-operation amongst themselves, but also that manufacturers in Great Britain are at last seeing the vital importance of research to industry. They are realising the urgent necessity, therefore, of having ready access to existing library resources and greater facilities for ascertaining what is being done from day to day throughout the world.

The pressure behind the movement came in the main from outside and not from within the library world. The absence of the research habit in Britain, in contrast with the position in Germany, became so painfully evident after a few months of the War that the Government had no option but to undertake a Scientific Intelligence Service, which though conducted primarily for military purposes, yet necessarily covered so wide a field that it included in its survey a great deal of what in normal times would form part of the civil work of the nation. Fortunately, the necessity for a continuance after the War of similar organised efforts towards a comprehensive scheme of scientific research was clearly recognised, and numerous industrial research associations were formed, under the ægis of the Department of Scientific and Industrial Research, to act as laboratories and as feeders of up-to-date information for the benefit of the subscribing manufacturers. It is a significant fact that it was due mainly to the initiative of one or two of these research associations that the first Conference of Special Libraries was held at Hoddesdon last year, and that this was followed by the formation of an Association and the much larger Conference at Oxford this year.

At a very liberal estimate, the number of scientific and technical libraries in Great Britain may be put at about a couple of hundred. This figure, though probably not one-third of the number of similar institutions in the United States, where the Special Library Association has been in existence for more than sixteen years, may not on paper appear an unreasonable one for British needs. But when consideration is given to the fact that certainly more than one-half of this number—and of these probably the largest and most representative—would be found in London and its immediate neighbourhood, and when the nature and relative efficiency of the various collections are taken into account, it will surely be felt that the fullest advantage is not being taken even of the undoubtedly great resources we already possess.

There is, or was until quite recently, an entire lack of co-operation between the different libraries, even amongst those covering the same or closely related fields. Each shut itself in a watertight compartment, selecting and arranging its books and the still more important periodical literature without reference to its neighbours, and with the view solely of suiting the needs of its own readers—usually the members of the private or semi-private institution to which the library belonged. This involved a great deal of unnecessary duplication and a needless waste of effort, some fields being more than adequately covered, whilst others were only poorly or even not at all represented. Well-known treatises and journals could be found repeated in a number of libraries within walking distance of each other, to the entire exclusion of less well known but not always less important literature. A few fruitless efforts at reform have been made from time to time, especially in the field of engineering, but so far nothing has been accomplished that can in any way compare, for example, with the establishment of the United Engineering Societies Library in New York.

A beginning is, however, now being made in Great Britain, and one interesting experiment calls for special notice, namely, the scheme whereby, under agreement with the Carnegie United Kingdom Trust, approved special libraries are being linked up with the Central Library for Students. Already under this scheme a number of libraries—those of the Royal Aeronautical Society, the Scottish Marine Biological Association, the Rowett Research Institute, and others—have agreed to lend their books and periodicals (other than exceptional rarities) to borrowers applying through the Central Library, the latter institution becoming responsible for their proper care and return. The benefits of such a scheme are obvious. The Central Library is relieved of the necessity of purchasing a number of books, etc., already to be found in these other libraries, whilst at the same time those who avail themselves of its services will be able to borrow many books and periodicals, including back numbers, not otherwise obtainable.

Co-operation of this character is especially valuable, and the establishment of central loan libraries will be of increasing importance in connexion with the small but highly specialised libraries that are being formed by industrial establishments, research associations, and so on. As these grow, the question of the provision of shelf space for their rapidly increasing literature will undoubtedly arise and will be solvable in one of two ways, either by diverting some of the not too extravagant funds now devoted to experimental research from the laboratory to the library, or by a periodical survey of the library shelves for the purpose of weeding out the less important material.

Happily for the future prospects of research, the latter alternative, granted proper co-operation between all concerned, is not only the most practicable, but also the most desirable one. It would usually be unnecessary for the type of library now being considered, concerned as it is mainly with the results of current research, to continue to keep on its shelves copies of old editions and long runs of patent literature, or of any but the most important periodicals. At the same time, no librarian would agree to discard such material unless he could be quite sure that it would be readily and immediately accessible in some other library, if and when required. A central library to which might be sent on loan conditions all literature that could ordinarily be dispensed with would meet his needs, and would in many other ways be an invaluable adjunct to all the special libraries of a district. The increasing specialisation, and the growing interdependence of the various branches of science, render it quite impossible for any but the very largest libraries to include all the literature that might at some time or another be wanted by its readers, and reliance on other sources is the only possible solution of the difficulty.

In this the greater public libraries of Great Britain may well play an important part. Many of the municipal authorities throughout the country—notably that of Manchester—are viewing with favour the formation as part of their library system of special technical sections having particular reference to the industrial interests of the district. It would not be a difficult matter to arrange that the special libraries of the neighbourhood should each restrict its selection of literature to that relating specifically to the subject with which it is mainly concerned, leaving the public library to provide for its needs in the way of general scientific works and the literature of neighbouring fields which might be required from time to time. The public library would also serve as the reservoir, of which we have spoken, for the less important material weeded out periodically from the specialist libraries to make room for current growth. By reciprocal loan arrangements, such material would always be available when required, and the public and specialist libraries would each be able to draw on the resources of the other in case of need. Any specialist library would thus have access to a far wider range of literature than it could possibly hope to provide for itself, and would at the same time, by the elimination of the necessity to provide works on subjects outside its immediate scope, be enabled to make its own collection more fully representative of its subject than would otherwise be the case. Consolidated catalogues kept up-to-date in each of the libraries concerned would be a necessary corollary.

In London, with its varied interests, a somewhat

different method might have to be introduced, and a separate loan library be formed as an auxiliary to the scientific libraries of the Metropolis, to which the rarely used volumes could be sent for the common use and benefit.

With greater co-operation between scientific institutions, we may expect to see an improvement in those indispensable tools of the research worker, abstracts and indexes of periodical literature. An enormous amount of unselfish work is being done in this field at the present moment, and unity of effort is being aimed at in more than one direction. The two leading chemical societies have since last year pooled their abstracting resources in the Bureau of Chemical Abstracts, and though two separate publications, differing in format, one for pure and one for industrial chemistry, are still being issued, it is understood that with next year the two publications will be combined into one. A much larger question arises when the actual number of journals abstracted or indexed is considered. Though we are still waiting for the second volume of the "World List of Scientific Periodicals," we shall not be far wrong in assuming that a considerable proportion of the current periodicals recorded in that invaluable work are not to be found in any British library. Dr. Chalmers Mitchell, at the Oxford Conference, made the bold suggestion that a central library should be established which should contain a copy of every current periodical issued throughout the world and publishing scientific and technical research, and keep it available for the use of indexers and abstractors for two years after publication. After that period the volumes would be distributed for permanent reference to other suitable libraries. Such a library would not be a lending library, but would be available only for abstractors and indexers from recognised organisations, and for the librarians of other libraries. A certain amount of cold water has been thrown on the proposal on the ground of the extensive nature of the work involved; but nothing is impossible unless we make it so.

Such are some of the many problems awaiting solution in the world of technical libraries, before these can render to the community that service which they alone can give, and, it may confidently be expected, will more and more be demanded of them. Improvements in the facilities provided and the growth of a healthy desire for knowledge of what others are doing in invention and research will proceed *pari passu*, for the two are mutually dependent and will stimulate each other. The newly formed Association of Special Libraries is supplying the necessary impetus. From the seriousness with which it is setting about its self-imposed task, there is distinct hope that one at least of the lessons taught by the War will not be forgotten

Ancient Assyrian Chemistry.

On the Chemistry of the Ancient Assyrians. By Dr. R. Campbell Thompson. Pp. 158+6 plates. (London: Luzac and Co., 1925.) 25s. net.

DR. THOMPSON'S brilliant monograph on ancient Assyrian chemistry is worthy of very careful study. To appreciate it fully one must be both an Assyriologist and a chemist, but even those who, like the present writer, have no knowledge of cuneiform, will delight in Dr. Thompson's skill in argument, lucidity of explanation, and quickness in perceiving the key to difficulties. His results and conclusions are of considerable importance, and, while one may not always agree with him entirely, he has certainly thrown a flood of light upon the chemical knowledge of one of the most talented nations of antiquity.

The texts concerned form part of the remains of the royal library of Ashurbanipal, now preserved in the British Museum. They describe in detail the processes of glass-making as practised by the Assyrians of the seventh century B.C., and give information not only on the composition of various kinds of glass but also on a variety of colouring matters used in the production of tinted glass. By subjecting these texts to a close and critical examination in the light of philology, checked at each step by appeal to chemistry and to known methods, ancient and modern, of glass-making, Dr. Thompson has succeeded in identifying a surprisingly large number of chemicals. It becomes evident, indeed, that chemistry of a practical and empirical nature must have been brought by the Assyrians to a level hitherto unsuspected.

Dr. Thompson points out that up to the present time the Assyrian words for minerals and stones have been much neglected, and that the custom has too commonly been to regard the large number of substances specified by the determinative for "stone" as (exclusively) "precious stones." He inclines to the view that "stone" in the scientific texts must have a much wider meaning; that it must, in fact, include mineral drugs and inorganic pigments. This suggestion, the fruitfulness of which is shown throughout the book, has a great deal to recommend it. Most important of all, perhaps, is the fact that in the related Semitic language of Arabia we find that the chemical writers habitually use the term *hajar* ("stone") for any inorganic chemical. Since the early Arabs undoubtedly derived many of their mineral-names, and possibly much of their empirical chemical knowledge, from Assyria, it is not incredible that this technical use of the word "stone" may have been handed down to them in the same way. Quite apart from this extraneous evidence, however, it is difficult for any one who follows Dr. Thompson's arguments to

disagree with his view that *abnu* (determinative of *stone*) must be allowed to bear a far more extensive interpretation than that hitherto given to it.

Consideration is next devoted to the solution of the problems presented by the glass-making texts. Here the author bases his procedure upon the principles involved in the technique of modern methods. The essentials in all glass-making are silica, an alkali, and lime or less probably lead. A decolorising agent, such as manganese dioxide, is usually added. That all these substances were used so far back as A.D. 79 is proved by an analysis of window-glass from Pompeii:—*silica*, 69; *soda*, 17; *lime*, 7; *alumina*, 3; *iron oxide*, 1 per cent.; *manganese and copper*, traces. Chemical analysis of ancient glasses has, moreover, revealed the nature of many of the colouring agents employed in the manufacture of tinted glass; thus Assyrian blue glass has been found to contain copper, and red glass cuprous oxide. Assyrian white glass contains tin oxide, while lead antimonate has been discovered in yellow.

From data of this kind, it becomes an easier task to identify the names of the principal constituents of Assyrian glass as given in the texts. *Uḫulu*, *immanakku*, and *namrutu* are the basic substances. The first, *uḫulu*, has long been recognised as “alkali,” and Dr. Thompson is able to show that *immanakku* probably represents a pure quartz sand. Since the word for lead (*anaku*) does not occur in any of the glass-texts, it is reasonable to assume that *namrutu* signifies a form of lime or limestone, and the author brings evidence to show that it is probably chalk. With the three main ingredients definitely settled, attention can be devoted to the rest, and it is here that Dr. Thompson's ingenuity and erudition achieve their most brilliant successes. It is here, too, that the chemist and philologist will find much to fascinate them—the first in the astonishing chemical knowledge which the texts imply, and the second in the discovery that many familiar names of minerals are of Assyrian origin.

To the chemist, one of the most interesting of the recipes is that which appears to describe a prototype of the Purple of Cassius. Dr. Thompson thinks that the aim of the operation described in this recipe is to produce an artificial pink or red coral. The ingredients of the mixture are given as 7200 parts of a glass base, 32 parts of *tuskū* (oxide of tin?), 20 parts of *abarū* (which Dr. Thompson identifies with antimony), (?) parts of *mil'u* (a salt), and 1 part of gold. The proportion of gold here stated (0.014 per cent.) is of the usual order of magnitude in the preparation of ruby glass.

The recipe just mentioned is of much interest to the philologist also, since it necessitates the identification of no less than three constituents. One of them is the

substance which is called *abarū*. Any one who has studied ancient chemical texts knows how tantalising this word is. Dr. Thompson, following Ibn Baithar, identifies the Arabic *al-abar* with antimony, and compares *al-abar* with the Assyrian *abarū*. But *abar* in Arabic chemical texts seems to have a good many different meanings, not the least common being that in which it is used for the elixir. Thus in a chemical poem attributed to Khālid ibn Yazīd the elixir is described as “that which the people of this Art (alchemy) call *Abar*,” and the same name is elsewhere applied by Khālid to the “tincture” of metals. Abu'l-Qāsim al-'Irāqī (XIIIth cent.), however, distinctly says that *abar* is another name for lead (in his book *Al-Aqālim al-Sab'a*). According to the *Mustā'inī*, again, *abar* is tin. I am inclined to think that the most satisfactory meaning to ascribe to *abar* is “the metal extracted from collyrium,” in which case it would mean either lead or antimony, between which early chemists could scarcely distinguish with accuracy. *Tuskū* Dr. Thompson tentatively identifies with oxide of tin, since (a) it signifies a substance used to make white (cloudy) glass, and (b) oxide of tin has actually been discovered in Assyrian glass. He also makes the interesting suggestion that in *tuskū* we may have the origin of the word *tutia*. *Mil'u* is identified temporarily with saltpetre, but it is worth pointing out that *milh* (salt) in Arabic chemical texts apparently never has this meaning, and that there is no reliable evidence that saltpetre was recognised as a distinct substance before the tenth century at earliest.

Other names of interest are *guhlu* (eye-paint), whence the Arabic *kuhl* and our *alcohol*; *šindu arqu* (yellow paint), whence *sandarach*; *šadanu*, whence the Arabic *shādāna*, hæmatite. The Arabic *urjuwān* (purple), a title often given to the Elixir and used, too, in the description of the colours of clothes (e.g. *Mufaḍḍaliyāt*, Sir C. Lyall's edition, Oxford, 1918, ii. 249), is shown to go back to the Sumerian *argamanu*, red purple. *Sapphire* is traced back to the Assyrian *šipru*, and means “the scratching stone” (from *šapāru*, scratch), a name no doubt given to it on account of its great hardness (it is next to the diamond in Moh's scale). *Marcasite* apparently comes from *marhašz*, which probably means “pyrites.” Finally, it is thrilling to find a mineral called *kiballu*, and one hopes that it may be possible to show a connexion between this and cobalt, though for the present Dr. Thompson refrains!

The book is clearly printed from type-written stencils, is amply indexed, and includes the cuneiform texts, which are given on six plates at the end. It is earnestly to be hoped that Dr. Thompson will continue his researches upon Assyrian chemistry, and we shall look forward with eagerness to his next volume.

E. J. HOLMYARD.

The Colour Line.

The Menace of Colour: a Study of the Difficulties due to the Association of White and Coloured Races, with an Account of Measures proposed for their Solution, and Special Reference to White Colonisation in the Tropics. By Prof. J. W. Gregory. Pp. 264+4 plates. (London: Seeley, Service and Co., Ltd., 1925.) 12s. 6d. net.

HAPPILY there is as yet no sense of the colour line in Great Britain in the sinister interpretation of the term, except perhaps among a restricted few. We may have prevented by law a few coloured musicians from entering Britain; but that is trade unionism directed against foreigners in general; and only recently a coloured actor has received an ovation in the press, all the more hearty because of, and not despite, the fact that he was a member of a race which has not normally been admitted to an opportunity to excel in this field. Yet if any are in doubt of the fact that the relations of races, at different stages of culture, who live side by side in the same community constitute one of the grave problems of the future, Prof. Gregory's book may be commended to them as an antidote for short-sighted optimism.

In "The Menace of Colour" the author has surveyed the main facts bearing upon the difficulties which arise when a white and a coloured population coexist in one and the same community. He has summarised some of the more authoritative views which have been expressed upon the question, and he discusses the arguments for and against the various solutions which have been proposed. Most attention has been given to those countries of which he has first-hand knowledge—the United States, South Africa, and Australia. Of these, the first two are countries in which the conditions, even though obscured by controversy, seem to demand action most insistently of all, while in the last named, the policy of "white Australia," of which Prof. Gregory is known as a staunch supporter, has been no less heatedly debated, although the danger, if any, is not immediate.

The problem is not the same in all three cases. In the United States the negro has for long, at any rate ever since the war of 1861, been a grave social difficulty. Recently the antagonism between white and black has been accentuated by the wave of racial feeling which has overrun the country and finds expression in the popular phrase "100 per cent. American." This feeling underlies the immigration laws and is grounded in a belief in the essential superiority of certain races and the inferiority of cross-breeds. It may be noted in parenthesis that certain American anthropologists, while fully recognising the differences in races, have not

hesitated to maintain that the argument is fallacious. The feeling against mixed marriages extends beyond negro blood to Indian and all non-white; and certain States have not only forbidden such marriages, but have even established bureaux to investigate pedigrees of would-be entrants into the matrimonial state to the remotest ascertainable degree. They are also carrying on a vigorous propagandist campaign on so-called eugenic lines in their schools. It is scarcely necessary to repeat what has been said so often on the mixed-breed question, that the inferiority of the cross is difficult to prove in man, when the evidence, apart from biological analogies, is almost universally vitiated by the disturbing factor of adverse social conditions.

In South Africa the problem is in part social, but to a greater degree it is economic and political. The enormously rapid increase in the black population—a feature to be observed almost invariably when white rule over African peoples puts an end to the normal checks on increase such as warfare, infanticide, or other customs of like effect—has aggravated the difficulties of adapting the native to the political and economic system, while it threatens the continued existence of South Africa as predominantly a white-man country. It has become unable to absorb the numbers of colonists required for this end, since the lower grades of labour are practically closed to any but the coloured population.

The case of Australia is in some ways the most interesting. The policy of a "white Australia" is based upon a definite political and economic theory. It is a trade union policy on a large scale. Two criticisms have been levelled against it. On one hand, it is said that it can be only partially operative, as the northern area of Australia lies within the tropics and is not, therefore, a white man's country; and, on the other hand, that it delays the filling up and development of the country. The latter point, though perhaps of more moment than is often assumed, is still perhaps not so immediately urgent as to force a decision. The former is more serious. The question of the adaptability of the white man to tropical conditions is discussed very fully by Prof. Gregory, who inclines on the whole to answer it in the affirmative. It is open to doubt, however, now that tropical disease may almost be eliminated as a factor in non-survival, whether all European races can be regarded as equally fitted for permanent settlement in such countries. Even in most favourable conditions, such as are afforded in the higher lands of East Africa, there is some evidence of a deterioration in the second generation. On *a priori* grounds the suitability of the Nordic type may be doubted. More definite evidence based on observation is needed. Up to the present the data have been obscured by the incidence of disease.

The colour problem is undoubtedly grave and difficult. It is one which affects vitally the British Empire with its vast populations of non-European culture. The solution to which Prof. Gregory inclines is that of segregation, a segregation, be it noted, in the mass, but not a segregation which excludes intercourse of individuals. Yet he is led by the tendency of European peoples during the present century to withdraw from interference with extra-European populations, notably, for example, in China and India, to the view that ultimately the whites will be confined to Europe, North America, and Australia. While, however, every one who is interested in what is called, for convenience, the native question, is convinced that it would be to the advantage of primitive populations to be protected from unrestricted contact with European civilisation, the course of events seems likely to be against the possibility of isolation. Prof. Gregory notes in his introductory chapters that at the present rate of increase the population of the world would double in sixty years. Even if that rate of increase were not fully maintained, the time for which the vacant places of the earth can be allowed to remain fallow is limited. Post-War conditions have obscured the difficulties of food-supply which were becoming apparent in 1914. They are not likely to become less acute. Their mitigation must ultimately depend upon the development of agriculture in areas in which white labour is not practicable. It therefore becomes an urgent question whether segregation would allow for the training of the primitive peoples themselves, along lines in harmony with their mentality and culture, to take their share in the development of their country and thus avert the exploitation of these lands and their inhabitants, which otherwise seems inevitable.

Birth-Control.

Population. By A. M. Carr-Saunders. (The World's Manuals.) Pp. 112. (London: Oxford University Press, 1925.) 2s. 6d. net.

PROF. CARR-SAUNDERS has given us in this little book a most admirable discussion of the whole population question. He emphasises strongly the point that over-population is a relative term, the value of which depends entirely on the economic resources of the area under discussion. Thus, in the early Middle Ages, England with 6,000,000 inhabitants might have felt the pressure of population more severely than it does to-day with 40,000,000. He directs attention to the fact that all through human history voluntary checks on population have been practised; that in no known people was the regulation of increase left to the crude issue of natural selection. In a word, birth-control is

as old as the hills. It was the Christian Church which put a stop to the methods of birth-control formerly in vogue, namely, infanticide and abortion, owing to its insistence on the value of the individual. It is not to be wondered at, therefore, that that Father of the Church, Tertullian, regarded war, pestilence, and famine as divinely appointed agencies for keeping the increase of the human race within bounds.

Prof. Carr-Saunders shows that throughout the Middle Ages the populations of the various countries either remained stationary or increased slowly, and that in the apprenticeship system we find a means of postponing marriage until economic fitness for it was attained. The extraordinary increase in population which occurred during the nineteenth century is something quite exceptional in human history and was only rendered possible by the introduction of steam power and of mass production, which constitute what is misleadingly termed the "industrial revolution."

Prof. Carr-Saunders then discusses the outlook for the future and has nothing very encouraging to suggest. He admits that the population of Great Britain is increasing by 400,000 every year, and that emigration is no remedy, for the Dominions quite rightly will only accept our very best, and the total number of emigrants whom it is feasible to induce to leave our shores every year is only a small proportion of our annual increase in numbers. He derives some comfort from Prof. Bowley's prediction, based on our diminishing birth-rate, that in fifty years the population will cease to increase and that the births will then balance the deaths. This prediction is based on the doubtful assumption that the death-rate will remain as high as it is at present, but in the meantime we shall have added 15 to 20 millions to the population and emigrated about 5 millions! Prof. Carr-Saunders wisely points out that even the fall in birth-rate is differential; that the least fit have still the largest families, and that whereas formerly this higher birth-rate was balanced by a larger death-rate, humanitarian legislation has largely abolished this distinction, so that our population is being principally recruited from our worst stocks. He indulges in a tirade against "nationalism," which he regards as the fount of "wars," and predicts a peaceful break-up of the British Empire. We utterly and completely dissent from this view; and suggest that "humanity" is too wide and vague a concept to attract the loyalty of any man, that a man's duty is first to his family and then to his country, and that it is his duty to strive to make both economically strong.

The immediate need of Great Britain is a wider spread of the knowledge of the means of birth-control amongst the poorer classes, and when that is accomplished, a system of sterilisation enforced against all those who

produce children in the absence of the means to support them. These measures will meet with a great amount of opposition on the part of those of our population who are swayed by vague sentiment, but it is our conviction that they will ultimately be forced on us by economic pressure
E. W. M.

Guide-Books for the Naturalist.

- (1) *Salzburg*. Von Prof. Dr. Max Hoffer und Prof. Dr. Ludwig Lammermayr. (Junk's Natur-Führer.) Pp. xvi+406. (Berlin: W. Junk, 1925.) 6 gold marks.
- (2) *Sächsische Schweiz*. Von Dr. Walther Friese. (Junk's Natur-Führer.) Pp. x+354+3 Karten. (Berlin: W. Junk, 1925.) 6 gold marks.

THE geologist has long been indebted to the enterprise of German publishers for several excellent series of guide-books. Junk's "Natur-Führer," previous volumes of which have dealt with Tirol, the Riviera, Switzerland, South Bavaria, and Steiermark, are guides not only to the geology, but also to all subjects likely to interest the naturalist in the field. Attractively produced, and of convenient size, they contain numerous photographic illustrations, but maps have been omitted, owing to their prohibitive cost.

Primarily a guide-book of this nature must consist of a collection of local details arranged for ready reference. A mere collection of facts will, however, only bewilder the visitor unless he has sufficient general knowledge to collate them. It is, therefore, very necessary that a naturalist's guide-book should contain a few introductory chapters, generalising on such subjects as the physical geography, the geology, the botany, and the animal-life.

(1) It is a pity that some such plan has not been adopted in the guide to Salzburg. The authors have brought together a large number of facts, but insufficient attention has been given to their arrangement for reference. Paragraphs are often three or four pages long, and sub-headings are completely absent. The type is of monotonous uniformity, and lists of species are printed in continuity with the rest of the text. Two introductory chapters deal with the geography and the early history, but the former is mainly statistical. The rest of the book is a detailed local guide, traversing the country roughly in the order adopted in the corresponding Baedeker. Floral lists, often filling a whole page, are given at frequent intervals. If these had been replaced by an introductory chapter dealing with the botany as a whole, with especial reference to the altitude-zones of Alpine vegetation, it would have been sufficient to direct attention to exceptional local occurrences. In Salzburg the geological

facts can only be presented by the aid of numerous sections. There is not one in the whole book, hence the details given are usually very lacking in precision.

(2) *Saxon Switzerland*, the hilly district through which the river Elbe flows where it leaves German soil, is probably little visited by British travellers, although a favourite retreat for the holiday-making German. To geologists it was long ago made familiar by the works of Geinitz, and it is to the hard Cretaceous sandstones, eroded into many picturesque crags and precipices, that it owes its particular charm.

Being only one-ninth of the area of Salzburg, and of infinitely simpler geological structure, its description in a guide-book must have presented a much easier task. On the whole, Dr. Friese has arranged his facts very well. A number of interesting chapters, dealing with particular aspects of the natural history, occupy two-thirds of the book, the remaining third being a detailed guide traversing most of the area in twenty-four excursions. There are maps of the river-system, a simplified geological map, and numerous diagrams and sections.

Our Bookshelf.

- (1) *A Student's Manual of Organic Chemical Analysis: Qualitative and Quantitative*. By Prof. Jocelyn Field Thorpe and Prof. Martha Annie Whiteley. Pp. x+250. (London: Longmans, Green and Co., 1925.) 9s. net.
- (2) *Introduction to Qualitative Organic Analysis*. By Prof. Hermann Staudinger. Authorised translation by Dr. Walter T. K. Brauholtz. Pp. xvi+112. (London: Gurney and Jackson; Edinburgh: Oliver and Boyd, 1925.) 6s. 6d. net.

THE difficulty with which qualitative organic analysis can be systematised, and the fact that the properties of the various organic groupings can be learnt best by experience, has rendered the literature on this subject very meagre in comparison with the comprehensive works published on inorganic analysis. The two books under review are welcome additions to the literature, treating the subject, as they do, from different points of view.

(1) Profs. Thorpe and Whiteley's book, as the title indicates, is intended for the student. Those who have worked under the direction of the authors will recognise in it the substance of their advanced practical organic course, amplified and arranged suitably for use as a work of reference. It is intended that a student with an elementary knowledge of organic chemistry will be able, after steadily working through the tests, to recognise and estimate the more common compounds and groupings and will be competent, with a little specialised experience, to undertake any type of organic analysis. The book includes detailed descriptions of both historical and modern methods of elementary analysis, and also gives a most comprehensive and up-to-date compilation of the methods used in estimating the more common types of organic substances. The

qualitative reactions of the important organic compounds are tabulated with full experimental details in a form which will be found very convenient for reference. The book will be found invaluable to all students and lecturers of practical organic chemistry by reason of its completeness of experimental detail and excellent manner of treatment. The type and illustrations are excellent.

(2) Prof. Staudinger's book gives no experimental details. It presumes that the student has already a good acquaintance with both theoretical and practical organic chemistry and is only concerned with the methods of separating the constituents of organic mixtures and identifying the class to which they belong. It gives no specific tests for individual substances or experimental details in performing the operations. The book is more a theoretical discussion of the methods employed than a practical aid in the laboratory. While it will prove useful in showing a student the way to deal with difficult problems, the methods given are too elaborate for ordinary use when the student has obtained practical experience; for example, many pages are used in discussing how to separate liquid mixtures which can be identified by their odour in a few minutes. The book has been translated into idiomatic English very ably, the only outstanding peculiarity being the expression "mixed melt test".

An Introduction to Physical Geology: with Special Reference to North America. By Prof. William J. Miller. Pp. xvi + 435. (London: Chapman and Hall, Ltd., 1925.) 13s. 6d. net.

SEVERAL books on physical geology, with special reference to North America, are already available, but Prof. Miller's contribution to the existing literature is sufficiently attractive to justify its choice as a college text-book. Although no new ground is broken, the order of treatment differs somewhat from that usually adopted. River work, for example, is not touched upon until rocks, weathering, earth-movements, and structural features have been dealt with. Underground waters, again, are considered only after volcanic action has been discussed. The effort after logical treatment in geology can, however, never be wholly successful, whatever the arrangement. Since the study of processes includes that of the alteration and origin of rocks, and that of the concomitant development of land-forms, the aspects of physical geology fall into at least three dimensions, and a written account, which is of necessity unidimensional, must therefore involve both anticipation and repetition.

Like all recent books of its kind, Prof. Miller's is weak on the theoretical side, perhaps deliberately in view of the variety of hypotheses now under discussion. But some mention might have been made of the controlling importance of radioactivity in contributing to the heat of the earth and to crustal disturbances. The grouping of weathering with metamorphism is an example of placing the logical significance of words before that of the processes they connote. Familiarity with Crook's important paper on classification, a paper that has been strangely overlooked in the United States, would have prevented such an error of judgment. The ideal text on physical geology, even relative to

existing knowledge, has yet to be written, but of its class, Prof. Miller's work is thoroughly good, and its exceptionally full illustration by photograph and diagram is an added virtue which should ensure success.

Roman Folkestone: a Record of Excavation of Roman Villas at East Wear Bay, with Speculations and Historical Sketches on related Subjects. By S. E. Winbolt. Pp. xiv + 199 + 21 plates. (London: Methuen and Co., Ltd., 1925.) 8s. 6d. net.

IN this volume Mr. Winbolt describes his excavation of the Roman site discovered at Folkestone in August 1923. He suggests, with good ground, that we have here the remains of the official residence of the Roman Commander of the British Fleet, which came into being somewhere about A.D. 43, with headquarters at Gesoriacum (Boulogne) and stations at Dover, Lympne, and at times Newcastle, and was probably disbanded about A.D. 290. The size of the villa testifies to its importance, and strategic considerations make it improbable that it was a purely private residence, especially as there is no other private building known along this coast. Mr. Winbolt has made a very careful record of the finds and describes them in detail. Having the interest of the general public in archaeological matters in mind, he takes his readers into his confidence, and not only gives for their benefit extracts from his diary so that they may follow the progress of the excavation day by day and share his enthusiasm, but he also explains with great lucidity how each type of find bears upon the solution of the problems of the excavator. His book, therefore, may be commended to those who have no technical knowledge of Romano-British antiquities as well as to the expert.

Non-Metallic Minerals: Occurrence, Preparation, Utilization. By Raymond B. Ladoo. Pp. viii + 686. (New York: McGraw-Hill Book Co. Inc.; London: McGraw-Hill Publishing Co., Ltd., 1925.) 30s. net.

THE technology of the non-metallic minerals has not before been treated so systematically and comprehensively as in this book. Merrill's well-known book is essentially geological and mineralogical, but Mr. Ladoo gives us not only the physical properties and mode of occurrence, but also methods of mining, uses, and market values, together with much miscellaneous commercial information. The materials discussed are listed under nearly ninety headings, arranged in alphabetical order, and to each section a bibliography is appended. The volume closes with a more general bibliography and an excellent index, so that as a work of reference it is both a valuable compilation and an admirable guide to a literature that is comparatively little known.

The author has covered a wide field, and to keep the book within reasonable limits of size and scope he has properly omitted all fuels such as coal and petroleum, and all other "minerals" of organic origin. These, like the metallic ores, have an extensive literature of their own, and the remaining minerals, hitherto somewhat neglected, have now for the first time received really adequate attention.

Plotting Upper Air Temperatures.

SIR NAPIER SHAW has recently devised a method of plotting upper air temperatures in the form of a curve which he has named a tephigram (T- ϕ -gram). The curve is plotted on squared paper on which the abscissæ represent absolute temperature and the ordinates entropy or log potential temperature. The condition of a mass of dry air can be described as well by its temperature and potential temperature as by its temperature and pressure, and the tephigram in utilising this method has an advantage over the older form of pressure-temperature diagram in that the work which will be done by a sample of air in rising through any given environment when conditions are unstable is shown directly on the diagram as an area which may readily be measured by planimeter. Tephigrams are

FIG. 1.

unfortunately somewhat difficult to comprehend at first sight, and are therefore unsuitable for presenting the results of upper air work to those who are not in close touch with the subject; but workers in this field of meteorology find that the graphs possess most of the advantages of the older pressure- (or height-) temperature diagram with the added advantage that, as explained above, they show the energy available from a sample of air placed in unstable surroundings at a glance.

If moisture did not exist in the atmosphere, the technique of plotting upper air data in the new manner might be regarded as fully worked out, but in all considerations of stability, moisture is of as great importance as lapse rate, and it is essential to indicate the water contents of the air by means of dew point or otherwise if the diagrams are to be of practical value.

To illustrate the following remarks a tephigram is sketched in Fig. 1. Potential temperatures are on the right of the diagram on a logarithmic scale, temperatures at the foot on a linear scale increasing from right to left, while lines of equal pressure slope down from left to right. Certain details have been omitted for the sake of clearness, only essential lines being shown.

The changes of temperature and potential tempera-

ture from the surface to the stratosphere are shown by the curve ABCD, the portion ABC where potential temperature changes but slowly being in the troposphere, while CD with its almost constant absolute temperature is in the stratosphere. If the air at the point marked B were saturated, the energy which would be liberated as one kilogram of the air rose from B to D is indicated by the whole area shaded on the diagram. The upper boundary of the area is an adiabatic line for saturated air, and it will be seen that as between B and D this line is everywhere to the left of the environment line ABCD, the rising air will throughout be warmer than its environment and will therefore have buoyancy and be capable of doing work as it rises.

The method of plotting humidities on the diagram which has been suggested by Sir Napier Shaw is to plot the dew point as well as the air temperature on each pressure line. Thus in the diagram B shows the temperature (286° A) at 800 mb. pressure and b the dew point (274° A). (See Q. J. Royal Meteorological Society vol 51, p 206, footnote.) The length of the line B b gives an indication of the dryness of the air. This method is probably the best that can be devised for showing the variations of humidity throughout an ascent, but it does not seem to be the most suitable for a study of the energy available in a mass of air rising from any particular layer. An alternative plan which appears to have advantages is to calculate the weight of water vapour per kilogram of dry air present in the air at B, and to mark the temperature β on the horizontal through B at which this weight of water vapour is the saturated content of air. Lines showing the number of grams of water vapour which will saturate one kilogram of dry air are printed on the tephigram paper (one is shown in the figure passing through b and β) and render plotting the point β easy. By this means the energy available in the actual non-saturated air at B is shown at once on the diagram, being the double shaded area which lies between the environment curve ABC and the saturated adiabat through β .

This is easily seen, for if a sample of air from B is raised in the atmosphere its temperature-potential temperature curve will run horizontally from B to β , where the sample will become saturated, thereafter it will follow the curved saturated line from β to C. During the first stage the air will be colder than its environment and work will be needed to raise it. During the last part of the course it will be warmer than its environment and will do work, as indicated by the double-shaded area. This method of plotting appears likely to have value in the study of instability in the atmosphere. It will make it plain that in many cases where large quantities of energy would be available if the air were saturated, in the conditions actually existing there is no energy available at all.

One criticism may be raised. On some few days the lapse rate reaches the dry adiabatic, and the environment curve ABC becomes for part of its course a horizontal line. Thus several successive points β may also fall on the same horizontal line, and it will be difficult to say which of the β 's corresponds with any one B. If, however, each point on the temperature curve is denoted by a separate letter, and each corresponding point on the moisture curve by a corresponding letter (B β , C γ , etc.), it will be easy to relate the two. It appears that if paper of a sufficiently open scale is used this objection need not be given too much weight.

Bismuth Trihydride and Silver Bismuthide.

GASEOUS bismuth hydride was first prepared by Paneth (*Ber.*, 1918, 51, 1704), who obtained it by treating an alloy of magnesium and thorium C or radium C with 0.2 normal hydrochloric sulphuric acid. He afterwards (*ibid.* p. 1728) prepared somewhat larger quantities of the gas by the action of either of the above acids (but of four times normal strength) upon an alloy of bismuth and magnesium, carrying out the reaction in a heated iron crucible and in a stream of hydrogen. A mirror of bismuth was obtained when the issuing gas was heated as it passed through a glass tube. The gas was, however, never obtained in large quantities, and we have endeavoured to make a considerable amount of this hydride and from this substance to isolate the silver bismuthide, analogous to silver antimonide (*vide* Weeks, *Chem. News*, 1923, 127, 319, Weeks and Lloyd, *ibid.* p. 362).

In view of our results with the solid hydrides of arsenic and antimony (Weeks and Druce, *Trans. Chem. Soc.*, 1925, 127, 1069 and 1790) it seemed likely that bismuth trihydride could be obtained by reduction of bismuth dihydride with hydrogen.

Thus, when the dihydride was heated *in vacuo*, it decomposed evolving bismuthine.

which could be decomposed on heating, with the formation of a mirror of bismuth. The gas was also drawn through solutions of silver nitrate to produce silver bismuthide, Ag_3Bi . The apparatus used in these experiments has been described in our communication to the Chemical Society on bismuth dihydride (*loc. cit.*). The most suitable reagent for absorbing bismuthine is ammoniacal silver nitrate solution, with which it forms a precipitate which was proved to contain only silver and bismuth. Analysis indicated that the composition of this compound corresponded closely with that demanded by the formula Ag_3Bi . The reaction is probably similar to the case of stibine and silver nitrate, namely:

Since the gas could never be obtained in large quantities by this method, we directed our attention to the reduction of the dihydride with hot hydrogen. For this purpose hydrogen was generated in the usual way and was purified by passing through solutions of lead nitrate, silver sulphate, potassium hydroxide, and potassium permanganate, and before being dried with concentrated sulphuric acid, it was passed through bulbs containing silver nitrate solution. These were inserted to ensure that the hydrogen contained nothing that would cause a precipitate to form with the silver nitrate used to react with the bismuthine which was obtained on heating the dihydride in this purified hydrogen. The gas issuing from the silver nitrate bulbs was ignited, and when the silver nitrate was largely decomposed, the flame assumed a steely grey colour and thin clouds of bismuth oxide were produced. Meanwhile, the silver nitrate slowly darkened with the formation of an almost black precipitate of silver bismuthide. It may be noted here that the bismuth dihydride must be free from traces of chloride, or silver chloride might be precipitated along with the bismuthide. This led us to prepare the dihydride by reducing a solution of a bismuth salt with aluminium and potassium hydroxide instead of the method described by us previously (Weeks and Druce, *Trans. Chem. Soc.*, 1925, 127, 1790). This product gave us a precipitate of silver bismuthide

uncontaminated with any silver chloride. The dihydride was reduced in accordance with the equation

Paneth has pointed out that the yields of bismuthine prepared from his alloys were very variable, and he concluded that the action of acids upon the alloys cannot be one of simple decomposition, since the best yields were obtained from magnesium which was merely coated with fused metallic bismuth. A possible explanation of this is that Paneth made a coating of bismuth dihydride upon the magnesium as soon as the acid acted upon the alloy. This view is supported by the work of one of us (E. J. W., *Chem. News*, 1923, 127, 87), in which it was shown that the yields of stibine from alloys of antimony and zinc appear to be independent of the composition of the alloy. It appears that the first action of the acid upon the alloy is the formation of the solid antimony hydride, which then decomposes in the following manner:

Silver bismuthide is an almost black crystalline compound, similar in appearance and properties to silver antimonide. It can be melted in a bunsen flame, and is unaffected by water or hydrochloric acid. It dissolves in warm dilute nitric acid giving but little bismuth trihydride, since further oxidation of this gas takes place.

The action $\text{Ag}_3\text{Bi} + 3\text{HNO}_3 = 3\text{AgNO}_3 + \text{BiH}_3$ is thus a reversible one, and this accounts for the difficulty experienced in absorbing the gas with aqueous silver nitrate. For this reason we employed ammoniacal solutions in order to remove the nitric acid as soon as it was formed. Silver bismuthide was also soluble in fairly strong hot sulphuric acid.

Flowering Plants as Epiphytes on Willows and Alders.

SINCE April, when trout fishing on many occasions in the river Chew, which enters the Avon between Bristol and Bath, I have been impressed with the large number of flowering plants, or Phanerogams, growing as epiphytes on pollard willows and alders by the river-side. I have listed about 103 species, in addition to the common Polypody fern. Some of these are of considerable interest in their strange habitat, and a single plant of *Lysimachia vulgaris* and two of *Nasturtium sylvestris* appear to be unrecorded species from the whole valley. The latter was also seen in the bed of the river during the drought of June.

The Chew extends from Chewton Mendip and East Harptree, Somerset, to Keynsham, a distance of about nineteen miles, or ten as the crow flies, and with a fall of about 400 ft. It is subject to heavy floods, and the average rainfall in the upper region is several inches greater than that at Clifton (35 inches) or Bath (30.84). The river rises rapidly, and occasionally to a height of eight or even ten feet above the normal summer level.

Doubtless the majority of the plants have been brought down and left stranded by floods, but not a few have been brought by birds, which are frequent in the valley, and several by wind dispersal of the seed. Cows, drinking and wading in some of the shallows, may be responsible for others. Many of

the trees have a considerable accumulation of humus, so that some of this vegetation may be regarded as well established.

Weeds of cultivated ground are few, for there is very little arable land in the valley, it being chiefly meadow or pasture. There are several mixed plantations near Compton Dando, three or four miles from Keynsham, but few woodlands in the upper part, except near the source of the stream. The number of woodland as distinct from hedgerow plants hitherto seen is extremely small. Ninety per cent. of the total plants have been noted between Keynsham and Compton Dando.

There is an apparent absence of any Leguminosæ—not even a vetch, clover or Lotus was observed. Many of the leguminous seeds would sink in water. Seeds (even from herbarium specimens) of practically all the British vetches and many others of that family sink in water, as experiment this autumn has proved. Compositæ is only moderately represented; but the comparatively large number of umbellifers is noticeable. The fact that no monocotyledons were seen, save *Juncus bufonius* and *Luzula campestris* (once) and a few grasses, is not surprising, except the paucity of grasses.

At least a dozen kinds of woody plants and shrubs have got established, namely, dog-rose, ivy, blackthorn, hawthorn, gooseberry, sycamore, elder, a small elm, ash, alder on two willows, and two or more species of Rubus in many places. No holly has been seen, nor maple with its winged samaras.

On April 30 I counted twenty-three Phanerogams, three mosses and two liverworts on a single old willow fallen half across the stream. These include *Ranunculus Ficaria*, *Arenaria trinervia*, *Rosa canina*, *Angelica*, *Conium*, *Anthriscus sylvestris*, *Torilis Anthriscus*, *Tussilago Farfara*, *Petasites ovatus*, *Symphytum officinale*, *Scrophularia nodosa*, *Stachys sylvatica*, *Nepeta hederacea*, *Plantago lanceolata* and three grasses, one of which proved later to be *Deschampsia cespitosa* in two fair-sized clumps.

There are a number of quite handsome plants in these lists, such, for example, as the comfrey, meadow cranesbill, hemlock, angelica, teasel, meadow-sweet, hemp agrimony, purple loosestrife, great mullein, and the picturesque woolly-headed thistle (*Cirsium eriophorum*), of which one poor specimen appeared. This most handsome thistle is very abundant on a steep bank overlying the Lower Lias, which descends in a great tongue-shaped mass almost to the river near Chewton Keynsham. It was from numerous dried specimens from this locality sent in 1922 to Dr. Petrak in Czecho-Slovakia, when monographing the genus, that his belief was confirmed that the English form differs slightly from the Continental. He has therefore called it sub-sp. *britannicum*. It is frequent in Somerset on the Lias, Keuper marls and Oolite, and was first noted in the county and for Britain by Lobelius in 1570.

Among the other plants growing upon some of the trees are *Thalictrum flavum*, *Ranunculus auricomus*, *R. acris*, *Nasturtium officinale*, *Brassica Rapa* (abundant and possibly native by the Chew), *Barbarea vulgaris*, *Cardamine pratensis*, *Viola Riviniana*, *Stellaria aquatica*, *S. neglecta*, *Lychnis dioica*, *L. Flos-cuculi*, *Geranium Robertianum*, *Geum urbanum*, *Adoxa Moschatellina* (once), *Galium Cruciata*, *Valeriana officinalis*, *Bidens tripartita*, *Lactuca muralis*, *Lysimachia Nummularia*, *Solanum Dulcamara*, *Prunella vulgaris* and *Ajuga reptans*. From these abridged lists most of the smaller plants and a few annuals have been omitted.

Tertiary Fossil Insects from Argentina.

A FEW years ago Mr. Geo. L. Harrington, of Buenos Aires, was prospecting in the Santa Barbara district of the Province of Jujuy, Argentina. In this region we find deep gulches with good exposures of the geological formations. A very conspicuous and important formation consists of green rock, easily breaking up into small angular fragments, commonly with conchoidal fracture. In its upper part it shows streaks of red, increasing until we reach an entirely red deposit. We interpret this as indicating increasing aridity, culminating in desert conditions with wind-blown sands. The red rock appears to be without fossils, and above it is a great mass (possibly 2000 feet) of yellowish deposit of more recent date. Dr. G. Bonarelli (1921) placed the green rock in the upper division of his Calcareo-Dolomitic horizon, but owing to the absence of fossils the age remained unknown. Mr. Harrington, following up the gulch which runs west from Sunchal, came upon a little deposit of fossil insects, and collected a number of specimens. Most of these were eventually transmitted to the U.S. National Museum, whence they were sent to me for study. They were found to consist of seven species of beetles and a caddis fly, almost certainly of Tertiary age. The horizon was in the typical portion of the green formation, where it is interbedded at intervals with heavy limestone.

This discovery was of quite extraordinary interest, as these were the first Tertiary insects ever found in South America, if we exclude a couple of small flies in amber of unknown age. My wife and I decided

1, *Cerambycites wilsoni*; 2, *Gryllus vociferans*;
3, *Psalis pachyura*.

that we could not spend the summer of 1925 better than by visiting the spot where there was a reasonable hope of further discoveries. Accordingly, after various adventures which it is not necessary to relate, the month of July saw us established in a small tent at Sunchal, within half an hour's walk of the insect beds. The locality proved interesting in many ways; the neighbouring slopes showed large columnar cacti, *Trichocereus terscheckii* (Parmentier) and *T. pasacana* (Weber), while the gulches were full of splendid trees, among which were flocks of green parrots. Sunchal proved to consist of a single, very poor ranch, with a few suburban sheds. We soon found Mr. Harrington's locality, as well as another not far away. In the course of several days we obtained a considerable collection of insects, mostly elytra of beetles. We also got a well-preserved fish, a species of *Corydoras*, a cat-fish of the family Callichthyidae. This represented a family of fishes not before found fossil. The general outcome is that the deposit is unquestionably fresh-water Tertiary, but the more exact position will have to be considered when the collections have all been gone over. The general impression is that the fauna is not very ancient, yet in some respects it recalls the Upper Eocene fauna of North America.

So far, we have only relatively small species of insects, with nothing specially characteristic of the

tropics I give figures of three of the most interesting. Fig. 1 is a cerambycid elytron, 9.5 mm long and 3 mm. broad, with large brown spots, the edges of which are darkened as in *Eburia*. It was found by my wife at our Station 2. I call it *Cerambycites uhlnallæ*, placing it in the blanket-genus *Cerambycites* because it cannot be definitely referred to a modern genus known to me. Fig. 2, which I call *Gryllus vociferans*, is part of the tegmen of a small male cricket, the part shown being only 4 mm long, the veins sepia brown. It is probably not a *Gryllus* in the strictest sense, but it is of particular interest as showing the male vocal organs fully developed, as in modern forms. This does not necessarily indicate a very recent age for the deposit, as similar specimens (three species) have been found in the Oligocene of the Isle of Wight. Fig 3 shows the forceps of an earwig, *Psalis pachynura*, the forceps reddish brown, 3.3 mm. long, simple, broad at base. The genus *Psalis* is doubtless an old one, being found on both sides of the world. I had referred the fossil to *Psalis* in a broad sense; and Mr. J. A. G. Rehn, to whom I sent a sketch, independently reached the same conclusion: "I should say from your sketch it would clearly be *Psalinæ*." These are the first orthopteroid insects found fossil in South America.

Now that attention is directed to these beds, others will doubtless investigate them, and we may expect to learn a great deal about the Tertiary insects of northern Argentina.

Opalina ranarum: a Flagellate.

MINCHIN, in his well-known volume, "An Introduction to the Study of the Protozoa," 1912, states that the species of the genus *Opalina* differ in certain peculiarities of structure and life history from all other ciliates. The life history has been studied by Metcalf and Neresheimer, whose accounts agree as

regards the general life history, but differ in some cytological details.

Neresheimer considers that the life-cycle of *Opalina* proves its affinities are with the Flagellata rather than with the Ciliata. This view did not find favour with Minchin, who placed *Opalina* in its usual position.

Recently we have carried out some work on *Opalina*, and have obtained results which we believe show conclusively that this protozoon is really a flagellate, as Neresheimer suggested from his study of the life history.

In a flagellate (Figs. 1-3, from Minchin) the flagellum nearly always passes into the substance of the organism and ends in a bead, vacuole, cyst or special granule of some kind. In various flagellates the granule may be specially well marked as a "solid," well-defined structure; in others it is apparently associated with a cyst of some sort.

In the typical ciliate, the cilia are almost invariably short structures arising from cortical granules which are nearly always quite small (Fig. 6). We know, however, of cases where the cilia have been described as entering right into the substance of the organism, and even impinging upon the nucleus, but such cases are rare, and unlike typical flagella.

Now, in *Opalina ranarum*, the "cilia" enter right into the substance of the organism, and take their origin from the peculiar granules which exist in very large numbers in the protoplasm of *Opalina* (Fig 5).

This system exactly resembles the arrangement in the choanocytes of *Grantia compressa* and *Spongilla* (Fig. 4) as described by Hirschler and Gatenby. We claim, therefore, that the motile organs of *Opalina* are flagellar in nature, and that this protozoon should be classified among the Flagellata.

The Geographo-Economic Institution at Leningrad.

IN 1919 the leading professors of the Geographical Institution, Leningrad, conceived the idea of creating a scientific institution for research upon geographical questions in which young men and women students of the Geographical Institution were to co-operate. From this sprang a "Scientific Collegium," which in 1923 was reorganised and named the "Geographo-Economic Institution."

This Institution is now under the direction of Prof. S. Sovietov and has eight departments: (1) Plant Geography, (2) Soil Science, (3) Zoo-geography, (4) Geophysics, (5) Economic Geography, (6) Geology, (7) Geography, (8) Ethnography. There are about thirty fellows and forty assistants now working in all departments. The principal work of the Institution is field studies. All the fellows and assistants are engaged during the summer in different parts of Russia, and during the winter the results of their work are discussed at the meetings of the Institution. This makes a very valuable training for young scientific workers in preparing them for responsible scientific positions. As Russian literature is very poor in good field manuals, the Institution has just published a handbook entitled "How can the Country be Studied?" Another large publication, a Geographical and Economic Atlas of the Leningrad country, is in preparation. This work will contain maps showing the distribution of different climatic and soil factors as well as of the various organisms—plants and animals, and of different peoples and their cultures.

The Institution has its own publication, "The Phyto-Geographical Atlas of the World," and would be glad to establish scientific relations with other similar Institutions of the world. The address is: Leningrad, Mramornyy Dvoretz (Marble Palace), Geographo-Economic Institution.

BORIS FEDTSCHENKO.

Some Modern Aspects of Physical Research.¹

By Sir ALFRED EWING, K.C.B., F.R.S.

IN this ancient and honourable Royal Society, we have an association of persons with a common motive, namely, to assist the advance of natural knowledge. The chief functions of such a society are (1) to provide facilities for intercourse, personal and formal; (2) to provide a library—and we have a great library of ever-increasing value, (3) to provide the means of publication. Records of scientific research are not a readily marketable commodity. They would fare badly if left to the mercy of the ordinary laws of supply and demand. So we meet the cost of publication, and they go out, after some winnowing of chaff from wheat, with our imprimatur. The published volumes of our Proceedings and Transactions contain papers by Kelvin and other fellows which may be said without exaggeration to mark epochs in the development of scientific thought.

The urge which we feel towards research—that urge which is our bond of fellowship—is not mainly utilitarian, it arises rather from a special type of intellectual curiosity. Often indeed the results of research undertaken with no utilitarian purpose have been found to possess a utility that was not in the mind of the discoverer. For example, Kelvin's theory of the oscillatory discharge of electricity, followed by Maxwell's recognition of electromagnetic waves in the ether, and by the detection of such waves by Hertz, though matters of purely scientific interest at the time, led in due course to wireless telegraphy and broadcasting. Again and again in the history of discovery an abstract research has turned out of quite unlooked-for practical value.

We may recognise, I think, two general types of research, both of which it is the business of a scientific society to foster. There is the inspired type—the flash of genius, of intuition, of imagination, which breaks new ground or brings the old into a new harmony by some far-reaching generalisation. There is also the plodding everyday systematic spade-work of research; a kind which goes on in a hundred laboratories; not inspired, not spectacular, not in the least intoxicating; but we should make a grave error if we were to underrate its importance.

Such a society as ours is, consciously or not, in some degree propagandist. One of its effects is to spread an interest in science beyond the bounds of the scientific workers. There is already a changed attitude on the part of the public towards scientific ideas and the scientific method. Formerly the voice of the specialist was that of one crying in the wilderness; now he commands the attention of the man in the street. In the training of engineers, in the carrying on of manufactures, in many different fields of social activity, we trace the permeating influence of science. Young men leaving the universities with a knowledge of scientific principles and able to manipulate scientific instruments are quickly absorbed into industry. One sees great industrial concerns setting up their own research laboratories, and finding that it pays them to do so. Research has found a place not only in manufacture

and industry, but also in the budgets of the politician. The Government endows individual researchers and encourages corporate efforts in various administrative departments, notably through its Department of Scientific and Industrial Research. The activities of that department are perhaps not so well known as they ought to be. Such an organisation can successfully undertake researches of a kind impossible for isolated workers. I have some personal knowledge of its work, for I am at present chairman of two of its scientific committees. One of these deals with the effects of moving loads in producing stress in railway bridges. This is an investigation which no private individual could conceivably have carried out: it needed, and has in fact received, the active co-operation of the railway companies. It is a long and costly inquiry, but I am able to say with confidence that the results already secured are such as to justify the expenditure, by the influence they will have on the future design of bridges and locomotives.

Looking back, it is curious to note the progress in pure and applied science that has come about within the period of my personal recollection. I am old enough to recall the very beginnings of electrical engineering, the first use of electric lamps, the first transformers and storage batteries, the first attempt to produce and distribute electric power. In student days I exhibited at a bazaar the first telephones of Graham Bell's invention, which had been brought across the Atlantic by Lord Kelvin. It happened too that, guided by a brief description in the *Times*, I made the first Edison phonograph ever made on British soil, an invention which has given us the advantages (if you so regard them) of the gramophone. I remember too the earliest form of motion pictures, from which has come the ubiquitous cinema. My memory goes back to the most primitive type of internal-combustion engine, the development of which has given us motor cars, and has made flying possible. It goes back also to the earliest application of refrigeration, which is now playing so large a part in bringing our food from overseas.

It was my privilege while a young professor at Cambridge to test for Parsons his earliest condensing steam turbine, and a little later his first turbine-driven steam-boat. The invention of the steam turbine, which we owe to Sir Charles Parsons, has been applied on a gigantic scale not only for ship propulsion, but also for the distribution of electric power from central stations. I recollect vividly hearing, in the early 'seventies, Lord Lister describe to this society his antiseptic method in surgery, and seeing him take from a sterilised flask its plug of cotton wool and drink down the milk it contained—milk which he had drawn from the cow three months before. Later came the two cardinal discoveries of radioactivity and the X-rays. Both of these soon became handmaids of surgery; but apart from that, they put novel instruments of unparalleled effectiveness into the hands of the physicist. Think of what all this discovery and invention has meant in making Nature more man's servant, in prolonging his life, in giving him more of comfort, of interest, of power.

¹ Presidential address delivered before the Royal Society of Edinburgh at the annual meeting on October 26

Younger men, who have been born into a world where these things are already familiar, cannot realise the excitement and delight of an earlier generation in seeing them spring, new and strange, from the brains of their creators.

•

Bliss was it in that dawn to be alive,
But to be young was very heaven!

I was really in middle life when, in the last decade of the nineteenth century, the great physical renaissance began, of which radioactivity and X-rays were the two chief starting-points, opening up as they did new vistas of thought as well as furnishing new tools for research. J. J. Thomson had shown in 1881 that a charged body derives additional inertia from the existence of the charge, but it was not until after his discovery (in 1897) of the electron as a disembodied atom of electricity, an indivisibly small unit, that it became apparent that all mass is electrical in origin. We used in older days to aim at explaining electricity in terms of matter; now we have come to regard matter as one of the manifestations of electricity. We recognise that the atoms of all substances are complex structures, which are built up out of only two kinds of brickbats, positive and negative units of electricity, called respectively protons and electrons. The positive brickbats, the protons, contribute nearly the whole mass, and it comes from the concentration of electricity into a very minute space. We may perhaps think of the protons and electrons as being electrified holes in the ether, imagining the proton hole to be about eighteen hundred times smaller in diameter than the electron-hole in order that it may have a sufficiently bigger mass. But I must admit that to suggest a definition of the ultimate particles of matter as electrified holes in a medium which perhaps does not exist, is more stimulating to the imagination than satisfying to the intelligence. Whatever the protons and electrons may be, they build up the atom in what Rutherford has taught us to regard as a sort of planetary system. There is a nucleus which contributes nearly all the mass. It is positively charged because it contains all the protons and only some of the electrons. The remainder of the electrons, in number equal to the positive charge, are disposed outside, much as the planets are disposed around the sun.

This conception of an atomic structure has led to the grouping of the elements in a systematic series, rising in regular steps by one unit of positive nuclear charge as we pass from one element to the next. The number of units of nuclear charge gives the atomic number of the element, and it goes progressively up from hydrogen = 1, helium = 2, lithium = 3, and so on, up to uranium = 92, forming a continuous series in which there are only two or three gaps still waiting to be filled. Towards this idea the way was paved by Barkla's discovery of the characteristic radiation of substances under bombardment by X-rays. The splendid generalisation of the atomic series was itself reached through the inspiration of Moseley. It justifies Prout's old hypothesis, the objection that the atomic weights of the elements do not come out as whole numbers having been completely removed by the discovery of isotopes, the discovery, namely, that some elements are mixtures of two or more substances having the same chemical

properties, but with integral differences in their atomic weights.

More or less concurrently with these developments of atomic theory came the recognition of series in the lines of optical spectra, initiated in 1885 by Balmer, a teacher in a secondary school at Bâle. His work was followed up by Lyman and Rydberg, and is now interpreted, thanks to the genius of Bohr, in a manner which connects the spectral lines with the complex atomic architecture of Rutherford. In this interpretation the quantum theory, which had been framed by Planck in 1900 to account for other and quite different phenomena, has received so complete a confirmation that we are forced to accept it as a rule in Nature's operations, although at present it is a rule we cannot understand.

In the hands of the Braggs, father and son, X-rays have served to show exactly how the atoms take their places in the tactical groups which constitute crystals. The whole development of modern atomic theory is a chain of discovery connecting phenomena that were previously separate, stretching link by link into regions that had seemed hopelessly outside the pale of exact knowledge. No one surely foresaw that it would be possible to weigh and measure the constituent particles which make up an atom.

Other romances of science are to be found in the recent progress of astronomy. A new departure was taken by Michelson in 1920 in the success of his device for measuring the sizes of certain stars. He found, for example, that in Betelgeuse we have a celestial giant two hundred million miles in diameter, big enough to take in the whole orbit of the earth, and more. This diameter had been foreseen by theory. In particular, Eddington has applied his imagination and his mathematics to the question. He shows that the surface temperature of a star is no criterion of the fervent heat within, where a temperature of perhaps twenty million degrees may be reached. Under such conditions the energy of the star is about equally divided between the energy of waves of radiation and that of the motion of particles. The radiation causes a disruptive pressure which acts against gravitation so strongly that the balance between those two forces is the factor which determines how much mass is condensed to form a single star. This explains why it is that all stars are roughly of the same order of magnitude.

Eddington pictures the radiant energy within the star as trying to escape into surrounding space but caged in by the material. It is tossed to and fro from atom to atom as the ball is tossed in a Rugby match, and only little by little does it reach the surface and find itself free. He shows how at the enormous temperature of the interior the atoms are stripped of their outer electrons, which then mingle in the throng as free particles. Deprived in this way of the crinoline or fender of electrons that would normally keep them apart, the nuclei may approach one another far more closely than they could otherwise do, and the star may therefore contract to a density which vastly exceeds that of any substance known in our laboratories. But in contracting from a giant to a dwarf, the substance of the star preserves the essential features of a gas, for the particles have still a relatively large mean free

path of movement in the intervals between their encounters. Owing to the removal of their crinoline, stellar atoms have only something like one-hundred thousandth the bulk of ordinary atoms, and so may be brought immensely closer to one another before the properties of a nearly perfect gas are lost. Finally, Eddington gives us reasons for imagining that in the course of its life history the star maintains its power of emitting radiation not simply by virtue of its contraction, but by converting into energy a portion of its own mass. His remarkable prediction as to the density of dwarf "white" stars has, during the past summer, been verified by Adams at Mount Wilson, who, by measuring the "relativity" displacement of lines in the spectrum of the companion of Sirius, has proved that star to have a density some two thousand times greater than that of platinum, and has directly confirmed the validity of the spectral shift as a test of Einstein's general theory of relativity.

Yet another romance is the story of helium, first inferred as an element in the sun by Lockyer in 1868 from observations of the spectrum of a solar prominence. It was not known to be a constituent of the earth until Ramsay found it in 1895 as a gas in the mineral cleveite. It takes an important place as the second member of the atomic series, the lightest of the group of inert elements which includes neon, argon, krypton, and xenon. It is found in small quantity in the atmosphere and in nearly all natural gases and spring waters. We now recognise it as a product of the disintegration of radioactive substances. Each alpha particle they shoot out is essentially an atom of helium. It is the nucleus of such an atom, which only requires to associate itself (as it can readily do) with two planetary electrons in order to become a complete electrically neutral atom of helium. The lightness and inertness of helium make it an ideal substance for the filling of airships, for it has a lifting power in the atmosphere not far short of that of hydrogen, along with the immense advantage of being completely unflammable. Helium is now assiduously collected from its natural sources for this practical purpose. From the point of view of theory it is also particularly interesting. As an agent for producing the extremest degree of cold it has been used by Onnes, who, by vaporising liquefied helium, has reached a temperature only about two degrees short of absolute zero. One may remark in passing that the absolute zero of temperature is almost the only absolute thing that is left to us in a universe given over to relativity.

Rutherford has put helium to another scientific use. He employs the alpha particle, which is the nucleus of helium, projected from a heavy radioactive substance

with a velocity of ten or twelve thousand miles per second, as a projectile with which to knock chips off the nuclei of nitrogen and certain other elements. In this way he produces hydrogen, for the chips which are knocked off are single protons, each of which forms the nucleus of a hydrogen atom. Thus in the hands of Rutherford the alpha particle is a veritable philosopher's stone by which the transmutation of elements, so long the dream of the alchemist, has become an accomplished fact. Quite lately we were told of laboratory experiments in which gold was reported to have been made by the removal of part of the nucleus of the element next above it in the list, namely mercury. The news was received with perfect calm by the scientific world, and even, I fancy, by the Governor of the Bank of England. For if you want gold it will doubtless be cheaper to find it by digging than to make it in that way.

There have been so many surprises in physics that the faculty of wonder is almost exhausted. Things have happened which a little while ago would have seemed to be miracles. We may think of Kelvin or of Tait as turning in his grave when an occupant of this chair speaks of there being no strict conservation either of matter or of energy, and accepts the possibility of transforming the one into the other. The foundations of the older physics have been rudely shaken, and the effect of such upheavals has been to alter the temper of the scientific mind. The old positiveness has gone. No longer are we positive about anything. The complacency, the facile dogmatism, which here and there showed itself in the last century, is now a rather absurd memory.

We are confronted by dilemmas and find no way out. We are obliged, one may say, to take the dilemma by the horns, boldly grasping both. The electromagnetic theory of light, established as we believed by Maxwell, is confronted with the view that there is no ether, nothing which will serve, in the words of the late Lord Salisbury, as a nominative to the verb to undulate; and, worse still, while the wave theory is amply supported by the facts of interference and diffraction, it is apparently inconsistent with the equally well-established facts of absorption and photo-electricity. How to reconcile these seeming contradictions we simply do not know. So while we may justly feel pride in all this progress and achievement, it is mingled with a consciousness of mystery, with a spirit of question. In a special sense is it true to-day that the widening of the circle of light has widened the circumference of darkness, and for the moment at least the darkness seems strangely impenetrable.

The Science and Art of Map-making.¹

By A. R. HINKS, C.B.E., F.R.S.

THE progress of invention has placed in the hands of surveyors a number of beautiful new methods, and some we have not yet scientifically explored. Would you measure a base? So far from painfully seeking a dead-level plain and clearing it of every petty obstruction, you will gaily take the suspended invar

tapes across country, and by preference run them up a hill at each end to get a better view for the base extension. Would you equip a party for primary triangulation? Look thankfully at Ramsden's 36-inch theodolite reposing in the museum of the Ordnance Survey; look doubtfully at the fashionable 10-inch; and before you take it any more into the field, examine whether the instrument of the future is not a 5-inch

¹ From the presidential address delivered at Southampton on August 27 before Section E (Geography) of the British Association

constructed on the new principles of Mr. Henry Wild, with circles etched on glass, and parallel plate micrometer that reads opposite points of the circle from the eye-end and takes the mean for you. When you lay out the triangulation, consider well the recent opinion of the U.S. Coast and Geodetic Survey, that it is better to be content with small triangles easily accessible, with automatic electric beacons tended by a party in a car, than to make enormous efforts at rays longer than Nature easily allows. Bear in mind also a remark which our lamented friend Col. Edmund Grove-Hills made to me not long before his death. I was saying how necessary it was to complete as soon as possible the late Sir David Gill's great arc of meridian in Africa; and to my horror Hills referred contemptuously to the meridian arc as an "obsolete method." He did not pursue the idea; but I think we can see what was in his mind, and that he was right. The old-fashioned arc stuck to the meridian or the parallel with a sublime disregard of the topographer's convenience. It had infrequent bases measured with pomp and ceremony. It had occasional astronomical latitudes and azimuths observed with an almost painful degree of internal precision by heavy instruments and prolonged sojourn on uncomfortable heights.

We can see now how mistaken it all was. The purpose of these astronomical observations was to compare the geodetic with the astronomical latitudes, as a contribution to the Figure of the Earth. But what use to aim at single tenths of seconds in the latter, when on the average they were divergent by several seconds owing to local deviations of the vertical? Our real need is for a latitude at every triangulation point, and those points thick upon the ground. "Obsolete" was Hills' word for the meridian arc; and I think we shall not find it too strong, when we look at a graphical plot of the contribution to our problem which Gill's arc in South Africa can make.

It seems that we shall be driven back to the old network stretching far and wide across the country like the triangulation of Great Britain; and that raises problems which can scarcely be discussed here. But let me not for one moment be taken as disparaging the practical value of Gill's great achievement. It has proved invaluable as a framework on which to hang boundary surveys. It stretches a long skeleton from Port Elizabeth to near Tanganyika—ready to be clothed with topographical maps; and still lying in stark nakedness, for there is something in self-government that is antipathetic to map-making. Our Crown Colonies are getting fairly well provided with maps, thanks in great measure to the work of that Colonial Survey Committee which was so active early in the century, and which we hope was not a casualty in the War. But our self-governing Dominions have not always much to boast of.

This is a well-worn subject, and geographers are getting tired of asking whether there is yet a single topographical sheet to be bought in Australia. I believe that the answer is still, No: though there are some thirty sheets for official use produced by the Department of Defence as an earnest of the thousands that are wanted to cover the continent. Canada has now a first-rate geodetic survey and the beginning of a good topographical map; but it is a big country that

began survey very late, and its settlement is marching faster than its maps. Thanks to the labours of Mr. Wallace, we do know at last, what Lord Southesk never did, where he went on his journey of 1859 in the Rockies, but there is still no published map good enough upon which to show the route.

It is a commonplace of books that the surveyor in the field can always find latitude or azimuth, but is in difficulty with his longitude. That is no longer true. The rapid establishment of powerful time signals has made it possible to get longitude as exactly as latitude, and this must have a profound effect on further survey, exalting the astronomical at the expense of the trigonometrical; facilitating marvellously the rapid reconnaissance survey; putting off the drastic remedy of triangulation; but heaping up trouble in the future. On the other hand, the method of wireless longitudes will tend to the solution of two great problems, one of respectable position and one a little parvenu. Is the equator a circle? No one has yet certainly challenged it, though Clarke and others have done their best with inadequate means. Are the continents floating, or rather sliding about slowly on a *sima-slide*? We are generally agreed that Wegener has not proved his case, because he had a naive trust in astronomical longitudes palpably weak. Yet the question has been deemed worthy of a serious and costly enterprise, warmly advocated by General Ferrié, and gradually assuming, I think we may say, without offence to that great enthusiast, a much more acceptable shape than the rather hard and unadaptable outline that was a little criticised by British geodesists and astronomers two years ago.

The need of a strong central authority is as evident in wireless time signalling as it is in the organisation of broadcast. Happily for geographers, the astronomers have organised themselves well since the War into a Union with thirty-two Commissions. The Union spends half its whole income on the sustenance of the Bureau International de l'Heure, over which one of the Commissions exercises a general control. The prodigality of the Union, stated thus, is impressive. In cold fact, its contributions, fixed unfortunately in French francs, do not go very far to pay the cost of the service, which can be carried on only because the Director of the Paris Observatory has not hesitated to place the instrumental resources and the magnificent house-room of his Observatory at the disposal of the Bureau; while the keen interest of General Ferrié has secured the benevolent and beneficent co-operation of the French radio-telegraphic services, military and civil. Geographers owe a great debt of gratitude to the French in this matter. But we hope that the British Government will not rest content with the modest part which Great Britain has played up to the present in this great development. We have—or shall have soon—an "Imperial Wireless Chain" stretched out from the new station at Rugby to the farthest Dominions; and we shall miss a great dramatic opportunity if from the opening of this service we do not insist that time signals from Greenwich shall be sent from Rugby and retransmitted in each link of the chain, that all Britain's Dominions beyond the seas, her ships on the ocean, and her travellers wherever they may be, shall be able to take Greenwich Mean Time direct from

the source. The technique of time transmission has been so greatly improved in these last years that there is no serious difficulty about it; and of the Imperial services for which the Rugby station is built, there can be none, I think, more really, if modestly, useful than the propagation of Greenwich Mean Time throughout the Empire.

The science of cartography is based upon the sciences of precise survey, and I make no apology for having dwelt for some time on the methods of securing the foundations. But when these are well and truly laid, it is time to press forward the visible building—the maps—and a problem we share with the larger world is that of building with speed and economy, not regarding too closely the interests vested in the old methods, but prepared if it seems wise to reinforce the ancient crafts with new. Two new powers have been added to the cartographer in these last years: flight to give him range of vision, and the stereoscopic plotter to give his photographic vision a new sense. For I do not exaggerate when I use those words—a new sense—to describe the power which the stereoscopic measurement of pairs of photographs has given the surveyor of topographical detail. The brilliant idea that this could be done automatically was due to Capt. Vivian Thompson. The credit of extending and perfecting the beautiful but marvellously simple geometry belongs to an Austrian, Lieut. von Orel; and of translating the geometry into sweetly working mechanism to the German firm of Zeiss. No more beautiful piece of optical machinery has ever been made, I willingly believe, than the stereoautograph of von Orel and Zeiss. But they made a sad mistake in marketing it, granting exclusive rights over a territory to an individual, and demanding from him not only a heavy price for the outfit, but also a large and perpetual royalty on his gross receipts as a stereoautographer. So strange a method of selling a scientific instrument was never known before.

Happily there is more than one mechanical and optical solution of the problem, and at least four different machines are now in the field abroad, while a fifth is under construction in Great Britain to the order of the Air Survey Committee. We are thus fortunately saved from the reproach that nothing has been done in this our country to develop a method first devised by an Englishman. But we may feel that our instrument-makers and our surveyors have been a little unenterprising, and there is nothing I would like to see more than a real effort, with adequate means, to try out stereographic surveying on geographical scales.

We know well enough that the stereoautograph can deal marvellously with a small piece of country on a large scale; but what has never yet been shown is that it can deal with a large piece of country on a small scale. It will contour for you an inaccessible cliff at 1-metre intervals on the scale 1/5000; but can it or a rival be made to tackle 100-metre intervals on the scale 1/250,000? That is a question which has never yet been answered, and I believe that it is our duty to answer it. Along the northern frontiers of India in the ranges of the Himalaya are at least 10,000 permanently snow-clad peaks. So long as the inch-to-the-mile map is incomplete in the plans, we can scarcely expect it in the mountains. Yet a really accurate map on the scale, say, 1/250,000 cannot be deemed superfluous for de-

fence; and even the poor geographer or traveller is entitled to ask for it. How is it to be obtained? Will stereoscopic survey do anything for us?

I feel certain that the answer is Yes; but much less certain that the photographs should, at least in the first instance, be taken from the air, which seems to be contemplated by the advanced school, and taken for granted by the newspapers. Air photography made a brilliant success in the War, when the cost was not too severely scrutinised. In peace we have to approach the problem with the fear of the Treasury in our hearts, and with more respect for that sort of precision which lets one go on in an orderly way for ever, without leaving accumulations of errors "to be absorbed in the desert," as they say in the Sudan.

Now, photographs taken with axis vertical cover a surprisingly small ground, even from extreme heights. With a lens of 6 in. focal length, about the minimum, you must go to 25,000 ft. to get a result on the scale 1/50,000, and then you can photograph only about three miles square on each plate. Flying at 90 miles an hour you must take plates every few seconds to avoid getting too much stereoscopic relief. It looks as if vertical photographs combined stereoscopically will fail in mountainous country.

I turn to obliques. The photographs taken in the air are taken from unknown points, and the first thing to do is to determine the position of the camera at the instant of exposure. The geometry of the method is none too strong, anyhow, and we could not expect to find the resulting place of the aeroplane with anything like the accuracy of a ground station. This leads me to think that stereographic survey from ground stations will be found to play an indispensable part in the future survey of mountainous country.

Suppose, for example, that political difficulties did not exist, and that we were able to survey the country south of Mount Everest. I think I would rather start out with a series of camera stations along the Singalela ridge, and fix all the visible crests stereographically with horizontal axes and vertical plates. A large part of the ground would be dead ground; but quite a good deal could be put in. Would this not solve the question of providing a fixed framework for the obliques from the air, perhaps combining each with a plate from a ground station, rather than in pairs of obliques? It will at any rate be worth the trial; and therefore I am anxious that we should not fail to exploit the relatively easy and inexpensive ground stations, while we are perfecting the vastly more difficult process of the oblique air photograph.

I suppose there never was a time when it was more difficult than now to forecast the future in surveying. We have seen already that geodesy is in a state of flux; we are not even allowed to believe that the pole or the continents stand fast in their right places. The methods that were canonical in field astronomy a few years ago are being rapidly displaced by new. The prismatic astrolabe is threatening to oust the theodolite; and Mr. Reeves has retaliated by inventing a small attachment to the theodolite that does the work of the astrolabe to perfection, and makes a separate instrument unnecessary. Sound-ranging and flash-spotting may yet be turned to the arts of peace, and there is something suspiciously like the latter in the

method proposed for connecting Egypt with Crete or Alaska with Siberia. Sound-ranging in air is perhaps not so likely to be useful to geographers as sound-ranging in water. But there is a post-War invention the future of which is brilliant. Who would have dreamed in the *Challenger* that her modern counterpart, the Royal Research Ship *Discovery*, would be equipped with deep-sounding gear on the method of echoes, that takes soundings in no time, or very nearly? It has become suddenly vastly more simple to measure the depth of the sea than the height of the land. There is much more sea than land, and a disproportionate part of it is very deep. Yet now for the first time we can begin to think of ocean contours drawn less by imagination and more by soundings in the new sense of the word.

If there was twenty years ago one branch of cartography that seemed stereotyped and unlikely to develop, it was surely the subject of map projections—a subject with a large and rather unprofitable literature; a science in which pure mathematics disported itself to the little advantage of maps; a science with a misleading title, since scarcely more than one of the useful projections is really a projection at all, the rest being only constructions; a science in which guiding principles were hard to find.

But in recent years the subject has taken on a new aspect. Tissot, and Jordan, and especially A. E. Young, have developed the expressions in infinite series—a process which sounds terrifying to those whose intelligences automatically shut up when they scent mathematics, but it is really an enormous simplification, because it reveals at once how much alike all these projections are in the first few terms, and precisely by how much they begin to diverge from one another when the sheet is extended. Moreover, this way of dealing with the subject allows the conscientious cartographer to distribute the errors judiciously by a process of cooking the projection, producing a flavour much appreciated by the connoisseur, though a taste not yet acquired by the common map-maker. But these refinements must not be looked at askance, as over-elaboration tending to preciosity. They have real practical advantages in the computing office.

This branch of our venerable science is therefore very much alive. It has even produced of late two new families—the retro-azimuthal projections which are the offspring of the Survey of Egypt, and the doubly-zenithal the father of which is Sir Charles Close. The former guides the Muslim in his prostration towards Mecca; the latter serves wireless direction-finding and other devices of the twentieth century. Could a student desire a subject of wider scope in which to exercise his powers?

The thought of the very charming modification of the polyconic projection devised by M. Charles Lallemand for the International Map on the scale of one in a million, leads us naturally to consider the outcome of that ambitious programme which was launched at the London Conference of 1909. Difficult as it was to secure enthusiastic co-operation before 1914 in producing sheets the marginal lines of which were necessarily drawn on a hard geometrical convention regardless of frontiers, it is trebly difficult now.

But I think it is fair to inquire if the original scheme was sound. There is an old proverb that if you want

a thing well done you must do it yourself, and with suitable modification this seems to me to apply especially to map-making. It is difficult enough for a single office to produce at intervals sheets that will absolutely match their neighbours. To expect uniformity from twenty or thirty reproduction offices is to expect altogether too much. One might indeed overlook slight differences in layer tints if one could only get the maps; but that is just the difficulty. Some countries are keen to meet their obligations, and some are not. India has produced a fine block of sheets; the North American Continent—I will not particularise—has produced three. I think we should find if we took a census that the majority of the Powers represented at Paris in 1913 have produced none, and show few signs of doing so.

With some trepidation I suggest, therefore, that the scheme for an International Map was bound to fail, because it required that each of many different countries should do its share, after a preliminary wrangle with its neighbours as to what that share was. Successful international co-operations have never worked that way. What has been the guiding principle of the successful enterprises? Surely that the reputed cost should be contributed by the nations in rough proportion to their populations, and that the work should be done by one. The Bureau International des Poids et Mesures, the old International Geodetic Association's Institute, the modern Bureau International de l'Heure, all these work or worked on that plan, with great success. The contributing nations get a great deal for a very small payment, and the nation which has the energy to take on the responsibility, and gets the credit, naturally contributes from its own resources, directly or indirectly, a large and essential part of the total cost.

The Survey of India has set us an admirable example in its map of India and Adjacent Countries, with a liberal interpretation of what adjacent means. Is it beyond hope that even in these hard times the Geographical Section of the General Staff might be given means to produce a map of the "British Empire and Adjacent Countries"—again without too much regard to the niceties of language?

Such a map of the world is indeed an almost necessary outcome of the P.C.G.N.'s work on names for British official use, for if unity of style could be achieved by miracle in an international map, there is no hope whatever for unity of spelling, or even of nomenclature. A sheet bears inevitably in its methods of transliteration the mark of its origin. We are all agreed that names in countries using the Roman alphabet should be spelled as in that country; the difficulty comes in transliteration from the non-Roman, and in descriptive names. The International Hydrographic Bureau at Monaco seems to me to have entered on a hopeless quest when it tries to obtain international agreement for the names of international waters. The French must surely always call Pas de Calais and La Manche what we call the Straits of Dover and the English Channel. The Germans will doubtless continue to speak of the Ost See, even though the bishop's wife protested to Elizabeth in Rügen that "the Baltic exactly describes it." Much can be done, no doubt, to eliminate superfluous variants and modern corruptions; but I do believe that the names for "British Official Use" must always

have a certain British flavour, however much we try to be scrupulous or even pedantic.

It will be agreed, I trust, that the science of map-making is healthily active and growing. Let us turn now to the art, which is twofold: the art of the convention by which the outline and the relief are reduced to the compilation, and the personal art of drawing the detail, the lettering, the divided margins, the ornaments, so that the finished map shall be clear, harmonious, and beautiful.

During the last thirty years we have seen the convention profoundly modified by the rapid improvement of colour lithography. Colour has, it is true, been used on engraved maps from the very first, and in my opinion the most agreeably coloured atlas ever published was the Rome edition of Ptolemy of 1486. But this was hand colouring, and no two copies are alike. In the years that followed the colour became more elaborate, but it was largely in the ornament, and the essential outline of the map was in black, from the single engraved plate. The great extension of possibilities came with the quite modern use of colour to distinguish the outlines of different classes: blue for rivers, brown for contours, red for roads, and so on. The enormous resulting improvement was conspicuously in the re-

presentation of relief. Layer colouring in particular, first employed on a large scale by the celebrated firm of Bartholomew, has given our maps all the advantages of a relief model without the inconveniences. It is a method in which the British have always excelled; and the supreme example of skill in layer colour-printing is the "Gamme" or colour scale attached to the report of the Paris Conference of the 1/Million Map in 1913: a scale which we may be proud to think was printed in England, at the War Office. There are infinite possibilities in the combination of layer colouring with contours, hachure, vertical and oblique hill shading; many of them have already been realised by the Ordnance Survey, particularly in their special maps of holiday districts, and in a map of South Devon which I regretfully remember in proof only, because it was found too expensive for issue. For we must note that a modern map passes through the press eight or ten or twelve times, and the cost of the machine work, apart from all the plates, is multiplied in the same ratio. The wonder is not that maps are expensive, but that in the circumstances they are so cheap. We should wish to believe, however, that the progress of invention may some day give us back that richness of tone that distinguishes the old engraved maps.

Obituary.

MR. J. Y. BUCHANAN, F.R.S.

THE last member of the original scientific staff of H.M.S. *Challenger* on her famous voyage of discovery in the great oceans has passed away by the death, on October 16, at eighty-one years of age, of Mr. John Young Buchanan. He holds an assured place as one of the founders of modern oceanography, and if his personal share in the fundamental researches is not more conspicuous in the text-books, it is largely because of his loyalty to the spirit of the expedition which gave the glory to the *Challenger* group rather than to individuals. He was in the most literal sense an original worker, always preferring to settle a point by observation or experiment rather than by books, and when reference to recorded work was necessary, always going direct to the fountain-head, never to a compilation. He paid no regard to authority or scientific orthodoxy, and did not get on comfortably with those who did. Censorship of research, even the reference to experts of papers submitted to a learned society, was obnoxious to him, and he spoke very plainly on this subject in communications to NATURE and elsewhere. So far as he allowed his singularly restrained and reserved nature to express itself in warm terms, he showed a passion for the freedom of research. He said: "To standardise research is to limit its freedom and to impede discovery. Originality and independence are the characteristics of genuine research, and it is stultified by the acceptance of standards and by the recognition of authority" (Preface to his "Comptes Rendus," 1917).

Buchanan was born in Glasgow in 1844, the second son of Mr. John Buchanan of Dowanhill, and was educated at the High School and University of his native city, where he graduated as M.A. Having decided to follow chemistry as a profession, he proceeded to study on the Continent, where he spent some time at the Uni-

versities of Marburg, Bonn, and Leipzig, and under Wurtz in Paris. On returning to Scotland he acted for a short time as assistant to Prof. Crum Brown in the University of Edinburgh. His leaning was always towards practical work rather than theoretical study, and he had little liking for teaching or lecturing. He excelled in manipulation, and especially in glass-blowing, a fact which weighed in his appointment as chemist and physicist on the *Challenger* expedition, where it was desirable that a scientific man should be able to make his own apparatus in case of need. The voyage of the *Challenger* lasted from December 1872 to May 1876, and most of Buchanan's time was occupied by routine work in measuring density of sea-water, collecting gas contents, and making qualitative analysis of all manner of natural deposits. He found time for several pieces of research which he afterwards developed in the private laboratory which his ample means allowed him to maintain, first in Edinburgh and latterly in London. The most important of these involved the thermal relations of sea-water and of salt-solutions generally, especially with regard to the formation of ice and steam.

A picturesque incident in the *Challenger* was his determination of the true nature of *Bathynus Hæckeli*, which Huxley believed from microscopic examination of preserved deposits to be a primitive organism covering the bottom of the sea. Buchanan proved it to be a gelatinous precipitate of calcium sulphate thrown down by alcohol, a fact which was very reluctantly accepted by the biologists on board, who were unwilling to think that Huxley, the highest authority, could possibly have made a mistake. Huxley himself at once accepted the correction in the frankest manner. A less dramatic but more constructive piece of work was the analysis of deep-sea deposits, especially of the red clay and the nodules of manganese peroxide embedded in it, on

which Sir John Murray based his theory of the formation of oceanic deposits and coral islands. Buchanan championed the hydrometer against chlorine titration as the measure of salinity, and he held to this view, although later work has convinced the oceanographers of to-day of the superior accuracy and convenience of the titration method. He made important experiments on the compressibility of substances at pressures existing in the depths of the sea, and the water and mercury piezometers which he made on board the *Challenger* yielded remarkable results in his hands, enabling him to measure depths and bottom temperatures irrespective of the length of line paid out. He pursued these investigations in later years, and read several papers to the Royal Society and the Royal Society of Edinburgh on the compressibility of solids.

The researches on sea-water initiated from the chemical or physical side were continued with the object of studying the conditions and movements of water in the sea and in lakes, thus leading their author from chemistry into physical geography. Buchanan made many scientific cruises in his steam-yacht *Mallard* on the west coast of Scotland and the lochs connected by the Caledonian Canal. Later he made a series of voyages on the cable-laying ships of the Silvertown Company along the west coast of Africa, and during the later years of his active life he was closely associated with the oceanographical researches of Prince Albert I. of Monaco. The Prince had a very great regard for him and consulted him in all details of his work on board the *Princesse Alice*, as well as in the organisation of the Monaco Oceanographical Museum and of the Oceanographical Institute in Paris.

During the 'eighties of last century the *Challenger* Office made Edinburgh a focus of activity in all branches of science, and Buchanan took his share in the intellectual revival, doing much to infuse new life into the flagging University Chemical Society, which he invited to hold its meetings in his laboratory. He helped in founding the Ben Nevis Observatory, and joined the Council of the Scottish Geographical Society soon after its formation. Above all, he furthered the work of the Scottish Marine Station which was opened at Granton in 1884. He fitted up his old chemical bench from the *Challenger* on board the floating laboratory *The Ark*, and when I was appointed chemist and physicist at the Granton station he proved a most helpful and kindly instructor. He was an exceptionally tidy worker, and planned a system of laboratory books for recording all observations, experiments and calculations, with scrupulous regard to dates and hours.

In 1889 Buchanan was appointed lecturer on geography in the University of Cambridge, and although he only occupied the position for four years, he found the social life of Cambridge so congenial that for twenty years he made Christ's College his home. This was probably the happiest period of his life, and he revealed more of his inner self in intercourse with his friends in the Combination Room than he was wont to do elsewhere. The coldness of his manner was probably due in part to shyness, in part to an extreme sensitiveness to the opinions of others, which he concealed by an assumption of indifference. He was never idle, and accumulated a mass of recorded observations, only a fraction of which was ever brought into shape for publication.

He had no freedom in writing, but he took immense pains to verify every statement and to make his meaning perfectly clear. His chief pleasure was in travelling, and he was an insatiate observer of things and men in all parts of the world. He had friends in every country in Europe, and was greatly affected by the outbreak of the War, during the course of which he resided in America and the West Indies.

Had Buchanan been a poor man, or bound to some permanent scientific position, he would probably have cut a deeper niche for himself in the Hall of Memory. As it is, he left no formal book behind him, though he long cherished the idea of producing a treatise on oceanography. After returning to England, he collected his more important and some of his slighter published papers in three volumes, which were brought out by the Cambridge University Press under the respective titles "*Scientific Papers, Vol. I.*" 1913, "*Comptes Rendus of Observation and Reasoning*," 1917, and "*Accounts Rendered of Work done and Things Seen*," 1919. In the remarkable synoptical tables of contents prefixed to these volumes, he gives notes and criticisms which throw an interesting light on his methods of work and modes of thought.

HUGH ROBERT MILL.

MR FRANCIS JONES.

AMONG chemists the name of Francis Jones is always associated—almost identified—with boron hydride. When Humphry Davy in 1809 heated the amorphous boron he had isolated with metallic potassium, and treated the grey mass with water, he found the hydrogen gas given off had a peculiar smell and took up more oxygen on explosion than did pure hydrogen. This observation was for seventy years the chief evidence of the existence of a hydride of boron, and after the researches of Wohler and Deville, who doubted its existence, chemical text-books and dictionaries maintained a strict silence on the subject. The discovery of the spontaneously inflammable silicon hydride by Buff and Wohler in 1857 left boron the one exception to the rule that all the non-metallic elements combined with hydrogen, and the methods adopted by these chemists—as well as the experience he himself had gained in determining the composition of the hydride of antimony—led Francis Jones to plan his research on boron.

Born in Edinburgh in 1845 and educated at the Edinburgh Institute and University, Jones decided at an early age to take up chemistry as a career and proceeded to Heidelberg to work in Bunsen's laboratory. It was his work here that led to his introduction to Roscoe, who brought him to Manchester in 1866 as research-assistant in his private laboratory. The years ahead were strenuous with Roscoe's great work on vanadium, whereby this element was first placed in its true order: and the young assistant could have had no better training-ground in chemical method or in manipulation. Four years later he was appointed demonstrator, and after two years' teaching at the Owens College, was chosen by the high master of the Manchester Grammar School to fill the place left vacant by Dr. Marshall Watts. His science work at the school soon won for it an almost unchallenged

position among the large schools of England: the writer remembers well the succession of brilliant candidates he sent up for the Brackenbury science scholarships at Balliol between 1879 and 1886. For forty-seven years he continued to direct the chemical laboratories and to take his full share of teaching in the school.

Francis Jones must be placed in that small class of science masters who, in spite of incessant calls on their time and energy, have advanced chemistry in England. His first important paper on the properties and composition of stibine appeared in 1876 (*J. Chem. Soc.*). The composition of the hydride of antimony had previously been based on the analysis of the black compound thrown down when the gas mixed with hydrogen was passed through silver nitrate solution—presumed to be pure SbAg_3 . But metallic silver is also deposited in this reaction, and the substance is really a mixture, as Jones showed by his analyses. His next attempts were to measure the increase in volume when 2 litres of the hydrogen and stibine were sparked, but the proportion of the stibine was too small to enable its composition to be determined from the increase in volume and the weight of antimony formed. He discovered, however, that stibine was decomposed by sulphur at ordinary temperatures in bright light:

By passing the mixed gases through weighed sulphur-tubes and absorbing the hydrogen sulphide, he showed that one atom of antimony was combined with three of hydrogen. The orange colour imparted by stibine to sulphur gives us a very delicate test for antimony.

In 1879 appeared the preliminary note on boron hydride. In his first experiments Jones attempted to make magnesium boride by the action of sodium on a mixture of magnesium chloride and potassium borofluoride—following the method for making silicon hydride. The reaction was violent, but no hydride resulted from acidifying the product. Then he tried with success the direct heating of magnesium powder with boron trioxide:

When hydrochloric acid was dropped on to the grey friable product a gas was evolved which burnt with a bright green flame and had a most disagreeable odour. He had obtained the hydride mixed with hydrogen.

Two years later a fuller paper was published (*J. Chem. Soc.*, 1891) by Francis Jones and R. L. Taylor. Other methods of preparing the hydride were given, but the simplest was that described above—which always contained a large excess of hydrogen. The hydride was decomposed by passage through a red-hot tube leaving a brown deposit of boron; when bubbled through silver nitrate it formed a black precipitate containing silver and boron. Combustion of the mixed gases by means of copper oxide showed the hydride molecule to contain more hydrogen than the molecule H_3B , and to approximate to H_4B . Twenty years later, Ramsay, by cooling the mixed gas with liquid air, extracted another hydride from it, to which he assigned the formula B_2H_6 .

In 1884 Francis Jones published a simple method for detecting a chloride, bromide, and iodide when the

three salts are mixed together. By the addition of dilute sulphuric acid drop by drop to the salts in the presence of manganese dioxide and water the iodine can be boiled-off, then the bromine, the residue with strong sulphuric giving the chlorine. His other published work dealt chiefly with the effect of different modes of heating and lighting on the air of living-rooms: he took an active interest in the crusade against air pollution.

For many years he acted on the council of the Manchester Literary and Philosophical Society, and was president for the two years 1909-11: he gave his services freely to the last, and his kindly and sage counsel was always appreciated. H. B. D.

MR. G. L. SMITH, who died at Chertsey on September 25, was head of the Instrument Research and Design Department of the Royal Aircraft Establishment. As such he was responsible for a large number of instruments used on aircraft. His remarkable genius for this type of work enabled him to accomplish much work of great importance, though his share in it is little known outside the circle of a few associates. Born at Aberdeen about 1870, Mr. Smith followed a number of scientific pursuits—among which may be mentioned the design and application of the aero fire alarm, which was extensively used in England and the United States. At the outbreak of the War, he offered his services to the Royal Aircraft Establishment, where he remained until illness compelled him to resign a few months before his death. While of a somewhat retiring and unobtrusive disposition, his kindly and sympathetic nature made him beloved and respected by every one.

G. M. B. D.

WE regret to announce the following deaths:

Dr. E. J. Babcock, professor of industrial chemistry, metallurgy and mining and dean of the College of Mining Engineering in the University of North Dakota, on September 3, aged sixty years.

Dr. H. R. Carter, assistant surgeon-general of the United States Public Health Service and a distinguished authority on yellow fever and malaria, on September 14, aged seventy-three years.

Prof. T. Case, formerly president of Corpus Christi College and Waynflete professor of moral and metaphysical philosophy in the University of Oxford, on October 31, aged eighty-one years.

Dr. Paul Héger, honorary professor of physiology in the Faculty of Medicine at the University of Brussels, aged seventy-nine years.

Dr. J. R. Henderson, C.I.E., formerly professor of zoology in Madras Christian College, and Superintendent of the Government Museum and Aquarium in Madras, on October 26, aged sixty-two years.

Prof. J. N. Langley, F.R.S., professor of physiology since 1903 in the University of Cambridge, on November 5, aged seventy-three years.

Prof. J. Massart, professor of botany in the University of Brussels, corresponding member of the Paris Academy of Sciences and foreign associate of the Royal Academy of the Lincei, aged sixty years.

Rev. E. F. Russell, of St. Alban's, Holborn, one of Huxley's early students, who contributed to our issue of May 9, p. 751, his recollections of Huxley and of the course of biology being given in 1875 at South Kensington, on November 7, aged eighty-two years.

Current Topics and Events.

His Majesty the King has approved of the following awards this year by the president and council of the Royal Society:—A Royal Medal to Prof. W. H. Perkin, for his work on the constitution of the alkaloids; a Royal Medal to Prof. A. C. Seward, for his researches on the palæobotany of Gondwanaland. The following awards have also been made by the president and council:—The Copley Medal to Prof. A. Einstein, for his theory of relativity and his contributions to the quantum theory; the Davy Medal to Sir James Irvine, for his work on the constitution of the sugars; the Sylvester Medal to Prof. A. N. Whitehead, for his researches on the foundations of mathematics; the Hughes Medal to Mr. F. E. Smith, for his determination of fundamental electrical units and for researches in technical electricity.

THE following is a list of those recommended by the president and council of the Royal Society for election to the council at the anniversary meeting on November 30:—*President*, Sir Ernest Rutherford; *Treasurer*, Sir David Prain; *Secretaries*, Mr. J. H. Jeans and Dr. H. H. Dale; *Foreign Secretary*, Sir Richard Glazebrook; *Other Members of Council*, Prof. J. H. Ashworth, Prof. L. Bairstow, Prof. F. O. Bower, Prof. S. Chapman, Sir Dugald Clerk, Prof. F. G. Donnan, Prof. E. J. Garwood, Prof. J. P. Hill, Prof. J. B. Leathes, Prof. J. C. G. Ledingham, Sir Thomas Lewis, Prof. F. A. Lindemann, Sir Robert Robertson, Sir Charles Sherrington, Dr. G. C. Simpson, and Mr. W. C. D. Whetham.

SIR ERNEST RUTHERFORD, O.M., who has been nominated to succeed Sir Charles Sherrington as president of the Royal Society, was born at Nelson, New Zealand, on August 30, 1871. Educated at Nelson College and Canterbury College, New Zealand, he proceeded to the University of Cambridge, entering Trinity College. He occupied the post of Macdonald professor of physics, McGill College, Montreal, from 1898 until 1907, when he left to become Director of the Physical Laboratories in the University of Manchester. From thence he went to Cambridge to take up the duties of Cavendish professor of physics, a post which he still occupies and adorns. Nobel Laureate in chemistry in 1908, Sir Ernest was Copley medallist of the Royal Society in 1922. In 1923 he was president of the British Association at its Liverpool meeting, and he remarked that it was in Liverpool in 1896 that he first attended any gathering of the kind, and that there he read his initial scientific paper. Sir Ernest's address was entitled "The Electrical Structure of Matter." The unknown appears, he said, as a dense mist before the eyes of man. In penetrating the obscurity we cannot invoke the aid of supermen, but must depend on the combined efforts of a number of adequately trained ordinary men of scientific imagination. It may be recalled that Sir Ernest Rutherford was the recipient, in 1908, of the Bressa quadrennial prize of 9600 lire (say 400*l.*) at the disposal of the Turin Academy of Sciences, instituted to recompense the most notable scientific achievement during the

particular period. We believe that no other Englishman has received this award.

DR. HENRY H. DALE, C.B.E., who has been nominated for the secretaryship of the Royal Society in succession to Sir William Hardy, is a Londoner, and was born in 1875. Educated at Tollington Park School and the Leys School, Cambridge, he graduated at Trinity College, Cambridge, taking up afterwards his medical career at St. Bartholomew's Hospital, London. At the present time Dr. Dale is head of the Department of Biochemistry and Pharmacology under the Medical Research Council. He gave a series of lectures in Johns Hopkins University, Baltimore, in 1919. Croonian lecturer at the Royal Society in 1919, he was last year awarded a Royal Medal of the Society in recognition of his researches in pharmacology and physiology.

MR. BALDWIN, Prime Minister, in his Rectorial address to the students of the University of Edinburgh on November 6, made a comparison between the aims of university study and the practice of politics. The student learns to acquire "habits of accuracy in measurement, precision in statement, honesty in handling statement, fairness in presenting a cause—in a word, to be true in word and deed." The politician, on the other hand, is concerned with persuading people to support his cause, so that truthfulness has often to be sacrificed to expediency. The result "is inevitably to place a veto on complete frankness, and to tempt recourse to words which are nebulous, hesitating, ambiguous, or misleading." While the discovery of truth is the purpose of scientific investigation, in the political field the truth may be tempered to the minds of an audience if a favourable impression is thereby secured. Mr. Baldwin did not for a moment suggest that such methods of political sophistry were worthy of an educated people, but he excused them as a consequence of a democratic constitution, and he urged that it was the business of universities to change the conditions which enable a modern demagogue to mislead the public. It will be a long time before the voters who decide how the State shall be governed will be able to distinguish between the special pleading of an advocate and the summing up of a judge when political questions are under discussion, and meanwhile they have the power to decide matters upon which they have no actual knowledge. The duty of those who object to this penalty of democratic control is to take an active part in enlightening the public and in securing the entrance into Parliament of members who not only know how to search for truth but also how to use scientific methods in its application to social life.

THE disaster in the valley of the Conway in North Wales on the night of November 2 adds another to the melancholy list of failures of dams, or retaining embankments, which have been constructed to the best of human knowledge and ability, and yet have developed some unsuspected source of weakness

resulting in collapse, unfortunately attended in so many cases by sad loss of human life and much destruction of property. The dam at Llyn Eigiau, North Wales, was constructed in 1908 for the purpose of impounding water to supply hydro-electric power for the aluminium works at Dolgarrog. It is a concrete embankment, shaped in plan like the letter L, with the angle, which, in reality, is slightly curved, jutting into the lake. The enclosure is estimated to have contained, before the collapse, about one thousand million gallons of water. A breach, which occurred near the junction of the two arms of the dam, apparently below the concrete work, allowed the whole or greater part of this mass of water to escape. For a distance of more than two miles, it traversed the relatively level bed of the stream which carries the normal overflow, and then precipitated itself down the mountain side in an almost perpendicular descent of nearly 1000 feet into the Conway valley below. Great boulders of rock, blocks of concrete, a girder bridge, a temporary iron church and a number of buildings were swept away and piled into a mass of debris and ruin along its course. The disaster is said to be the greatest of its kind which has occurred in Great Britain since the catastrophe at Bradfield, near Sheffield, more than sixty years ago, though more notable and devastating failures have been recorded in other countries.

COMMENTING ON OUR note (NATURE, October 24, p. 620) concerning his recent article on the position of the classics, Prof. J. P. Postgate writes that although it was not unfair to mention that the committee of the British Association had unanimously rejected the claims of Latin to be chosen as the international auxiliary language, it must not be forgotten that the committee, with one dissentient, also rejected the claims of English; and that although reporting in favour of the adoption of an artificial language, namely, Esperanto or Ido, the committee was unable to decide between them. "Their conclusion, then," he says, "was a purely negative one, and in present circumstances it could hardly have been otherwise." We thank Prof. Postgate for reminding us of the further decisions of this committee, but we cannot agree with him that the recommendation of Esperanto or Ido was a "purely negative" conclusion. Esperanto, in particular, is showing much vitality as an auxiliary language, "a special tool for a special purpose"; and we do not think that the position of the classics as a means of culture would in any way suffer if an easier, synthetic language were adopted for scientific and commercial purposes, or even as the medium for the exchange of international thought generally. Did not Mr John Galsworthy declare recently that such exchange was the only possible salvation of the world?

THE work of M. Léon Guillet is well known to British metallurgists as well as to his compatriots, and many will be interested to know that his recent election to the Paris Academy of Sciences has been made the occasion of a proposal to raise a fund for a testimonial to M. Guillet, in recognition of the services

rendered by him to education, science, and industry. His work has covered a wide range, but his name is best known in connexion with researches on the alloy steels and on bronzes and other alloys of copper, particularly in regard to the changes brought about in them by quenching and other forms of heat treatment. A circular containing an appeal for subscriptions for this purpose has been issued, and is signed by many metallurgists, England, Belgium, Sweden, Italy, Denmark, and the United States being represented as well as France. Subscriptions should be sent to M. Roszak, 8 Rue Jean-Goujon, Paris VIII^e.

IT is a gratifying indication of the position of scientific metallurgy in Great Britain that the two principal metallurgical societies, the Iron and Steel Institute and the Institute of Metals, have practically become international organisations, numbering a large foreign membership, and serving as the medium of publication for a mass of important work from foreign countries. We have received from the Institute of Metals a booklet addressed to metallurgists in the United States, containing a list of the two hundred members of the Institute resident in that country, and giving particulars of its activities. Recent volumes of the Journal of the Institute have contained many important papers from foreign sources, whilst its abstracts are much more complete than anything published elsewhere. There are obviously great advantages in a common medium of publication and a common source of reference to metallurgical literature, serving the whole of the metallurgical world acquainted with the English language, and the growth of American membership is a healthy sign.

IN the *Forum* for September several articles deal with China. Of these the more important are "China in Ferment," by Walter Littlefield, an attempt to analyse the present political situation in its bearing upon the covenants of Washington of 1921-1922, and "The Foreign Devil in Young China," by John Brailsford, in which the author seeks to define the relation of western industrialism and western revolutionary thought in China. Neither writer offers much ground for optimism. The former, while crediting Washington with sincerity in forming the covenants through which China was to preserve her territorial and political entity, considers that both China and the other Powers signatory to the convention who are interested in the exploiting of China have proved indifferent to Washington's solicitude. The author fails to see that his naive conclusion that not only is it difficult to gauge the real attitude of the individual Manchus but also that any one of these who may hold Peking is prepared to assent to measures which he is unable to guarantee will be carried out, and his still more naive confession that Washington does not appear to have grasped this fact, are not only a criticism of the United States diplomacy, but also an endorsement of the attitude of Great Britain that China must first place her house in order before anything can be done in regard to treaty rights. Of this attitude he is both critical and suspicious. In

the second article, Mr. Brailsford shows that the intellectuals and students, whether Christian or heathen, have eagerly embraced revolutionary ideas out of sympathy with labour in opposition to western industrialism. They favour, on the whole, a class struggle rather than peaceful reform by development of the Chinese guild and social systems. As the adverse conditions of western industrialism have had as yet little or no opportunity to develop in China, the revolutionary attitude seems unreal and doctrinaire as well as misdirected. The need for political and administrative reform is real enough.

MR. R. A. CHATTOCK, the electrical engineer to the City of Birmingham, gave a short but interesting presidential address to the Institution of Electrical Engineers on October 22. He pointed out that the new processes being introduced for the production of steam enable us to obtain more perfect combustion and higher temperatures. The difficulties with regard to furnace linings have been overcome by screening the furnace walls with water tubes which form part of the boiler itself. He then pointed out some of the advantages of pulverised fuel. He reminded his hearers that if the distillation of coal proves to be commercially feasible, from 30 to 70 per cent more weight of coal will have to be handled so as to get a given electrical output. Hence although in some cases it will be profitable to adopt this process, the number of pounds of coal for a given output will compare very unfavourably with that required by a station burning coal to destruction. There is also, as in the case of the gas industry at the present time, a serious financial risk of finding it impossible to dispose of the by-products at a remunerative price. Mr. Chattock laid stress on the importance to a power station of having the ratio of the average output to the total output, that is, the load factor, as large as possible. A residential neighbourhood has only a power factor of about 10 per cent. If prices to the consumer are to be reduced, it is necessary to foster the use of electricity for heating and cooking by an attractive two-price tariff. He is opposed to the political agitation for constructing a few large power stations and distributing over considerable distances to many substations. In his opinion the cost of distribution would in general be so great that no appreciable reduction in the price would be possible. It will be remembered, however, that the main reason for Mr. Snowden making the suggestion in 1924 was that it would reduce the number of unemployed. Mr. Chattock is also strongly opposed to having a single standard frequency for alternating current supply. He pointed out the great convenience of having mercury arc rectifiers in order to convert alternating to direct current supply. Most engineers are in favour of standardisation, but if it be adopted too soon, it will only hamper progress.

On Saturday, November 7, the Marchese de Pinedo landed at Rome, after having completed a flight in a Savoia 16 flying boat of about 35,000 miles to Australia and Japan and back again. This remarkable journey commenced on April 21 last, and the route followed was via Baghdad, India, Burma, Singapore, and the

Dutch East Indies, to Australia. Leaving Australia and turning north, Japan was reached, and here a new engine was fixed. Thus some 20,000 miles were covered by the first engine, and the second sufficed to bring the seaplane home via the coast of China to Burma, and then along the usual airway to Europe. Throughout the journey, which took 370 flying hours, the Marchese de Pinedo was accompanied only by one mechanic. The achievement was noteworthy as regards both the skill and endurance shown by the airmen and the general trustworthiness for transcontinental and transoceanic travel which the seaplane has shown itself to possess.

THE hundredth annual course of Christmas Lectures for juveniles at the Royal Institution will be delivered this year by Sir William Bragg on "Old Trades and New Knowledge." The trade of the sailor is the title of the first lecture, to be given on Tuesday, December 29, and the following five lectures will be on the trades of the smith, the weaver, the dyer, the potter and the miner.

THE president of the Executive Committee of the International Research Council has summoned a meeting of the General Assembly of that body to be held at Brussels on June 29, 1926. The object of the meeting will be to discuss the advisability of removing from the statutes the restrictions which have hitherto stood in the way of admitting the Central Powers of Europe to the Research Council.

APPLICATIONS for the Royal Society Government Grant for Scientific Investigations for 1926 must be received by, at latest, January 1 at the offices of the Royal Society, Burlington House, Piccadilly, W.1. They must be made on a printed form obtainable from the clerk to the Government Grant Committee, Royal Society.

AN informal lecture will be delivered before the Chemical Society at Burlington House on Thursday, November 26, by Prof. R. Robinson, professor of organic chemistry in the University of Manchester, who has chosen as his subject "Recent Researches on the Structural Relationships of some Plant Products." The lecture will be given at 6 o'clock, and not at 8 o'clock as originally announced.

THE first broadcasting station in the Irish Free State has been erected by Marconi's Wireless Telegraph Company, Ltd, in the McKee Barracks in the outskirts of Dublin. The studio will be in Denmark Street, off Henry Street. The transmitter, which will operate on a wave-length of 390 metres and will use the call sign 2RN, is a Marconi 6 kw. type Q set. This is the same type as that used at the majority of British broadcasting main stations, and also at a large number of foreign stations. It is expected that tests will begin shortly, and that the service will be inaugurated during December.

AN exhibit of winter-flowering begonias, showing the wild species from which these winter-flowering begonias have been derived, has been arranged at the Royal Botanic Gardens, Kew, in the house which is devoted to objects of special and current interest. The two wild species which are particularly

concerned are *Begonia socotrana*, from the Island of Socotra, and *Begonia Dregei*, from South Africa. *B. socotrana* was introduced in 1880 by the late Sir Isaac Bayley Balfour, Regius Keeper of the Royal Botanic Garden, Edinburgh. This, in itself a beautiful winter-flowering species, has proved of immense importance as the progenitor of our present-day race of winter-flowering Begonias. From 1883 onwards Messrs. J Veitch and Sons produced many fine winter-flowering varieties by inter-crossing it with various tuberous-rooted varieties of begonia from the Andes of South America. Some of the most recent hybrids resulting from these crosses are "Exquisite," "Fascination," and "Optima," which are shown in this group. The leaves tend to resemble those of the Andean species rather than those of *B. socotrana*. Though they are very beautiful plants, as can be seen from the display in the Kew Conservatory, they are not very generally grown as their cultivation presents some difficulties. M. Lemoine, of Nancy, in 1892 crossed *B. socotrana* with the South African species, *B. Dregei*. The resulting hybrid was *B. Gloire de Lorraine*, of which there are now several varieties, including some of American origin, such as "Glory of Cincinnati" and "Mrs. Petersen." These are now some of the most popular and easily grown plants for winter decoration. There are now four additional sets of picture postcards in colour on sale at the Royal Botanic Gardens. These comprise a set of stove and greenhouse plants, two series of rock garden and hardy herbaceous plants, and a set of Himalayan rhododendrons.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned.—A professor of materia medica at the Royal Veterinary College, Camden Town, N.W.1—The Secretary (November 21). A lecturer in the department of electrical engineering of Bradford Technical College—The Principal (November 24). The professorship of physics at University College, Nottingham—The Registrar (November 28). A county analyst under the Lancashire County Council—Clerk of the Lancashire County Council, County Offices, Preston (November 28). An assistant lecturer in mechanical engineering at the Manchester Municipal College of Technology—The Registrar (November 30). A lecturer in pathology and bacteriology in the Welsh National School of Medicine, Cardiff—The Secretary (December 4). An assistant lecturer in physics at Natal University College, Pietermaritzburg—The Registrar (December 31). A part-time assistant in the department of zoology and geology of University College, Southampton—Dr. W. Rae Sherriffs. A lecturer in education in the University College of Wales, Aberystwyth—The Secretary. A professor of biology and a professor of bio-chemistry in the College of Medicine, Singapore—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1. A laboratory assistant in the physics department of the Liverpool Collegiate School for Boys—Director of Education, 14 Sir Thomas Street, Liverpool. A male junior assistant in the Research Department, Woolwich, for computing work in connexion with ballistic observations—Chief Superintendent, Research Department, Woolwich.

Our Astronomical Column.

NOVEMBER METEORS.—Mr. W. F. Denning writes: "The return of these meteors is due on the mornings of November 15 and 16, but they are not expected to be unusually abundant. In certain years, however, when the display was not anticipated, it came with special activity.

The orbit of the stream extends out to beyond the path of Uranus, and the cometary system, to which it owes its parentage, has a period of about $33\frac{1}{2}$ years. All along this lengthy ellipse the meteoritic particles are distributed, and they are certainly clustered more abundantly in certain sections of the orbit than in others. Hence the annual displays vary in their character, some being much richer than others.

This year there will be no moonlight to interfere with observation. The radiant point does not rise until nearly 10.30 P.M., and the meteors cannot be seen before that time; in fact, the most promising period at which to watch for them lies between 1 and 5 in the morning. The splendid display of 1866 reached its maximum at about 1.10 A.M., when one observer counted about two hundred meteors per minute.

The meteors of this system are generally bright, very swift, and leave luminous trails which often linger for several seconds and, in the case of very bright objects, may endure for 10 or 15 minutes. The directions of the meteoric flights are from the well-known "sickle" of stars in the western part of Leo.

The comet associated with this shower was last

seen in 1866. It will return in 1933, and for several years before and after that time showers of these mid-November meteors should be as abundant as they are attractive.

Though one of the richer sections of the stream which gave us the display of 1866 was sufficiently disturbed by the attraction of Jupiter to enable it to pass outside the earth's orbit in about 1899, there are other regions of the system capable of inducing rich displays, as in 1867, 1868, and 1869. There were also fairly abundant exhibitions of meteors in 1901 and 1903."

THE MASSES AND COLOURS OF THE STARS.—*Astr. Nach.* No. 5394 contains two papers on these subjects by G. Shain and Miss V. Hase, of the Simeis Observatory, Crimea.

The former contains arguments favouring Eddington's masses, deduced on the assumption that absolute luminosity is a function of mass, rather than those of Seares, deduced from the principle of equipartition of energy (*i.e.* assuming that Mv^2 is constant for all stars). The latter principle is shown to fail for the brighter giant stars, notably those of type B, though for the dwarfs it agrees fairly with Eddington.

In the other paper it is argued that there is a correlation between colour and absolute magnitude, the giants of a given spectral class being redder than the dwarfs, and the dwarfs having the higher temperature for a given intensity of spectral lines.

Research Items.

THE ROYAL MAGICIAN IN ANCIENT EGYPT.—Attention has frequently been directed to parallels in the customs of the ancient Egyptians and of African races. Such a parallel has been suggested by Sir Flinders Petrie as an explanation of a frequent scene in the royal functions of ancient Egypt in which a king is seen rapidly striding or running and bearing certain objects. This performance has been termed by Hermann Kees *Opfertanz*; but, as Sir Flinders Petrie points out in *Ancient Egypt* for September, the action is that of running, not dancing. Nor is the purpose to sacrifice or make an offering. He suggests that these scenes represent a ceremony analogous to the rain-making ceremonies of the African chief. They are usually found at the ends of the lintels in great temples, but occasionally elsewhere. The general meaning is indicated by certain signs such as the three *adeb* signs signifying cultivated land, which connect the ceremony with the cultivated fields, a small female figure frequently accompanying the king, with the plant of Lower or Upper Egypt on her head, and inviting him to come and bring the inundation, and, frequently, a galloping bull representing the Nile. This invocation begins as early as the sixth dynasty. The origin of the ceremony is indicated by the flail which is shown. This appears to have been derived from the bull's tail, which was used as a fertilising lash before the artificial form took its place. Thus it appears that the king went round the fields ceremonially to drive away evil influences, fertilising them with the lash and leaving blessings behind him. Fans are also shown. These are divine symbols, and are the regular adjunct of African rulers down to the present day. Later ceremonies (eleventh dynasty) show the oar, and (eighteenth dynasty) two vases for pouring water in the hands of the king. It would therefore seem clear that Egypt had a king of that African type of which the principal function is to act as a magician who controls the rain. In Egypt, as there was no rain, it was his duty to bring the inundation which made fertile the cultivated lands.

FAMILY NAMES IN FRANCE.—Dr. Albert Dauzat in *La Nature* for October 3, discusses the origin of French family names. After the disappearance of the Roman system of nomenclature, surnames only reappear with the stabilising of the feudal system in the ninth and tenth centuries. Between the eleventh and fifteenth centuries the individual name is followed to an increasing degree by a surname which tends to become the family name by passing from father to son. This tendency is particularly apparent from the time of Philip Augustus, beginning in the south and spreading rapidly to the north and the Rhine area. With the establishment of registers in certain parishes at the end of the fifteenth century, these surnames began to be fixed. Jewish family names, however, were not legally established until 1808. French family names fall into four principal categories. First are individual names which have been perpetuated without modification, such as Henri, Louis, or with modification: Jacques, Jacoton, Cottin. Many are individual names no longer in use, mostly of Germanic origin, e.g. Aymon, Rambaud, Arnaud. These are also modified in various ways. A second category includes names derived from location or habitation (Caseneuve, Dubois, Delaval, Delarue) or origin (Le Breton, Paris, Le Normand, Langlais). Thirdly come names of profession or occupation—Chausseher, Feuvre, Fournier. The fourth class, which is very large, consists of soubriquets and includes

such names as Le Grand, Le Gros, Poincaré, Roussel, Rousseau, Bossu, Bossuet, Chappedelaune, Legendre, and the like. In addition to patronymics, a number of matronymics, such as Marguerite, Collette, and so on, also occur.

CLIMATE AND HUMAN ENERGY.—In an interesting analysis of the results of the Olympic Games of 1920 (Antwerp) and 1924 (Paris), which Dr. Guillermo Hoxmark, of the Weather Bureau, Buenos Aires, has published in *Ecology* (New York), vol. 6, No. 3, July 1925, success in the competition is correlated with mean temperature as a suggested index of the relation of energy and climate. This study follows the lines taken by Huntingdon and others in establishing zones of human energy and civilisation. Twenty-six countries were represented, and the number of inhabitants of each is here divided by the number of points gained, thus giving the number of thousands of inhabitants per point. The countries are then ranged in the resulting order. An index number is assigned to each, the smallest number of thousands per point being 100. When brought into relation with mean annual temperature, it appears that a low index number, i.e. high average athletic ability, and a low average temperature go together. The figures of the two competitions, taken separately and together, give approximately the same result. In each case, Norway, Finland, and Sweden head the list in the order named. Great Britain stands twelfth, Spain, Czecho-Slovakia, Japan and Egypt are among those at the bottom of the list.

WARM FEBRUARY OF 1925 IN THE UNITED STATES.—The *Monthly Weather Review* for May contains a discussion by Mr Alfred J. Henry which shows that February 1925 in the continental United States was the warmest February during the last forty years. No other February has averaged so much as 5° 8 F. above the normal for the country as a whole. The monthly departures ranged from a minimum of 1° 2 above the normal in the Florida peninsula to 10° 1 above in the region embraced by the States of Montana, Wyoming, and the western parts of South Dakota and Nebraska. An attempt is made to ascertain the cause of the temperature departure. Both primary and secondary cyclones lacked in intensity during the month, and naturally strong pressure gradients were absent. The anticyclones experienced were not associated with an indraught of cold air. A detailed examination was made by the author of the pressure conditions existing over the Pacific and elsewhere with the object of tracing, if possible, the relation between these varying conditions and the exceptionally warm weather experienced in the United States. The author concludes that the explanation of the warm weather experienced must be referred to the presence of an oceanic cyclone over the Gulf of Alaska which occasioned suitable atmospheric conditions for ill-defined cyclonic systems to be detached from the primary oceanic cyclone and to pass along the northern boundary towards the Atlantic, inducing on their fronts an unusual frequency of southerly winds. Attention is directed to the growing belief on the part of meteorologists that the cause of unusual seasonal variations is associated with conditions prevailing in the Arctic and Antarctic regions, and reference is made to the difficulties of verifying this supposition.

CARBONIFEROUS FOSSILS FROM CHITRAL.—Dr. F. R. Cowper Reed has completed the sixth volume of the new series of the *Palæontologia Indica* with a well-

illustrated memoir on the Upper Carboniferous fossils collected by the late Sir H. H. Hayden in Chitral and the Pamirs in 1914. Most exhaustive comparisons are made, and the fauna is shown to be distinct from any hitherto found in India or Kashmir. It is specially characterised by the abundance of the foraminifer *Fusulina*. The whole fauna resembles that found in the Upper Carboniferous of the Ural mountains, and it may be inferred that the late Carboniferous Eurasiatic Mediterranean Sea extended across Chitral into Turkestan and Central Asia.

MIOCENE ANTHRACOTHERES FROM BALUCHISTAN.—In 1909 and 1910 Mr C. Forster Cooper made an important collection of mammalian remains from a Lower Miocene deposit at Dera Bugti in Baluchistan. The specimens were prepared for study at the British Museum, where they are now preserved, and most of them have been described by Mr. Forster Cooper in a valuable series of papers and memoirs. The latest of these contributions is an exhaustive study of the primitive hoofed mammals known as Anthracotheriidae, published as a memoir in the *Palaeontologia Indica* (new series, vol. 8, No. 2). Most of the fossils representing this group are fragmentary jaws and teeth, but they suffice to indicate great diversity both in size and form. They make known a remarkable assemblage of mammals, all of one family, living side by side and presumably fighting together to some extent for the means of subsistence, some of them closely allied to one another and some evolving on marked lines of their own. They remind us of some of the assemblages of antelopes still or until recently existing in Africa.

RONTGEN RAYS AND PALÆONTOLOGY.—In the Geological Museum of the Russian Academy of Sciences, Drs. A. Hartmann-Weinberg and S. A. Reinberg have been experimenting on the detection, by means of X-rays, of fossils enclosed in pieces of rock, and they have just published their results in the *Bulletin of the Academy*. They have been especially successful in finding pieces of bone in sandstone, and a little less successful in detecting similar fossils in shale. They have used pieces of concretions containing reptilian bones collected by the late Prof. Amalitzky in the Permian sandstone of the Northern Dvina, and their radiograms of several specimens are sufficiently clear to guide the preparator in uncovering the various fragments. They have also been successful with an ammonite in sandstone. They find that, for the purpose, no piece of sandstone should be more than 30 to 40 cm. in thickness. The authors, however, point out that buried fossils can only be detected by X-rays when they differ considerably in constitution from the enclosing rock. Bones impregnated with calcite, for example, are not shown in the radiograms when the surrounding rock is limestone. The latter result accords with the experience of the British Museum when an attempt was made some years ago to examine the skeleton of *Archæopteryx* by the same method.

MOUNT LOGAN.—An account of the first ascent of Mount Logan, the loftiest summit in Canada, appears in the *Dominion Land Surveyors' Journal* for October. Mount Logan, which lies some forty miles to the north-east of Mount St. Elias, was photographed from the south by the Duke of the Abruzzi's expedition to Mount St. Elias in 1897, and its great height was not established until the survey of the Alaska-Yukon boundary in 1913. The ascent was made this year by a small party of Canadians under the leadership of Mr. A. H. MacCarthy, who was accompanied by Mr.

H. J. Lambert of the Geodetic Survey department. The climb was made from the west up the Ogilvie glacier and the King glacier. Above 14,500 ft. the reduced pressure hampered the climbers. Progress was very slow, and it was difficult to get a restful sleep. However, on June 23 the summit was reached at 19,850 ft. Mr. Lambert's article is illustrated with several photographs.

EARTHQUAKES IN THE UNITED STATES.—How numerous are the earthquakes in the United States is evident from a short article published in the *Volcano Letter* for September 17 of the Hawaiian Volcano Research Association. During the nine years 1915–23, the total number of earthquakes was 955, or more than a hundred a year, felt in as many as 42 States. Had the record been continued up to February 1925, every State would have been represented except Delaware, Florida, and Louisiana. The most frequently disturbed State is California, with 594 earthquakes. In the eastern States, the most active regions lie along the middle part of the Mississippi River, and it is noteworthy that some of the earthquakes there affected areas nearly as great as that disturbed by the San Francisco earthquake of 1906, though at the surface the damage caused was slight. This shows that the foci in the east of the country are more deeply-seated than those in the west. During the first part of the period considered, several earthquakes were experienced at or near Charleston, the scene of the great earthquake of 1886.

NEWER MAGNETIC PHENOMENA.—In the November issue of *Conquest*, Prof. J. A. Fleming gives a short account of some of the recent discoveries in magnetism. Many of them depend on the fact that iron can exist in two allotropic forms, α below 780°C , and γ above. The former is magnetic and the latter not. A steel containing 12 per cent. of manganese and a cast iron containing 6 per cent. of manganese and 9 per cent. of nickel are non-magnetic at low temperatures. On the other hand, iron alloyed with 78.5 per cent. of nickel is in weak fields more magnetisable than wrought iron, and Heusler's alloy, MnAlCu_2 , is as magnetisable as cast iron. The effects of alternating fields on feebly magnetic iron ores, discovered by Mr. Mordey and used for the separation of ores, are traced to the lag of the magnetisation behind the field as shown in the hysteresis curves.

THE ISOTOPE EFFECT IN THE SPECTRUM OF SILICON NITRIDE.—The spectrum of silicon nitride can be produced by introducing silicon chloride vapour into active nitrogen, and in the *Physical Review* for September, Dr. R. S. Mulliken describes the structure of the bands, in the fourth paper of a series dealing with the isotope effect in band spectra. The structure is of a simple type, resembling in some respects the spectrum of cyanogen (CN), and it is shown that the bands are due to a diatomic emitter, both the chemical evidence and the isotope effect indicating that this is SiN . A striking feature is the unusual prominence of the null line, or missing line, in each band; this is also the case in the cyanogen bands. Weak satellite band heads due to Si^{29}N , and slightly weaker ones due to Si^{30}N , accompany the stronger Si^{28}N bands, as reported by Mulliken in *NATURE*, March 22, 1924, p. 423, and in agreement with Aston's positive ray work on the isotopes of silicon. Equations have been worked out for the positions of the band heads and for the band structure; from these it is deduced that the distance between the atomic nuclei is 1.56×10^{-8} cm. in the vibrationless molecule. In a paper in the July number of the *Physical Review* the isotope effect in the

band spectra of copper iodide (CuI) is dealt with in detail, the spectra of copper fluoride, chloride and bromide having also been partially investigated. The effects of the two isotopes Cu^{63} and Cu^{65} are clearly shown in the spectra.

THE STRUCTURE AND DISTRIBUTION OF BAND SPECTRA.—In a series of papers in the *Comptes rendus Acad. Sci.*, Paris, ending with one on October 5, M. H. Deslandres puts forward the following formula for the distribution of the principal and secondary bands in the infra-red spectra of simple chemical structures:

$$\nu = qd_1/rs \pm q'd_1/r's',$$

where ν is the frequency, d_1 a universal constant or fundamental frequency = 1062.5 , s the number of atoms or of large rings of electrons in the molecule, s' the number of exterior electrons of an atom and q, r, q', r' whole numbers; r in the examples given in the paper of September 28, which relate to the first term, r *e. g.* to the principal bands, being 1, 2, 3, 4 and in some cases 6 for different bands. The second term in the equation represents the secondary bands which appear in the principal band with sufficient dispersion. The first term has been verified with twenty absorption spectra of substances of very simple structure. The author found in 1919, in 11 infra-red and 29 luminous or ultraviolet spectra, that the most intense band frequency is almost exactly a multiple of d_1 , which follows from the above formula in the case of the infra-red bands. The line spectra emitted by single atoms are connected with the constant d_1 by the same simple law. The author considers that the facts imply the existence of a new series of vibrations intimately connected with the fundamental frequency d_1 ; he supposes that they originate in the nucleus of the atom or in a "protective" sphere connected with the nucleus.

THEORY OF THE PHENOMENA AT THE CATHODE IN GLOW DISCHARGE.—A large amount of work has recently been carried out by Dr. A. Güntherschulze on the glow discharge, and in the *Zeitschrift für Physik* of August 31 he develops the theory of the phenomena observed at the cathode in terms of recent developments in the determination of the behaviour of electrons accelerated in an electric field through a gas at low pressure. He makes use of the results of Brose, who has determined the field intensity in the space between the edge of the negative glow and the cathode, the "fall space," in the case of the abnormal cathode fall; and assumes that the curve of field intensity has the same form in normal cathode fall. The dark space observed by Aston in the case of hydrogen and helium, between the cathode and the thin luminous layer of the cathode glow, is ascribed to the fact that here the electrons given out by the cathode have not acquired the velocity necessary for the excitation of the atoms. In the cathode glow the excitation velocity is reached, and the excited atoms give out light; but Seeliger has shown that when the velocity becomes still higher excitation diminishes, and this is why the Crookes space is nearly dark. Ionisation takes place here, free secondary electrons being split off from the atoms and positive ions being formed, which move towards the cathode, and colliding with it produce a further supply of electrons from its surface. The above secondary electrons are accelerated by the field in the Crookes space, and a large number of them reach excitation velocity at the edge of the negative glow, where the luminosity rises very quickly, falling off again farther on when, owing to the continued acceleration, the number of electrons with the exciting

velocity has diminished. A number of relations between the length of the fall space, the voltage drop in it, the current density and other variables are worked out.

THE POLARISATION OF THE ZODIACAL LIGHT.—Visual observations have given contradictory results as to the polarisation of the zodiacal light. M. J. Dufay has recently carried out a series of measurements photographically, using first a nicol prism and then a doubly refracting analyser, which gave two images of the opening in a diaphragm illuminated by a small region in the zodiacal light (*C. R. Acad. Sci.*, Paris, September 28). In this way it was possible to photograph simultaneously two components the vibrations of which were at right angles to one another, and to study the relative intensities with the microphotometer on the photographic plate. Thus the depolarisation, ρ , of the original light, that is, the ratio of the intensity i , of the beam the vibrations of which are in the plane passing through the line of sight and the sun, to that, I , of the beam the vibrations of which are perpendicular to this plane ($I > i$), can be determined, and from this the proportion, p , of the light which is polarised in the above plane. A number of measurements have been made of small regions near the plane of the ecliptic and distant from 30° to 95° from the sun; ρ appears to diminish from 30° to 60° , passing through a minimum and then increasing much more rapidly. The values obtained for the same angle differ, however, from night to night according to the state of the atmosphere. Further observation is necessary to obtain results which will give full information as to the nature and distribution of the material which causes the zodiacal light; the measurements made, however, make it clear that the light is diffused sunlight, and that it cannot be due to gaseous molecules, since in that case, while the curve for ρ would be of the form observed, the values of ρ would only be from half to one-third as large. The particles must have dimensions which are not negligible as compared with the wave-lengths concerned.

CARBONISATION OF COAL.—In pursuance of a policy mentioned in NATURE (September 20, 1924, p. 441) the Fuel Research Board has tested the carbonisation plant of Midland Coal Products Ltd., Netherfield, Nottingham, and the results have been published (H.M. Stationery Office, 9d. net). The coal treated is a poorly caking local slack which is first briquetted. Carbonisation is effected by internal heating in a tall brick-lined shaft, water-jacketed at the base, a portion of the fuel being gasified by the air-steam mixture injected. The producer gas so generated reduces the calorific value of the gas to 190 B.T.U. per cubic foot—a figure too low for public supply. The yields of products obtained were: coke 7.5 cwt., gas 58,300 cubic feet or 112.5 therms, tar 21 gallons. The ammonia liquor was too dilute for profitable recovery. The coke was well carbonised with 2 per cent. only of volatile matter, and though suited for use in stoves, it was unsuitable for open grates. Its ash content was 9.13 per cent. The temperature reached in the charge was 1200°C. , and the process cannot be classed as a low temperature carbonisation in the sense commonly understood. The tar yield was high, but the proportion of light oil was small. The pitch obtained was used for the briquetting. It was considered that the grade of coke might be improved by the use of more suitable elevating plant. No attempt is made to assess the commercial success, but the results do not suggest that the process is one which will prove a general solution to the problem of providing smokeless fuel.

Geneva Congress of the History of Medicine.

THE Fifth International Congress of the History of Medicine was held at Geneva on Monday, July 20–Friday, July 24, under the presidency of Dr. Charles Greene Cumston, lecturer in the history of medicine at the University of Geneva, with Sir D'Arcy Power as president of honour. The meetings, which were held at the Athénée, where the conference leading to the formation of the Red Cross took place in 1863, were well attended, representatives being present from Belgium, Cuba, Denmark, France, Great Britain, Holland, Italy, Morocco, Poland, Spain, Switzerland, and the United States.

At the opening meeting the president gave an account of the medical celebrities of Geneva, including Daniel Le Clerc (1652–1728), whose history of medicine was published twenty-nine years before Freind's "History of Physick"; Jean Antoine Sarasin (1547–1598), the author of a treatise on plague, and Théophile Bonet (1620–1689), who wrote a work on morbid anatomy entitled *Sepulchretum*, which secured him a European reputation. Dr. André Patry, president of the Medical Society of Geneva, then gave a sketch of ophthalmology in Switzerland from Roman times. Addresses were next delivered by M. André Oltramare, Chief of the Department of Public Instruction, representing the Council of State; M. Georges Werner, Rector of the University of Geneva; Dr. Hugues Oltramare, representative of the City of Geneva, and Dr. Tricot-Royer, of Antwerp, president of the International Society of the History of Medicine. Prof. Eugène Pittard, of the University of Geneva, then delivered a lecture on the prehistoric period of medicine, illustrated by skulls and implements from French and Swiss burial mounds. He showed that trephining of the skull was fairly frequent among prehistoric peoples, being usually performed in the parietal and rarely in the occipital or frontal regions.

On Tuesday papers were read at the morning session by Dr. J. D. Rolleston, on Voltaire and English doctors; by Sir D'Arcy Power, on Albert von Haller and the *Disputationes Chirurgicae Selectae*, i.e. M.D. theses written in various European universities between 1699 and 1742 and edited by Haller; by Dr. John Comrie, of Edinburgh, on Robert Whytt, an eighteenth-century neurologist, by Dr. A. Guisan, of Lausanne, on the life of Fabricius Hildanus, a Basel practitioner of the sixteenth century, by Dr. J. G. de Lint, on Tronchin and the Suttons' method of inoculation, by Dr. E. Wickersheimer, on syphilis in Geneva at the end of the fifteenth century, who combated the view that the disease had been imported for the first time by Columbus from America; by Prof. Wiki, on Dr. Karl Nicolaus Lang, who described the epidemics of ergotism at Lucerne in 1709 and 1717, by Dr. Maillart, on abdominal ex-votos found in the Museo delle Terme at Rome; and by Mlle. Eugénie Droz, on a plague tractate of the thirteenth century.

The afternoon session was taken up by papers by Dr. Paul Delaunay, on the doctors of Le Mans in Switzerland during the sixteenth century; by Dr. J. W. S. Johnsson, of Copenhagen, on an autograph letter of Fracastor in which poetry is described as a kind of disease, by Prof. F. M. Messerli, on three sanitary edicts at Lausanne in the fifteenth and sixteenth centuries, by Mr. C. J. Thompson, on hygiene and public health in early civilisations; and by Prof. P. Capparoni, on anatomical instruction at Rome during the sixteenth century.

After the close of the session the members of the Congress were entertained by Dr. and Madame Rilhet

at Vengeron, where they were able to inspect the library of the paediatrist, Dr. Frédéric Rilhet.

On Wednesday morning papers were read by Dr. R. O. Moon, on Paracelsus and medicine; by Dr. E. B. Krumbhaar, on the medical literature of the seventeenth century as exemplified in the Elzevir press, by Dr. H. Renaud, on some recent discoveries bearing on the history of Arabian medicine in Morocco; by Prof. Jeanselme, on the Germanic conceptions of surgical anatomy at the time of the barbaric invasions, by Dr. Tricot-Royer, on the history of lepers at Antwerp and Louvain; and by Dr. M. A. van Andel, on medicine and architecture.

In the afternoon session papers were read by Mrs. Lilian Lindsay, on the growth of dentistry in England from the earliest times to the beginning of the nineteenth century; by Prof. Wrzosek, on Remak and Polish science, showing that Remak published several scientific works in Polish before he settled in Berlin, and on Emmanuel Glibert, who organised the medical school at Grodno (1776–1780), at a time when numerous French doctors were practising in Poland; by Dr. E. Wickersheimer, on Jean Gispaden, a fifteenth-century surgeon of Annecy and Grenoble; by Dr. Tricot-Royer, on Isaac Ammon, otherwise known as Palatino Chaldaico, a physician and astrologer; by Dr. de Metz, on the barber-surgeons of Antwerp; by Dr. Dubreuil-Chambardel, on the houses of refuge on the pilgrim routes in the tenth, eleventh, and twelfth centuries; by Dr. Laignel-Lavastine, on his ancestor, the oculist Jacques Daniel, who performed the first operation for cataract on April 8, 1785, at Marseilles, and by the same speaker, in collaboration with Dr. Jean Vinchon, on demoniacal possession in the sixteenth century.

After the meeting a visit was paid to the public library, where a special exhibition of manuscripts, incunabula, and other works bearing on the history of medicine, had been arranged, and portraits of Geneva physicians from the sixteenth to the eighteenth century were on view. In the evening there was a reception by the Administrative Council of the City of Geneva at the Palais Eynard.

Thursday was devoted to a tour on the Lake of Geneva, a visit being first paid to the Château de Chillon, and then to Evian-les-Bains.

On Friday morning, when the Congress was brought to a close, Dr. Wierzbicki read a paper by Prof. A. Wrzosek and himself on auscultation in Poland in the first half of the nineteenth century; Dr. J. W. Courtney, of Boston, dealt with Benjamin Waterhouse, who introduced vaccination into the United States; Dr. De Alcalde, of Madrid, showed an iron crown found in a Spanish cloister which was credited with the power of curing diseases of the head and mental disorders; Dr. Bugiel described the life of the Polish students at the Paris Faculty of Medicine in the thirteenth, fourteenth, and fifteenth centuries; Dr. J. B. Hurry contributed a paper on J-Em-Hetep, Prime Minister to King Zoser and afterwards the medical god of Egypt; Dr. A. De Peyer, the general secretary of the Congress, read a communication from Prof. Pierre Gautier on the history of typhoid fever in the child, and himself contributed a paper on his ancestor, Johann Conrad Peyer, a seventeenth-century physician of Schaffhausen, who has given his name to the patches of lymph follicles in the small intestine.

The next Congress of the History of Medicine will be held in July 1927 at Leyden, under the presidency of Dr. J. G. de Lint.

Economic Problems.

THE proceedings of Section F (Economic Science and Statistics) of the British Association were marked this year by the variety and the number of the topics discussed. They were noticeable also in that a lady economist, Miss Lynda Grier, occupied the presidential chair of the Section. Taking "The Meaning of Wages" as the subject of her address, Miss Grier stated that it was not her intention to put forward a new theory of wages but rather to analyse and restate certain aspects of the wages problem under the three headings: (1) the distributive or competitive aspect, (2) wages as the product of the worker, and (3) the effect of the wages paid on the work and the supply of workers. We are being forced increasingly to discuss, she remarked, those measures which attempt to add to the normal wage rate or to "stretch" the rate so that it will pay for things that it did not previously pay for. Such measures include schemes for fixing minimum wage rates which do not increase productivity, cost of living sliding scales, systems of family allowances, compulsory insurance schemes, and schemes for subsidising certain sections of the wage-earners of the community.

In opening a joint discussion with the Agricultural Section on the "Marketing of Agricultural Products" Mr R. B. Forrester said that in Britain very little serious attention has as yet been directed to the examination and analysis of marketing methods. Recent developments in other countries seem to show that a widespread tendency has set in towards improvement of marketing methods by means of control of quality and the setting up of grades or standards. So far, this has been especially associated with the efforts of the farmers themselves, though government

action has been of great help in providing scientific assistance and impartial inspection. It would seem that the British producer will also be compelled to give attention to marketing developments, which so closely affect competition in the home market. No alterations of a radical character are, however, to be expected in Great Britain unless they have the support of the farmers themselves, since changes in marketing are bound to involve important modifications in the system of production.

A young Swedish economist, Mr Fabian v Koch, gave an interesting account of unemployment relief in Sweden. The abnormal conditions of the post-War period are now practically at an end in that country. No insurance scheme has been initiated, though a provisional and restricted system of unemployment relief has been organised. The available funds have gone for the most part to State relief work, and only a small fraction has been devoted to the granting of doles or unemployment benefit. The principle has been accepted that relief work wages shall in all cases and localities be less than the ordinary wages that are paid.

Dealing with "The Economics of Family Endowment," Mrs Stocks asserted that inadequate attention has been given by theoretical economists to the problem of the family and its place in the economic structure. But, from recent statistical and social investigations, the fact has emerged that current output is insufficient to ensure the payment of a living wage so long as wages are paid at a flat rate without respect to the family responsibilities of the wage-earner. This is the basis of the plea for family endowment and the argument on which its advocates base their case.

The North Atlantic in Tertiary Times.

THE resemblances between the Tertiary faunas of the West Indies and those of the Mediterranean region have long been noticed and have been taken to indicate the former existence of shallow water across the Atlantic from the West Indies to Northern Africa, along which the migration of animals could take place. This subject, so far as the Miocene and Pliocene periods are concerned, has been more fully investigated by W. P. Woodring (Bull. Geol. Soc. America, 35, 1924, pp. 425, 867), who finds that the resemblance of the Miocene mollusks of the West Indies to those of the Mediterranean area is even closer than was formerly supposed—the resemblance being particularly striking to the fauna of the Piedmont basin of Italy. The similarity reached its maximum in the Helvetian period, when the Miocene transgression of the sea was at its greatest in both regions.

The Miocene faunas of the east coastal part of North America give clear evidence of the existence of climatic regions, in fact the distinction between tropical, sub-tropical, and temperate faunas is almost as striking as at the present day. It is therefore only natural that some differences should be found between the Miocene faunas of the Mediterranean and those of the West Indies; the former include temperate elements which are unknown in the latter and give them a sub-tropical aspect. The Mediterranean faunas are also characterised by the large number of exotic genera. The fact that so many genera, belonging to many different families, are common to both regions can scarcely be explained except by migration.

It is evident that this migration of tropical or sub-tropical genera could not have taken place along the northern border of the Atlantic, and Woodring concludes that there must have been series of shoal-water banks or islands extending across the southern part of the North Atlantic in Miocene times, but that these disappeared in late Miocene or Pliocene times, when the resemblances between the faunas of the two regions diminish. The present configuration of this part of the Atlantic floor, however, shows no sign of the former existence of shallow water or islands. In the Mediterranean region the sub-tropical faunas of the Miocene and Pliocene periods were replaced in Quaternary time by a temperate fauna coming from the North Atlantic.

In a later memoir, Woodring (Carnegie Institution, Publ. 366, 1925) describes the Miocene lamellibranchs and scaphopods from Bowden, Jamaica, and expects in a subsequent part to discuss the character and significance of the fauna. Dr T. Wayland Vaughan has on more than one occasion pointed out resemblances between the coral faunas of the western side of the Atlantic and those of the Mediterranean region in Eocene, Oligocene, and Miocene times. In a short paper (Bull. Geol. Soc. America, 35, 1924, p. 823) he recurs to this subject and states that in the West Indies the resemblance is greatest (1) between the Upper Eocene of St. Bartholomew and the Priabonian of Northern Italy, and (2) between the Oligocene of Antigua and the Rupelian of Northern Italy.

Engineering and Shipbuilding.

THE causes of the present depression in engineering and shipbuilding and ways and means of mitigating the results formed the subject of the address delivered by Sir Eustace H. Tennyson d'Eyncourt on October 16, as president of the North-east Coast Institution of Engineers and Shipbuilders. Employers and employees, manufacturers and owners must pull together and not attempt to row the boat in opposite directions, this is especially necessary now, since there has never before been a time when such strenuous efforts were being made to stir up strife. One of the chief causes of the present trouble is the over-production which took place in the later years of the War and immediately following. There is little doubt that many of the vessels laid up at present are old, or becoming obsolete, and probably will never be put in service again.

Improvements in machinery and other features of ships are so rapid that older vessels soon have to give way to more up-to-date craft which can be run more economically. Higher steam pressures will come, and we shall soon see boilers and turbines with at least double the usual present-day pressure—one vessel is now being built on the Clyde, for passenger traffic there, with high-pressure boilers and turbines. Our knowledge of the best dimensions for propellers has been considerably added to, as has also the improvement in the form of the hull, on both of which important work has been done at the Froude Tank at the National Physical Laboratory, and at other tanks.

In the construction of the hull there is room for considerable improvement in steel. The ordinary mild steel has remained practically unchanged in quality during this century. Special attention has been given to high-tensile steel in the Navy, and Sir Eustace thinks that steel of improved quality could be made and adopted at any rate for the more important portions of the structure of merchant ships.

Labour questions, including that of the loss of many of our highly skilled men who have gone to other countries, were also touched upon. The present conditions are jeopardising the supremacy of our industries, and Sir Eustace thinks that the whole position is more clearly understood by other nations, both on the Continent and in the United States. He has made a close study of relative costs, and thinks that the low prices which can be accepted abroad are due to a combination of factors—longer hours and slightly lower wages, lower rates and taxes; more elasticity allowed to workmen doing various kinds of work, full advantage taken of labour-saving appliances; many of the materials used are somewhat less costly, less elaborate and expensive ship's fittings are accepted by owners. In fact, a somewhat lower standard of living is accepted by the workers, and a lower standard of article by the purchasers.

University and Educational Intelligence.

BIRMINGHAM.—Prof. F. W. Burstell, for some time Dean of the Faculty of Science, has been appointed Vice-Principal, in succession to Sir William Ashley, who resigned at the end of last session.

The Walter Myers Travelling Studentship (value 300*l.* for one year) has been awarded to Miss Edythe Milne Bankier.

The date of the celebration of the Centenary of the Medical School is fixed for December 8 next, but arrangements for the celebration are not yet complete.

CAMBRIDGE.—On November 3 the Senate discussed some of the statutes proposed by the Royal Commission, and many points were raised. Among them was the suggestion that the Forestry Department should be made a part of the Faculty of Agriculture. Some speakers felt that it was unfair to place a limit on the period of tenure of demonstratorships.

The Council of the Senate has presented a report in which it is pointed out that whereas the possession of a Cambridge degree is supposed to signify that the bearer has participated in the life of the University, it is now possible in certain circumstances for research students to obtain degrees after only three terms of residence. It is proposed that the new statutes shall require at least five terms of residence, a scheme which would undoubtedly enhance the value of research degrees. Concessions would be made to graduates of Oxford and Dublin.

It is proposed that a committee of management shall be set up to deal with the Polar Research Institute, for which 13,000*l.* was provided from the Captain Scott Memorial Fund.

Dr. Dean, professor of pathology, and Mr. T. Knox Shaw, tutor and mathematical lecturer of Sidney Sussex College, have been elected members of the Council of the Senate.

Among the fellows recently elected at St John's College were Dr F. H. Constable (biochemistry) and Messrs E. G. Dymond and T. G. Room (mathematics).

Mr H. Godwin has been elected to a fellowship at Clare College. Mr Godwin was formerly a scholar of the College and is now junior (University) demonstrator in botany, he is carrying on research work on the respiration of leaves.

Queens' College now elects its entrance scholars on the results of the Higher School Certificate Examinations; of the five elections recently announced, one is for science and one for science with mathematics. At Pembroke College, of eight 80*l.* exhibitions announced last week, two were for mathematics and two for science.

Applications are invited for the Pimsent-Darwin Studentship in Mental Pathology. The studentship is of the annual value of about 200*l.* and is tenable for three years. Further particulars may be obtained from the Registry of the University of Cambridge, and applications for appointment should be sent before December 1 to the Secretary, Pimsent-Darwin Studentship, Psychological Laboratory, Cambridge.

LONDON.—Applications are invited for the Rogers prize for 1926 for the best essay on "The Value of the Various Methods of investigating Diseases of the Pancreas." The value of the prize is 100*l.*, and the competition is open to all whose names appear on the Medical Register of the United Kingdom. Information can be obtained from the Academic Registrar, University of London, South Kensington, S.W.7.

ST. ANDREWS.—Dr. F. Nansen has been elected Rector of the University to succeed Dr. Rudyard Kipling. The following appointments have been made by the University Court: Mr. H. J. R. Kirkpatrick to be lecturer in regional anatomy and assistant to the Bute professor of anatomy in the United College, Mr. D. L. Pritchard to be assistant in mathematics, and Dr. Margaret Scott Dickson, assistant in public health.

The degree of D Sc has been conferred on Mr. R. S. Vaidyanathaswamy, of Madras, for a mathematical thesis entitled "Studies in Form-Theory."

THE British Research Association for the Woollen and Worsted Industries announces the following

awards for the year 1925-26.—Research fellowships to Mr. J. R. Nichols, to enable him to continue his researches at the animal Breeding Research Department of the University of Edinburgh, on the fibres of various breeds of sheep; and to Miss J. S. S. Blyth, to conduct research at the Animal Breeding Research Department, Edinburgh, on the microscopical examination of the fleeces of British breeds of sheep; advanced scholarships to Mr. H. S. Bell, at the University College, Nottingham, and to Mr. W. Riddle, at the Scottish Woollen Technical College, Galashiels.

For the sixth year in succession, Trinity College, Cambridge, announces the offer of a Research Studentship open to graduates of other universities who propose to come to Cambridge in October next as candidates for the degree of Ph.D. The value of the studentship may be so much as 200*l.* a year. Applications must reach the Senior Tutor by July 25, 1926. The College is also offering, as usual, Dominion and Colonial Exhibitions of 40*l.* or (in cases of special need) about 72*l.* to students of Dominion and Colonial universities who wish to come to Cambridge next October as candidates for the degree of B.A., M.Litt., M.Sc., or Ph.D. Candidates must apply through the principal authority of their university, and applications should reach the Senior Tutor (from whom further particulars may be obtained) by July 1, 1926.

TRAVELLING studentships for university graduates are provided on a remarkably liberal scale by the National University of Ireland. In the new Calendar, particulars are given of five such studentships of the value of 200*l.* each, open to graduates of the University, offered in the following subjects for competition in 1926: economics, experimental physics, agriculture, physiology, and modern languages (two of—English, French, and German). Reference is still made in the Calendar to the Royal College of Science, Dublin, as an institution at which may be taken the practical course required to be pursued in the second year of the course for the bachelorship in engineering. We understand, however, that the buildings and equipment are being transferred to University College, Dublin.

THE Charles' University (Universita Karlova) of Prague has published in English a prospectus, specially prepared for foreign students, of its Faculty of Science. It offers a doctorate in science (Rerum Naturalium Doctor) on conditions which do not necessarily involve a knowledge of the Czech language or a prolonged stay in the country. Any part of the required four or five years of university work may be taken at any university of recognised standing, the thesis may be in English, French, German, or Russian, and the two (oral) examinations may be conducted in any of these languages. The thesis must embody the results of original research constituting a distinct advancement of science. Among the departments in which facilities for specialist study and research are offered are those of meteorology, pharmaceutical botany, anthropology and demography, photography and photochemistry, methodology and history of the natural sciences and of the exact sciences. The University maintains a Department of Athletics and Physical Training which offers, free of charge to students, facilities for football, swimming, rowing, tennis, ski-ing, skating, etc., and the Faculty of Science arranges ski-ing parties for which special reduced student rates for railway journeys and hotel accommodation are obtainable. Special arrangements are made by the student body for welcoming foreign students and helping them to find suitable accommodation.

Early Science at Oxford.

November 15, 1687. A letter was read from Dr. Garden concerning the formation of animals. In which he reconciles the opinions concerning the formation ex Animalculis and ex Ovo, in these positions: first animals are formed ex Animalculis, 2d that these Animalculæ are in semine Marium et non in fœminis; 3dly that the ovum fœminarum is this nidus requisite to the production of the animals.

There was also read a relation of a dismall tempest at Hullavington, communicated by Mr. Cole of Bristol.

November 16, 1683. Dr. Plot shewed us ye two peices of a magnet, which he had lately cut *secundum Equatorem*; they were now two Magnets, and referred to one another, as when they were one whole; contrary to what was found in ye division *secundum Meridianum*.—And, with Dr. Tyson, he gave an account of Hair-balls. 'Twas observed that ye grain of ye hair, was all one way, which was caused (possibly) by ye motion of ye ball in ye stomach.

Mr. Piggot read an account of Chylification, which was put into his hands by a freind of his, who desires to be anonymous to us: the Author says, he has a liquor, some few drops of which will turn spittle, ye broths of beef, mutton, and veal, as also ye flesh it self, to a white color; arguing from thence, that probably ye great menstruum of ye stomach, may be of ye same nature, with his liquor, Mr. Piggot says he saw these experiments tried with success.

November 16, 1686. An account of one Mrs. Brown in Oxford who dyed of a *dropsie*, out of whose body was taken by measure 16 gallons of water wanting a quart, all contained in one great bag which was continued with the ovarium.

An account was received from Mr. Halley of a *little man*, lately presented to the French king, being 37 years old, and with a great beard, and yet but 16 inches high. Likewise of a transparent substance lately invented in France, made out of Hogs bladders, fit to be used instead of coach glasses because it will not break.

An account of an experiment made at the spire of the Cathedral in new Sarum, Nov 1684, with the *Baroscope* by Colonel Windham and Mr. Warner.

November 17, 1685. Mr. Bobart presented a catalogue of ye leaves and seeds of plants lately brought from St. Christopher's and shewn us ye last meeting.

Mr. Pigot junior informed ye Society, that not long since he opened a dog by entering ye abdomen a little above ye Os Pubis according to Dr. Lister's direction, ye dog was kept above a fortnight after this, (in which time he recovered gradually) and then ran away. Mr. Pigot farther informs ye Society that in a late dissection of a dog he observ'd Lacteals to rise from ye bottom of the stomach, contrary to the opinion of some late anatomists.

Dr. Plot comunicated ye *Byssus marinus* of a *Pinna marina* mentioned by Rondelet.

November 18, 1684. A letter from Mr. Aston was read, giving an account of severall experiments mentioned in a book lately written by Kunckell, being sent over by ye Elector of Brandenburg, these experiments were ordered to be tried. Mr. Desmastes took ye trouble upon him.

A letter from Mr. Packer, Physitian at Reading, mentions a hollow oak, not far from Early Court in Berk-shire, which, as he is inform'd, is 18 yards in compass at ye bottom, but lessens apace from ye ground. He promises a full account of this thing as soon as his occasions will suffer him.

Societies and Academies.

LONDON.

Royal Society, November 5.—L. Ballif, J. F. Fulton, and E. G. T. Liddell: Observations on spinal and decerebrate knee-jerks, with special reference to their inhibition by single break-shocks. Simultaneous mechanical torsion-wire myograph and electrical records have been obtained of knee-jerks in decerebrate and spinal preparations. The spinal knee-jerk differs from the decerebrate: the mechanical response of the spinal jerk is two to three times longer in duration than that of the decerebrate jerk (or the motor twitch); the curve of relaxation of the spinal jerk is different; the electrical response tends to be more prolonged in the spinal knee-jerk; the interval between the tap and the electrical response is greater in the spinal preparations; and the spinal jerk is more difficult to elicit. The shortest spinal knee-jerk observed seems to be produced by a repetitive discharge of at least 4 to 8 volleys of impulses recurring somewhat asynchronously at 100 to 200 per sec. Both spinal and decerebrate knee-jerks may be inhibited by a single appropriately timed break-shock applied to an ipsilateral afferent nerve, the former much more readily than the latter. When recovering from an inhibition, the spinal knee-jerk has the same duration as a twitch or a decerebrate knee-jerk.—K. Furusawa: (1) Muscular exercise, lactic acid, and the supply and utilisation of oxygen. Pt. xiii. The gaseous exchanges of restricted muscular exercise in man. A simple ergometer, capable of being worked at any speed by the arms, has been constructed. As regards oxygen requirement, there is a marked optimal speed but no optimal load. Oxygen intake rises much more slowly to its maximum value than it does in the case of exercise involving most of the muscles of the body. It seems that lactic acid produced in excess by violent activity of a localised group of muscles may diffuse from them into the blood, and thence to other parts of the body (particularly resting muscles and liver), and there be removed or restored to glycogen under the influence of oxidation occurring in those tissues. There appears, therefore, to be possibility of an exhaustion due to complete using up of lactic-acid precursor, when the exercise involved is localised in a small group of muscles. (2) A spirometer method of studying continuously the gaseous metabolism of man during and after exercise. A new method is described of studying continuously the rapidly altering gaseous metabolism of man during and after muscular exercise. A spirometer of large capacity is used, the gases inside it being kept continuously stirred, the total ventilation being measured every 10 litres, and samples being abstracted at intervals for analysis.—D. T. Harris: The effect of light on the circulation. Irradiation of a localised area of skin with ultra-violet energy causes a widespread peripheral vaso-dilation. Consequently, only a very slight transitory rise of blood-pressure results from the small increase in pulse rate of from two to five per minute in dark and white subjects respectively. The reaction was always less in pigmented subjects. The vaso-dilator response to ultra-violet radiation is enhanced by a previous exposure; this is not the case with radiant heat. The vascular response appears to be a nervous reflex initiated by a nocuous stimulus; the whole phenomenon is one of incipient injury.—A. V. Hill: The surface tension theory of muscular contraction. The amount of lactic acid liberated when a muscle fibre 1 cm. long develops a force of 1 dyne is 1.46×10^{-11} gm. This is very

nearly 10^{11} molecules. Spread out in a continuous mono-molecular film these would occupy about 2.1×10^{-4} sq. cm. If the mechanical response of muscle were due to a change of surface tension caused by such a film, the coefficient of surface tension required would be about 4800 dynes per centimetre. This is about 230 times the tension of a water—olive-oil interface, clearly an impossible value. Reckoned per gm. of muscle, the amount of lactic acid liberated in a maximal contraction of a frog's muscle is about 0.033 mgm., which would occupy an area of about 470 sq. cm.; i.e. about the surface area of the fibres composing the muscle.—J. F. Fulton and E. G. T. Liddell: Electrical responses of extensor muscles during postural (myotatic) contraction. Simultaneous mechanical and electrical records have been obtained of the responses of quadriceps femoris and rectus femoris of decerebrate cats to various forms of postural (myotatic) reflex. The knee-jerk seems to be produced by a somewhat asynchronous volley of impulses. The comparative absence of electrical responses in stretch reflex is due to complete asynchronism of afferent stimuli, for when a large number are recruited synchronously an action current invariably occurs. Since the exaggerated stretch reflex characteristic of the decerebrate condition is in large measure responsible for rigidity of extensor muscles in the decerebrate animal, we have inferred that these sustained postural reactions are produced by asynchronous all-or-nothing contractions of individual muscle fibres rather than by hypothetical fixing mechanisms.—L. N. Katz: On the supposed pluri-segmental innervation of muscle fibres. In the frog, when the two components of the sciatic nerve are stimulated in succession in an isometric tetanus, the sum of the tension developed is considerably greater than the tension produced when both components are stimulated simultaneously. The total heat developed on stimulating the two components of the sciatic nerve separately is, however, the same as that produced when they are stimulated simultaneously. This indicates that there is no pluri-segmental innervation of frog's muscle fibres apart from possible infrequent chance variations.—L. N. Katz and C. N. H. Long: Lactic acid in mammalian cardiac muscle. Pt. i. The stimulation maximum. The mammalian heart is dependent on its contemporary oxygen supply, and fails rapidly in its absence; the skeletal muscle, on the other hand, is independent at first of its contemporary oxygen supply. The data obtained from cats and rabbits show that the mean lactic-acid stimulation maximum of the heart is approximately one-third that of the skeletal muscle. The maximum "oxygen-debts" of these two tissues should therefore be in the same ratio.—H. J. G. Hines, L. N. Katz, and C. N. H. Long. Lactic acid in mammalian cardiac muscle. Pt. ii. The rigor mortis maximum and the normal glycogen content. The rigor mortis maximum, or the caffeine rigor maximum, of lactic acid in the heart is only half that in the skeletal muscle. A lack of lactic-acid precursor is not the cause of the relatively low stimulation maximum in the heart. The glycogen content of the heart is much smaller than that of skeletal muscle in well-fed cats. There is in the heart a greater discrepancy between resting glycogen content and the lactic acid produced in rigor mortis, than there is in skeletal muscle. It indicates that a greater portion of the lactic-acid precursor of the heart is in some other form than glycogen.—Phyllis Kerridge, L. N. Katz, and C. N. H. Long: Lactic acid in mammalian cardiac muscle. Pt. iii. Changes in hydrogen-ion concentration. The hydrogen-ion concentration of cardiac and of

skeletal muscles stimulated to fatigue are different; the difference is of the order of 0.2 pH, the skeletal muscle being the more acid. In rigor mortis the difference is of the order of 0.4 pH, the skeletal muscle being the more acid. Cardiac and skeletal muscle have different buffering powers which vary at different pH's. The maximum difference is at approximately 6.3 pH, when the ratio of the buffering power of skeletal to that of cardiac muscle is about 2:1.—W. E. Garner: The mechanism of muscular contraction. It is suggested that the tension generated on applying a stimulus to a muscle fibre is due to the formation of a solid film on the surfaces of the ultimate fibrils of the muscle. Liquid crystals composed of long-chain carbon compounds are present in the anisotropic segments of the muscle, and the molecules of the long-chain carbon compounds are orientated with their chains in a direction parallel to the axis of the fibre. It is suggested that glycogen is converted into sodium lactate according to the series of reversible reactions

where A is a product formed from glycogen and B is an intermediate active form of both A and lactic acid. The direction of the chemical reaction may be influenced by alteration of the surface energy of the membranes during movements of the muscle. When the energy liberated during the conversion of glycogen into lactic acid is not utilised in doing external work, it may be stored, in part, by a reversal of the reactions.—R. W. Riding and E. C. C. Baly: The occurrence of helium and neon in vacuum tubes [Proc. A 749 (September), pp. 186-193].—O. W. Richardson: Structure in the secondary hydrogen spectrum (iii). [Proc. Gurney: The number of particles in the beta-ray spectra of radium B and radium C. [Proc. A 751 (November), pp. 540-561].

MANCHESTER

Literary and Philosophical Society, October 27.—S. J. Hickson: The life and work of Georg E. Rumphius (1627-1702). Among the early pioneers of the sciences of botany and zoology, Georg Everard Rumphius (or Rumphius) occupies a prominent if not

an outstanding position. His work was done in the remote island of Amboyna in the Malay Archipelago, but owing to a series of calamities only his two books, "Het Amboinsche Kruidboek" and "D'Amboinsche Rariteitkamer," were preserved in a form sufficiently complete for publication. His three books on the land, air and water animals of Amboyna were lost, as were also the greater part of his books on the history of the island and the description of the country. Rumphius was born and educated in Hanau, a German city, but there is reason to believe that his family was of Dutch descent. The date of his birth must have been either 1627 or 1628. He arrived eventually in Amboyna in 1653, at the age of about twenty-six years. He exchanged from the Dutch army into the Civil Service and settled down as a Resident in the northern province of Hitoe of the island of Amboyna, and it was in the capital town, Hila, on the sea coast of this beautiful island, that the greater part of his work was done. For some years his life appears to have been happy and uneventful, but in 1670, when he was forty-three years of age, he became totally blind by cataract in both his eyes. He was removed to Amboyna, but with the help of his son Paul continued his work until his death in 1702. In 1674 his wife and youngest daughter were killed in the terrible earthquake that ravaged the island in that year. In 1687 many of his books, manuscripts and drawings were destroyed in a disastrous fire that burned down his house, and to complete the misfortunes of this most unfortunate man, the whole of the original manuscripts and drawings of the first six books of his Amboyna Herbarium were lost when the ship *IVaterland*, in which they were being conveyed to Holland, was captured by the French and destroyed. Fortunately, by the order of the Governor-General a complete copy of this work was made before it left Java, and this copy reached Holland in safety.

PARIS.

Academy of Sciences, September 28.—F. E. Fournier: The prevention of collisions at sea. The international rules at present in force are insufficient to prevent collisions between vessels during fog. A scheme of wireless signals giving greater security is suggested.—H. Deslandres: Complementary researches on the structure and distribution of band spectra. On the basis of the data of Coblenz on infra-red spectra, the author finds confirmation of his general formula given in earlier communications.—E. Bataillon: The first parthenogenetic kinesis in *Bufo vulgaris* and the mechanism of the regulation.—A. S. Besicovitch: Some points in the theory of nearly periodic functions.—F. Carlson: Some mean values of an analytical function.—Jean Dufay: The polarisation of the zodiacal light. Visual observations have given contradictory results regarding the polarisation of the zodiacal light. The author has made use of a photographic method, details of which are given, and finds that his results confirm the view generally held, that the zodiacal light is only diffused solar light.—Arabu: The tectonic of the field of faults of Ribeaupillé (Haut-Rhin) to the north of Strengbach.

WASHINGTON, D. C.

National Academy of Sciences (Proc. Vol. 11, No. 9, September).—C. Dale Beers: Encystment and the life cycle in the ciliate *Didinium nasutum*. Under favourable and adequate conditions, there is no definite life cycle, and encystment does not occur periodically. Scarcity of food causes the formation

of cysts which are all considered to be protective in nature. Excretion products of *Paramoecium* inhibit encystment. excretion products of *Didinium* promote it—Sophia Satina and A. F. Blakeslee. Studies on biochemical differences between (+) and (-) sexes in *Mucors* tellurium salts as indicators of the reduction reaction. Of the 264 heterothallic races of *Mucor* examined, the (+) races show a higher average power of reducing certain tellurites and selenites than the (-) races. This reducing power seems to be influenced by the sex differential, but other non-sexual factors exert an influence which varies from race to race—Howard B. Frost. Tetraploidy in Citrus. "Thick-leaved" citrus appears to be tetraploid (18 chromosomes, but the number is very variable), the doubling of the chromosome number taking place in the nucellus or in the very young embryo—C. E. Seashore and Milton Metfessel. Deviation from the regular as an art principle. Emotion in music is expressed by slight deviation from the exact and can be analysed by photographing the sound waves. These records show the character of the vibrato used to express emotion in singing, and indicate how various singers obtain their effects by gliding to a note, attacking it, correcting for illusions of hearing by singing what is actually a wrong note, and making slight deviations from exact time.—C. E. Seashore. The rôle of mental measurement in the discovery and motivation of the gifted student. A new type of senior high school examination testing training and aptitude gives a forecast of probable success in college. This is followed by a freshman examination in each subject, which makes possible the immediate organisation of sections on the basis of fitness. These records give a trustworthy measure of each student's capacity—G. A. Miller. Arithmetisation in the history of mathematics—Francis G. Benedict. Skin temperature and heat loss. Skin temperature surveys are made rapidly under various conditions by thermojunction, heat loss is measured by pyranometer (for radiation) and calorimeter chamber (total). Generally there is distinct correlation for all parts of the body, for skin temperature and temperature of the environment. As regards radiation of heat, the human skin seems to act as a true "black-body". Except under exceptional conditions, heat production and heat loss are essentially independent processes—A. J. Dempster. The passage of slow canal rays through hydrogen. Protons of velocity 4.16×10^7 cm per sec (900 volts) pass through many molecules without causing ionisation or exciting light—George Porter. Paine Energy transformations in an unobstructed air current, in an air current containing a dry obstacle, and in an air current containing an evaporating surface; with applications to an aerodynamic psychrometer and to the measurement of atmospheric humidity.—Samuel K. Allison and Alice H. Armstrong. Note on the experimental determination of the relative intensities of some of the molybdenum and copper *K* series lines and the tungsten *L* series lines—P. A. Ross. (1) X-rays scattered by molybdenum. The radiation scattered from the molybdenum shield of the cathode of a standard tungsten tube and of a water-cooled molybdenum tube was examined by an ionisation spectrometer. In each case the measured change of wave-length agreed well with that calculated from Compton's theory of scattering. (2) Ratio of intensities of unmodified and modified lines in scattered X-rays. A photometric study was made of numerous spectrograms and some of Compton's results were incorporated. There is roughly a linear relation between atomic number and the ratio of the intensities—Ernest Merritt. The effect of light on the behaviour of selenium contact rectifiers. The high resistance of

the selenium contact and the tendency of the surface to deteriorate make it unlikely that it will prove of value in radio work. Illuminating the contact has different effects on the rectified current according to the contact pressure and other circumstances—Carl Barus. The acoustic pressure in tubes capped by high resistance telephones, vibrating in different phases.

Diary of Societies.

FRIDAY, NOVEMBER 13

ROYAL ASTRONOMICAL SOCIETY, at 5.—B. P. Gerasimovic. On the Masses of Stars of Spectral Types F to K.—W. M. H. Graves. The Solar Motion from Stars of Spectral Types F to M.—W. J. Luyten. A List of Dwarf M Stars.—Prof. E. A. Milne. The Equilibrium of the Calcium Chromosphere (second paper).—W. M. H. Graves, and C. R. Davidson. Preliminary Note on the Determination of Effective Stellar Temperatures by the "Prism-spectrograph" Method.—K. Lundmark and W. J. Luyten. The Relation between Mass and Luminosity.—K. Lundmark. Double Spiral Nebulae.—Prof. A. S. Eddington. Electrostatic Forces in a star and the Deviation from the Law of a Perfect Gas.—W. M. Smart. A Comparison of Schlegel's Proper Motions of the Har and AG Zones with Proper Motions Photographically Determined at Cambridge.—L. H. Jeffreys. On the Surface Waves of Earthquakes.

SATURDAY, NOVEMBER 14

ASSOCIATION OF MINING ELECTRICAL ENGINEERS (North of England Branch) (at Newcastle-upon-Tyne), at 3.—J. A. B. Horsley. The Selection Layout, and Maintenance of Electrical Equipments at Collieries.

INSTITUTE OF TRANSPORT (North-East Centre) (at Newcastle-upon-Tyne), at 8.—O. J. Allen. British Main Line Passenger Train Services.

INSTITUTE OF CHEMISTRY AND SOCIETY OF CHEMICAL INDUSTRY (Bristol and S.W. Section) (at University College, Exeter), at 7.30.—Dr. S. Glasstone. The Measurement of Over-Voltage.

PHYSIOLOGICAL SOCIETY (at Cardiff).

MONDAY, NOVEMBER 16

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge), at 5.—F. Rodd. The Origin of the Tunnies.

ROYAL SOCIETY OF MEDICINE, at 5.30.—Sir Arthur Keith. Man's Structural Defects (Lloyd-Roberts Lecture).

ROYAL AERONAUTICAL SOCIETY, at 6.—Informal Discussion on The Autogyro.

INSTITUTION OF ELECTRICAL ENGINEERS (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.—T. Carter. The Engineer his Dis and his Duty in Life (Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30—Capt R. K. Hubbard The Requirements of the Military Motor Vehicle.
ARISTOTELIAN SOCIETY (at University of London Club), at 8—Dr L. A. Reid The Nature of Beauty.
FARADAY SOCIETY (at Chemical Society), at 8—E. D. Campbell A Chemical Theory of Permanent Magnetism—Prof. J. R. Partington and N. L. Anthonioff An Improved Form of Electric Vacuum Furnace—J. R. H. Coultas and E. M. Grouther: A Source of Error in the Mechanical Analysis of Sediments by Continuous Weighing—D. Weimer A Simple Method of obtaining the Size Distribution of Particles in Soils and Precipitates—J. A. V. Butler. Co-ordination and Co-valency—F. G. Tryhorn and W. F. Wyatt Adsorption by Charcoal from Alcohol-Benzene and Acetone-Benzene Mixtures—F. L. Usher. The Nature of the Interfacial Layer between an Aqueous and a non Aqueous Phase.

TUESDAY, NOVEMBER 17

ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15—G. Udny Yule Why do we sometimes get Non-sense-Correlations before Time Series? A Study in Sampling and the Nature of Time Series (Presidential Address).
ZOOLOGICAL SOCIETY OF LONDON, at 5.30—Secretary. Report on the Additional made to the Society's Menagerie during the month of October 1925—Dr G. D. Hale Carpenter. Speke's Tragelaph on the lower Isles of Lake Victoria—Dr P. R. Lowe On the Classification of the Tubenares or Petrels—S. Hirst On some New Genera and Species of Arachnida—H. C. Wilkie. The Auditory Apparatus of the Common Mole (*Talpia europaea*)—J. R. Kinghorn A New Genus of Sea Snake and other Reptiles collected by H. M. A. S. *Chelonia* during a Cruise to North Australia.
INSTITUTION OF CIVIL ENGINEERS, at 6—Prof. W. E. Dalby. The Mechanical Properties of Steel.
INSTITUTION OF ELECTRICAL ENGINEERS (East Midland Sub-Centre) (at the College, Loughborough), at 6.45—J. A. Aiton Steam Pipes for Extra High Pressure and Temperature.
INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at 17 Albert Square, Manchester), at 7—P. Dunsheath. Dielectric Problems in High-Voltage Cables.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7—J. C. Dollman Specialisation and Versatility.
INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Graduate Section) (at Broadgate Cafe, Coventry), at 7.15—G. A. Goshing, C. Ballard, and others Discussion on Traffic Control and Organisation.
INSTITUTION OF AUTOMOBILE ENGINEERS (Wolverhampton Centre) (at Wolverhampton), at 7.30—Capt. R. K. Hubbard The Requirements of the Military Motor Vehicle.
INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (Glasgow), at 7.30.
NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middleborough Branch) (at Cleveland Scientific and Technical Institution, Middleborough), at 7.30—W. T. Butterwick Tonnage.
ROYAL ANTHROPOLOGICAL SOCIETY (Indian section), at 8.15—Dr E. H. Hunt Recent Work on Hyderabad Carni Rituals.

WEDNESDAY, NOVEMBER 18

ROYAL METEOROLOGICAL SOCIETY, at 5—Sir Gilbert Walker and E. W. Bliss On Correlation Coefficients their Calculation and Use—Miss Catherine G. Statens. Note on the Variations in Transparency of the Atmosphere observed by Means of a Projected Telescopic Image of the Sun—N. L. Silvester. Notes on the Behaviour of certain Plants in relation to the Weather.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5—Prof. W. Wright The Medieval Conception of the Anatomy and Physiology of the Central Nervous System (Thomas Vicary Lecture).
GEOLOGICAL SOCIETY OF LONDON, at 8.30—W. L. F. Nuttall A Revision of the Orbitoides of Christmas Island (Indian Ocean)—W. Campbell Smith The Volcanic Rocks of Christmas Island (Indian Ocean).
INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6—J. Kennard Address.
GLASGOW UNIVERSITY ALCHEMISTS' CLUB, at 7.30—Dr. F. W. Ayton Isotopes.
INSTITUTION OF ELECTRICAL ENGINEERS (Sheffield Sub-Centre) (at Royal Victoria Hotel, Sheffield), at 7.30.
ROYAL MICROSCOPICAL SOCIETY, at 7.45—M. T. Dennis A New Microscope—S. Dickinson A Simple Method of Isolating and Handling Individual Spores and Bacteria—Dr R. S. Clay and T. H. Court Two Microscopes made by G. Adams for King George III.
ROYAL SOCIETY OF ARTS, at 8—J. C. Goodison The Furniture of Hampton Court.
ENTOMOLOGICAL SOCIETY OF LONDON, at 8.
INSTITUTE OF CHEMISTRY (Annual General Meeting).
SOCIETY OF GLASS TECHNOLOGY (at Leeds).

THURSDAY, NOVEMBER 19

ROYAL SOCIETY, at 1.30—J. W. Pickering and R. J. Gladstone The Development of Blood Plasma. Part I. The Genesis of Coagulable Material in Embryo Chick—D. J. Scourfield On a new type of Crustacean from the Old Red Sandstone (Rhynie Chert Bed, Aberdeenshire). *Lepidocarpus Rhynianus*—J. R. Norman The Development of the Chondriocranium of the Eel (*Anguilla vulgaris*) with Observations on the Comparative Morphology and Development of the Chondriocranium in Bony Fishes—J. Needham and Dorothy Needham The Hydrogen-Ion Concentration and Oxidation-Reduction Potential of the Cell Interior before and after Fertilisation. A Micro-Injection Study of Marine Eggs—R. P. Armstrong Studies on the Nature of the Immunity Reaction—R. J. Lindford The Cytology of Tar Tumours—E. Ponder The Inhibitory Effect of Blood Serum on Hemolysis—L. Brull and F. Eichholz (a) The Effects of Calcium and Potassium Ions on Urine Secretion as studied in the whole Animal. (b) The Secretion of Inorganic Phosphate by the Kidney—F. Eichholz, R. Robinson, and L. Brull. Hydrolysis of Phosphoric Esters by the Kidney in vivo.

LINNEAN SOCIETY OF LONDON, at 5.—Dr H. G. Holden and S. H. Clarke: On the seedling structure of *Tilia europaea* L.—L. R. Crawshaw On Sponge Fishery.—Dr G. Claridge Bruce Recent Additions to the British Flora.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6—T. Carter The Engineer: his Due and his Duty in Life (Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (London Graduate Meeting) (at Watlington House, Adelphi), at 7.30—S. C. Vince and C. F. Gifford Modern Methods of Omnibus Chassis Overhaul.

CHEMICAL SOCIETY, at 8—Prof. E. C. O. Baly and R. W. Riding The Constitution of the Metallic Oxides—Prof. T. M. Lowry and I. J. Faulkner Studies of Dynamic Isomerism. Part XX. Amphoteric Solvents as Catalysts for the Mutarotation of the Sugars—Prof. T. M. Lowry and G. Owen Studies of Valency. Part V. Absorption Spectra of Halogen and Sulphonic Derivatives of Camphor. Origin of the Ketonic Absorption Band—Prof. T. M. Lowry and R. R. Ness Studies of Valency. Part VI. General and Selective Absorption of Halogen-Derivatives of Methane. The Origin of General Absorption—R. G. W. Norrish and G. Jones Studies of Valency. Part VII. Surface Polarity and the Reaction of Ethylene and Chlorine. The Effect of the Adsorbed Water Layer.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (Laboratory Meeting) (at London School of Hygiene and Tropical Medicine), at 8.15—Demonstrations by Col. A. Alecock, Dr. A. Balfour, Dr. H. A. Baylis, Major K. K. Chatterji, Dr. A. Castellani, Dr. J. T. Dunneau, Dr. T. Jerke, Prof. R. T. Leiper, Mr. H. H. Newham, Dr. H. H. Scott, Lt. Col. H. Marrian Pettit, Dr. N. A. D. Sharp, Dr. J. G. Thomson, and Dr. C. M. Wenyon.

INSTITUTION OF MECHANICAL ENGINEERS (Birmingham Branch)—H. W. Coulter. Some Hydraulic Problems.

INSTITUTION OF MECHANICAL ENGINEERS (Glasgow Branch, jointly with Association of British Foundrymen (Scottish Section))—Discussion on Cast Iron for Diesel Engines.

INSTITUTION OF MECHANICAL ENGINEERS (North-Western Branch, Graduate Section) (at Manchester)—Lt. Col. E. Kitson Clark. Archaeological Engineering (Annual Lecture).

FRIDAY, NOVEMBER 20

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30—Prof. E. P. Stebbing Recent Progress in Indian Forestry.

SOCIETY OF CHEMICAL INDUSTRY (Liverpool Section) (at Liverpool University), at 6—Dr. A. Holt and others Discussion on Chemical Journals and Chemical Societies.

INSTITUTION OF MECHANICAL ENGINEERS, at 6—H. F. L. Orcutt Characteristics and Uses of Ground Gears.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7—A. C. Ranfield. Heliostatic Photography.

PHOTOGRAPHIC SOCIETY (at 4 Fetter Lane), at 7—Members' Evening.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30—G. E. Wills Dehydration of Tar.

SATURDAY, NOVEMBER 21

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (jointly with Institute of Mining and Mechanical Engineers) (at Neville Hall, Newcastle-upon-Tyne), at 3.
BRITISH MICROLOGICAL SOCIETY (at University College).

PUBLIC LECTURES.

SATURDAY, NOVEMBER 14

HORNIMAN MUSEUM (Forest Hill), at 3.30—R. A. Smith Aspects of Roman London. II.

MONDAY, NOVEMBER 16

GOLDSMITHS' HALL (E.C. 2), at 4—Sir Oliver Lodge The Link between Matter and Matter (Norman Lockyer Lecture).
UNIVERSITY OF LEEDS, at 5.15—Sir Charles F. Clowe Some International Aspects of Geography.

TUESDAY, NOVEMBER 17

KING'S COLLEGE, at 5.30—Miss Hilda D. Oakley The Philosophy of Aristotle. Philosophy of the Universe. Nature. The First Mover.
GREBBIAN COLLEGE (Basinghall Street), at 6—A. R. Hinks Meteorites and Meteor. (Succeeding Lectures on November 18, 19, and 20).

WEDNESDAY, NOVEMBER 18

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4—Dr. C. W. Saleeby The Role of Clothing in the Prevention and Arrest of Disease.
ROYAL SOCIETY OF MEDICINE, at 5.15—Sir Wilfred Beveridge Insects in Relation to Public Health (Chadwick Lecture).

THURSDAY, NOVEMBER 19

BEDFORD COLLEGE FOR WOMEN, at 5.15—Sir Robert Witt. Eighteenth-Century Art.
DYER'S HALL (Dowgate Hill), at 6—Dr. E. F. Ehrhardt The Patent Law as it affects the Dye-making and Dye-using Industries.

FRIDAY, NOVEMBER 20

ROYAL SOCIETY OF MEDICINE, at 5.30—Dr. Howarth The Slaughtering of Animals for Human Consumption (Benjamin Ward Richardson Memorial Lecture).

SATURDAY, NOVEMBER 21

HORNIMAN MUSEUM (Forest Hill), at 3.30—G. C. Robson: Animal Life in the Depths of the Sea.

SATURDAY, NOVEMBER 21, 1925.

The Norman Lockyer Memorial Lecture.

ON Monday last, the first Norman Lockyer lecture, under the auspices of the British Science Guild, was delivered by Sir Oliver Lodge in the hall of the Goldsmiths' Company, his subject being "The Link between Matter and Matter." It is fitting that the Guild should thus honour the memory of the man who, more than any other, was responsible for its formation, and no happier choice for the first lecturer could have been made than that of Sir Oliver Lodge. Lockyer was essentially a man of wide vision; his mind sought instinctively for generalisations. A fact was to him only of importance in so far as it was related to the general principles which underlie all facts. He was not content with a laboratory; he would have an observatory. He was not content even with an observatory; he would have a theory which would embrace all the revelations of the laboratory and the observatory and bind the whole physical universe into a single entity. The key to Lockyer's scientific career is to be found in this overpowering tendency to generalise, and no one who is not to some extent under the dominance of the same tendency can rightly interpret the apparently erratic course which his genius led him to pursue.

Sir Oliver spoke briefly of his personal association with Lockyer, which began so far back as the year 1873 when Lockyer was working in rooms generously placed at his disposal by Frankland in the new School of Science at South Kensington. He then referred to the discovery of helium, which, for twenty-six years after Lockyer had found it in the sun, remained a mere spectroscopic curiosity, but which, since Ramsay's isolation of the element from cleveite, has been instrumental in bringing about some of the most important advances of modern physics and astronomy. "Thus it is," he said, "that little discoveries, at first apparently isolated and without obvious meaning, turn out not to be little at all, but fundamentally important, being systematised by future workers until they furnish the clue to a magnificent series of discoveries about the constitution of matter." Lockyer, however, did not wait for future workers. He had his ideas about the constitution of matter long before helium was generally admitted to exist even in the sun, and he was fundamentally right.

Sir Oliver went on to speak of the human aspect of Lockyer's work. "Lockyer's work and speculations were never really remote from humanity; he kept before himself continuously, and eloquently urged upon others, the necessary bearing of all scientific discovery on human and social progress." It was the conviction that science was the chief factor in the material progress

of nations that led him to found the British Science Guild, and to choose for the subject of his presidential address to the British Association in 1903, not the development of his own individual researches, wide as they were, but the importance of science to national progress—"The Influence of Brain-Power on History," as he called it. The same conviction was an important factor in his determination, in the year 1869, to inaugurate a new journal of science—*NATURE*—in order that the progress of science might be followed by all, and not only by those actively engaged in scientific pursuits.

Coming to the subject indicated by the title of his address, Sir Oliver defined "the link between matter and matter" as "the impenetrable uniting ingredient, or cosmic unit, which connects the otherwise dissociated or dissevered atoms of matter, and enables them to act on each other even from a distance. This ingredient . . . is essentially 'radiation,' that is to say, a disturbance in the ether, or in space, which travels at one absolute velocity, which journeys without loss or dissipation of energy, and produces even at enormous distances its singular and striking results." This link between matter and matter is required to explain gravitation and the propagation and chemical action of light. One of its surprising characteristics is the power—commonly known as photo-electric action—"of unlocking the atom and enabling it to fling away one of its constituent electrons." Sir Oliver raised the question "whether the energy of . . . photo-electric emission is applied instantaneously by the radiation stimulus, or whether it is gradually accumulated in the atom up to some critical point, when it can wait till radiation of the right frequency pulls the trigger." He is of the opinion that there is something to be said for the second alternative, and that the discontinuity of the quantum might be found in the discontinuity of atomic construction rather than in "the otherwise demonstrated continuous activity or continuity of etheric radiation."

Radio-activity is another example of an apparently spontaneous process, but this also might really be due to the impact of radiation of critical frequency. "I believe that some people, I for one, are beginning to suspect that all atomic changes are due to radiation. And I would even venture to surmise that this etheric mode of inter-communication, the transmission of waves from one piece of matter to another, has more influence on ordinary, the most ordinary—even mechanical—processes than we are yet prepared to admit." The pressure of light, for example, has lately been found in certain circumstances to be very large and of cosmic importance—for instance, in the interiors of stars. Sir Oliver was not prepared to say whether or

not it ought to be taken into account in the intimate structure of atoms. The stability of Bohr's atomic orbits was a fact which had not yet been accounted for, and our aim should be to explain this and other facts on dynamical principles—"perhaps not the ordinary dynamics but etherial dynamics."

Some attempt has already been made to assimilate matter with radiation "by the very unlikely path of thermodynamics." Radiation has been treated almost like a gas, and results have been arrived at which, though they have not yet been rationally accounted for, are nevertheless true. Thus we can speak of the "temperature" of space or of radiation, and we form the conception of matter in thermodynamic equilibrium with radiation. Developing the conceptions thus generated we arrive at the quantum. "If the energy could be absorbed or emitted continuously, all the energy of matter would go into the ether, and the universe would fade away. The effect of discontinuous emission and absorption saves the universe from destruction, and makes the planet possible."

These are all fundamental considerations, and it is characteristic not only of Sir Oliver Lodge but also, to some extent, of the age in which we live, that they should be so. We are deeply involved now in problems which, fifty years ago, could not be said to have existed; they are expressible only in terms of conceptions which had not then been formed. We see now no clear dividing lines between mechanics, physics, chemistry, geology, and astronomy. None of these departments of science is complete without the others, and it is becoming increasingly clear that the physicist can no longer exclude even the principles of metaphysics from his field of inquiry. Our age is prospective; it builds the unity of the cosmos. But in Lockyer's day things were far otherwise. The progress of that time, very real though it was, lay mainly in the discovery of isolated facts, which were interpreted in the light of old and long-established principles. "Our age is retrospective," wrote Emerson; "it builds the sepulchres of the fathers."

Into this age, with its rigid formulation of the fundamental bases of a number of discrete sciences, Lockyer came with his iconoclastic, unifying mind. He was one born out of due time into a generation unprepared for his message. Much of his work which now suggests itself as so obvious a line of research to follow, and which the mistakes present themselves so clearly to our view, must be seen against the background of the prevailing ideas of the time in order to be estimated at true value. Although Kirchhoff had shown in 1859 how the solar spectrum was to be interpreted by laboratory experiments, no one before Lockyer (in 1869) combined the work of the observatory with that of the laboratory.

Because the atom was held to be indivisible, no one but Lockyer believed that physical conditions could influence the spectrum of an element. Lockyer at once cut across current ideas by proving the contrary in the laboratory and pointing to the spectra of the sun and stars for further evidence, not hesitating for a moment even to declare the atoms to be dissociated in order to explain his observations. Although in 1859 Darwin had finally established the conception of evolution in biology, no one before Lockyer spoke of the evolution of the chemical elements and of the stellar universe. It is easy, with our wider knowledge, to point to his mistakes in the formulation of his conceptions, and to the "obstinacy" with which he held to details now finally discredited. It is not so easy to estimate how great an influence his courageous individualism and breadth of vision have had in preparing the way for the relative enlightenment of our own day.

"All Lockyer's information," said Sir Oliver, "was derived from a study of radiation. The chromosphere, the partitioning of the solar atmosphere into regions, and the observation of red flames without an eclipse—represent the broodings of his genius on the information brought him by tremors or quivers in the ether of space." That is true, but Lockyer did not explicitly concern himself with radiation at all. To him it was not the link which bound matter to matter; it was the instrument which told him what he wanted to know about matter itself. Of the two great physical entities (or must we now call them one?) matter and energy, he confined his attention to matter alone. Perhaps with his mental and physical equipment he could have done no other, yet it appears that it is to the ether and radiation that we must now look for the completion of Lockyer's ideas. His two great generalisations—the dissociation hypothesis and the meteoritic hypothesis—were in error mainly in so far as they ignored the radiation factor. He saw that atoms might be dissociated, but he did not conceive that absorption of radiation was the agency through which the dissociation was brought about, and herein lies the relative barrenness of his view when compared with its modern equivalent, ionisation. He saw also that stars with similar spectra might be very different in physical state, but he did not imagine that the difference was related to the pressure of radiation and the generation of etherial energy from mass, which is the source of the fruitfulness of our latest conceptions. He could not, of course, have foreseen these things. Essential as they were to the completion of the ideas he held, he had no data from which they could have been suspected; yet, single-handed and faced by many obstacles, he came nearer to the conceptions which we now hold than any of his contemporaries. H. D.

A History of Mathematics.

History of Mathematics. By David Eugene Smith. Vol. 2: *Special Topics of Elementary Mathematics.* Pp. xii+725. (Boston, New York and London: Ginn and Co., 1925.) 21s. net.

THE two volumes of this history (the first of which was noticed in NATURE of November 15, 1924) deal with the subject from two different aspects. The first volume, described as a "General Survey," is devoted to showing "the growth of mathematics by chronological periods with due consideration to racial achievements," and to "relating the development of the science to the development of the race, revealing the science as a great stream rather than a static mass, and emphasising the human element." Details of the lives of mathematicians, their dates, and their relation to contemporary history accordingly find their place in the first volume, which in this respect follows the plan adopted by most of the writers of histories of mathematics, both English and foreign. The first volume is thus comparable with such useful and popular histories as those of Rouse Ball, Cajori, Günther-Wieleitner, and others. It contains, however, features of additional interest in the many portraits of mathematicians, pictures of mathematical instruments and illustrations of their use, facsimiles of pages from printed books and manuscripts, which are given in their proper places.

The second volume now before us, called the "Topical Survey," deals with special topics of elementary mathematics. (We may perhaps observe incidentally that, as the sub-title of each volume limits its scope to elementary mathematics, it might have been better if, with the view of avoiding misapprehension, the whole work had been called a "History of Elementary Mathematics," rather than a "History of Mathematics" simply.) That is to say, the history is here arranged according to subjects. As the author remarks in the preface:

"The teacher of arithmetic will now see, in three or four chapters, a kind of moving picture of the growth of his subject,—how the world has counted, how it has performed the numerical operations, and what have been the leading lines of applications in which it has been interested. In geometry he will see how the subject arose, what intellectual needs established it so firmly, what influences led to its growth in various directions, and what human interest there is in certain of the great basal propositions. In algebra he will see, partly by means of facsimiles, how the symbolism has grown, how the equation looked three thousand years ago, the way its method of expression has changed from age to age, and how the science has so adjusted itself to world needs as now to be a necessity for the average citizen instead of a mental luxury for the selected few."

Here Prof. Smith has no predecessors in English and only one comparable one in German, so that the work was well worth undertaking. Of his German predecessor's work, the "Geschichte der Elementar-Mathematik in systematischer Darstellung mit besonderer Berücksichtigung der Fachwörter," by Dr. Johannes Tropfke, Prof. Smith says truly that it is the best history of elementary mathematics. The first edition of 1902-3 was in two volumes of 322 and 496 large pages respectively; but the new edition, in seven volumes or parts issued between 1921 and 1924, is greatly enlarged and improved, and runs to a total of 1268 pages.

With such a model before him, Prof. Smith's difficulty must have been to compress his material, with the addition of illustrations, facsimiles, etc., into a volume of 725 pages of smaller size. It would have been comparatively easy to write a smaller volume containing only the most salient details, served up to suit the palate of the ordinary non-expert reader. But Prof. Smith's object is different; he wishes to supply the professional teacher of mathematics with all that he needs in order to be able to teach his subject with a proper sense of perspective derived from a real knowledge of the manner of its evolution. The difficulty is to give just sufficient details and no more, and not to leave out anything which is essential to make the subject comprehensible. In the general compression which Prof. Smith has found necessary, some topics suffer unduly. Logarithms, for example, are disposed of in the all too short space of ten pages. We could have wished to have a fuller statement of what Napier's logarithms exactly were, how evolved, and how related to the so-called Napierian or hyperbolic logarithms and also to Briggs's system. On the other hand, there is a very useful chapter on the history of the calculus as a separate subject.

Every effort has been made to produce a readable as well as a comprehensive book. A long chapter is devoted to elementary problems (including mathematical recreations, commercial problems, magic squares, and the like); another to measure (weight, length, capacity, time, etc.). In the second volume, as in the first, there is a wealth of interesting illustrations, facsimiles, etc., and a valuable collection of references in the notes. The labour involved in the whole work must have been prodigious, and we can only wish for it the success which it deserves.

It is inevitable that in a book containing such masses of detail there should be mistakes which have escaped detection, some being doubtless mere printer's errors. On p. 287, Pamphila, a historical writer of the first century A.D., is quoted as Pamphilus. On p. 291, "Lucian (second century), the scholiast to the Clouds

of Aristophanes" should be "Lucian (second century) and the scholiast, etc." On p. 304 it is conveyed that Hippocrates of Chios showed how to square one type of lune only, whereas he actually squared three out of the only five types of lune which can be squared by means of the geometry of the straight line and circle. On p. 307 (note) Rose's edition of Vitruvius is cited as giving $4\frac{1}{2}$ ft. as the diameter of a wheel of circumference $12\frac{1}{2}$ ft.: this should apparently be $4\frac{1}{6}$ ft., making the value of π assumed by Vitruvius to be 3 and not "less than 3." On p. 313, Archytas is said to have solved the problem of the two mean proportionals by means of "two cylindric sections"; the surfaces actually employed by Archytas were three, namely, a right cone, a cylinder, and a tore or anchor-ring with inner diameter nil. $\xi\kappa\theta\epsilon\sigma\iota\varsigma$ (p. 496) is said to be a "selling out," where "setting out" is what is meant. The strangest case is that in note 1 on p. 615 referring to Ptolemy's division of the circumference of a circle into 360 parts and of the diameter into 120 parts. The note states that the parts were " $\tau\rho\acute{\eta}\mu\alpha\tau\alpha$ (trēmata, literally 'holes' and hence the holes, or pips, of dice)." We confess to being baffled as to the source of this statement; the word actually used by Ptolemy is $\tau\mu\acute{\eta}\mu\alpha\tau\alpha$, which simply means "segments," i.e. the parts into which a line is "cut" ($\tau\acute{\epsilon}\mu\omega$).

The Ravages of Sea-Water.

Department of Scientific and Industrial Research. Deterioration of Structures of Timber, Metal and Concrete exposed to the Action of Sea-Water: Fifth (Interim) Report of the Committee of the Institution of Civil Engineers. Edited by P. M. Crosthwaite and Gilbert R. Redgrave. Pp. vii+65+8 plates. (London: H.M. Stationery Office, 1925.) 3s. 6d. net.

THE Committee of the Institution of Civil Engineers which has been investigating the deterioration of structures of timber, metal, and concrete in sea-water since 1916, with the assistance of grants from the Department of Scientific and Industrial Research, has prepared a fifth interim report which has recently been published. It consists of a brief review by the Committee of ten reports included in the publication, together with the reports themselves and a number of abstracts received from correspondents.

During the past year further examinations have been made of the steel and other specimens exposed for corrosion tests at Auckland, Colombo, Halifax, Nova Scotia, and Plymouth, and detailed reports of the present condition of the steel bars, accompanied in some cases by photographs, have been received from the engineers in charge. A comparative statement has been drawn

up by Mr. Carothers for Mr Savile, the Civil Engineer-in-Chief of the Admiralty, which presents in small compass the chief features of these periodical inspections in a form convenient for study. It is pointed out in certain of the reports that, owing to the constantly increasing growth of marine organisms and the heavy incrustation which is now attached to some of the frames, it is becoming exceedingly difficult at the present time to form a correct judgment of the condition of the metal work and bars; nor will it be possible in these cases to do so until they are taken out for final examination and measurement. Dr Newton Friend's researches on preservative coatings for ferrous metals have been continued. The specimens tested are at Southampton, under the charge of Mr. Wentworth Shields.

Various experiments bearing on the protection of timber are still being prosecuted, while a further number of specimens impregnated with different poisons have been exposed during the year at Lowestoft; and certain timbers injected with creosote and D.M. (an arsenical organic compound) have been sent to Colombo, as the ravages of the *Teredo* have been found to be very severe in that port. Prof Berger deals in his report with the changes made in the exposure of the specimens at Lowestoft. Specimens of wood tested at Plymouth have been more resistant than those at Lowestoft, and the experience there indicates that remarkable protection was secured by 2.2 per cent of carbazole. A full account is given of the mechanical tests on sixteen varieties of Colonial timbers specially procured for this purpose from Australia, New Zealand, and Ceylon. An abstract has been prepared by Mr Hamer reporting on the specimens of local timbers under exposure at Auckland. It would appear that none of the preservatives employed has altogether prevented the attacks of marine borers, though in some instances the specimens have shown considerable powers of resistance.

It was stated in the previous annual report that in consequence of defects found in a concrete building erected by the Admiralty and exposed to the action of sea-water, a thorough investigation of all similar structures controlled by the Admiralty had been agreed upon. The results of this inquiry are set forth in the present report. It would appear that in some cases considerable injury was found in the upper portions of certain of the jetties, especially on the underside of deck beams. In order to remedy these defects and to avoid similar imperfections in future, certain precautions are recommended for executing works in reinforced concrete that are to be exposed in the sea or in the neighbourhood of high-water mark. A paper on the disintegration of cement in sea-water, contributed to the American Society of Civil Engineers by Messrs. Attwood and

Johnson, forms the subject of an abstract in the present volume. Dr. Ternent Cooke, who had been requested by the Harbour Board of South Australia to examine certain samples of decayed concrete prepared for a partially constructed breakwater, recently published an article on the subject, of which an abstract has been prepared for the volume. He states that it would appear from the chemical examination that organic matter from beds of decaying seaweed permeated the outer layers of the concrete and caused disintegration. The lime was then leached out and the superficial layers of the concrete were gradually decomposed.

The Department of Scientific and Industrial Research having intimated that its grants in future must be conditional on half of the expenditure being hereafter met from other sources, a number of Port and Dock Authorities were invited to contribute to a fund for five years. A very gratifying response was made to this appeal and a sum of 738l was received during the past year. A considerable portion of this total has been promised for a series of years.

Huygens' Discovery of Saturn's Ring.

Œuvres complètes de Christiaan Huygens Publiées par la Société Hollandaise des Sciences. Tome Quinzième: Observations astronomiques, système de Saturne, travaux astronomiques, 1658-1666. Pp. iv+619. (La Haye: Martinus Nijhoff, 1925.) n p

AFTER an interval of nearly five years (vol. 14 was reviewed in *NATURE*, vol. 107, p. 4) another instalment of this magnificent edition of the works of Huygens has made its appearance. It contains his astronomical observations and his publications on Saturn. Unfortunately the manuscripts recording the observations (1657-1694) are far from being complete. The chief source is a MS. called "K," in which Huygens evidently intended to copy all his observations from the originals. But in some cases the original records are not now extant, while there are signs that some of the records in still existing MSS., which have been copied into "K," are not themselves originals. In particular a "parvus libellus" containing observations earlier than December 1657 is lost; but the letters of Huygens and his book on Saturn have enabled the editors to draw up a supplementary list for the years 1655-1690. There were, however, long periods of almost complete inactivity as regards observing, due probably to ill-health or other work, although remarks found here and there in his letters show that Huygens had not very much sympathy with enthusiastic observers like Hevelius or Cassini. During his long residence in Paris, he observed occasionally at the king's library or at the observatory.

The telescope with which Huygens found the Saturnian satellite, now known as Titan, and the true explanation of the strange appearance of Saturn, had a focal length of about 11 feet, an object glass of 2.7 inches aperture (still preserved at Utrecht), and magnified 50 times. It was only in use for about a year, and was then superseded by another of about 23 feet f.l. and 4 inch o.g., made by Huygens and his brother Constantin, while others of about the same size were also made and used. In 1682, after his final return from Paris, Huygens made and tried to work with enormously long telescopes, but like everybody else found them too difficult to manage. Most of the glasses were kept together until 1754, when they were sold by auction and scattered. Seventeen of them can still be identified, of which three belong to the Royal Society, while the rest are at Leyden or Utrecht; but only five were made by Christian Huygens, the rest by his brother.

The observations printed in this volume fill 109 pages, and are illustrated by facsimile copies of Huygens' sketches. Nearly all of them are studies of the planets and their surface markings, and naturally most of them refer to Saturn. So early as 1659, Huygens considered it very probable that Mars rotated in about 24 hours. How some of his sketches have turned out to be very valuable for the exact determination of the period of rotation of Mars, is well known. He made attempts to measure the diameters of the planets in various ways, by comparing them with the breadth of a lamella at the focus or by an arrangement similar to W. Herschel's lamp-micrometer. But his search for satellites to the planets turned out to be of more value, as on March 25, 1655, he discovered a satellite of Saturn (Titan), the first satellite found since Galileo announced that Jupiter is accompanied by four satellites. The discovery was published in a small pamphlet of a few pages ("De Saturni Luna observatio nova"), which has now become so extremely rare (if it exists anywhere) that the editors have had to reprint it from the old edition of Huygens' "Opera Varia" (1724).

The fact that the satellite moved in a plane passing through the mysterious "handles" of Saturn, confirmed Huygens in the belief which he reached in the winter of 1655-1656, that these strange and variable appearances were due to a very thin, broad, plane ring surrounding the planet but detached from it. After the manner of those days, he announced his discovery in an anagram at the end of the pamphlet on the satellite, "in order that if any one thinks he has found the same thing, he will have time to announce it, so that it may not be said that he has borrowed it from us or we from him." The challenge was accepted by three people. by Hevelius, who thought that

Saturn was a spheroid to the ends of which were attached two handles; by Roberval, who assumed the planet to be a sphere surrounded by vapour except at the poles; by Hodierna, who believed Saturn to be shaped like an egg, with two non-luminous spots near the ends of the longest axis. In his book "Systema Saturnium" (1659) Huygens did not find it difficult to show how impossible it was to account for the varied appearances of Saturn by any of these hypotheses, while he showed in detail how well his own theory agreed with all the observations made during the fifty years elapsed since the invention of the telescope. But a determined attack on the theory was made in 1660 by Eustachio Divini, whose little book on the subject was known to be inspired by the Jesuit Honorato Fabri. As it was difficult of access to people in the Netherlands, Huygens reprinted the whole of Divini's attack in the reply which he published in the same year; and some years after he had the satisfaction to learn that Fabri had recognised the truth of the ring-theory.

In addition to the above-mentioned writings, the volume under review contains a number of appendices to them, extracted from Huygens' notebooks, and dealing with various minor astronomical problems. Among these may be mentioned an approximate determination of the orbit of a satellite of Saturn from two observations, occasioned by Cassini's discovery of Iapetus and Rhea.

By the many hitherto unpublished memoranda, by the valuable, detailed introductions, by the French translations of the texts of the books published by Huygens himself (no doubt welcome to many readers), and last, but not least, by the beautiful paper and print, this edition forms a monument worthy of the great Dutch astronomer.

J. L. E. D.

Guy Patin and his Times.

Guy Patin and the Medical Profession in Paris in the XVIIIth Century. By Dr. Francis R. Packard. Pp. xxii + 334 + 10 plates. (London: Oxford University Press, 1925.) 18s. net.

THE present volume by Dr. Francis Packard, whose "Life and Times of Ambroise Paré (1510-1590)" was noticed in our columns on March 3, 1923, p. 281, has been reprinted with additions from the "Annals of Medical History," of which he is the editor. The work is divided into nine chapters, commencing with a historical foreword which contains an account of contemporary politics, the later chapters dealing with Patin's education, his home life and literary interests, his opposition to cinchona and antimony, and his relations to the surgeons, barber surgeons and apothecaries. A special chapter is devoted to a description

of the Paris medical faculty in which Patin's life interest was centred. "No praise," says Dr. Packard, "was too fulsome for those who furthered its cause and no abuse too savage for those who dared to attack it." Of particular interest are the pages concerned with Patin's relations to Molière, his controversy with Théophile Renaudot, the gazetteer and quack, and his quarrel with the physicians of Montpellier.

Guy Patin was born in 1601 at a village in Picardy, graduated in medicine at Paris in 1627, was elected dean of the faculty of medicine in 1650, and died in 1672, so that his active life covered the greater part of the seventeenth century. The historic value of his letters, on which his fame rests, has been impugned by such critics as Bayle and Voltaire, but Dr. Packard rightly maintains that as pictures of the life of the day they are invaluable. It must be remembered that they were never intended for publication.

Patin was an upholder of the old Greek medicine as represented by Hippocrates and Galen, and a bitter opponent of the new chemical remedies which had been introduced by Basil Valentine, Paracelsus, van Helmont, De Mayerne, and others. Like most of his contemporaries, Patin was firmly convinced of the value of copious bloodletting and free purgation in diseases of all kinds. "There is no remedy in the world," he said, "which works as many miracles as bleeding."

Dr. Packard points out that though Patin never became in the strict sense of the term one of the physicians to the Court, his letters are full of references to medical matters connected with the Court and of tales of physicians honoured by the king.

Patin's scholarly tendencies are illustrated not only by his interest in the history and literature of his profession, but also by his lively concern in general literature, as shown by the allusions in his letters to new editions of Vossius, Lipsius, Casaubon, Scaliger, Grotius, and so on.

The work is illustrated by contemporary portraits of Guy Patin, his son Charles Patin, professor of medicine at Padua, of whom Voltaire said that "his works were read by scholars, while his father's letters were read by the idle," Cardinal de Richelieu, Cardinal Mazarin, Jean Riolan the Younger, Gabriel Naudé, the librarian of Cardinal Mazarin and author of a well-known book on the history of magic, and François Guénault, physician to Louis XIII. and, owing to his advocacy of antimony, one of the men whom Patin most detested. In the bibliography which is appended, special attention is given to the articles by Chereau, and the editions of the letters published by Pierre Pic and Paul Triaire.

Dr. Packard's book is a scholarly achievement, written in an attractive style, and gives an admirable picture of French medicine in the seventeenth century.

Our Bookshelf.

Die Süsswasserflora Deutschlands, Oesterreichs und der Schweiz. Herausgegeben von Prof. Dr. A. Pascher. (Jena: Gustav Fischer, 1913-1925.)

THE series of volumes comprised in Pascher's "Süsswasserflora" first began to appear in 1913 and is now rapidly approaching completion. Those so far published deal with the Flagellatæ, the Isokontæ (apart from Volvocales and Desmidiaceæ), the Bacillariales, Heterokontæ, Phæophyceæ, Rhodophyceæ, Charales, and Bryophyta. The work deserves to be more widely known among those interested in the study of freshwater Algæ, for since each volume is compiled by a specialist on the particular group, it usually embodies the results of critical work and is strictly up-to-date. It is far more than a popular summary of what is known. At the same time, keys for the determination of genera and species are numerous and as a rule carefully prepared, so that even a relative novice is put in the position of being able to identify common forms both speedily and easily.

As with all such collective publications, the treatment is somewhat unequal. Perhaps the most disappointing was the volume on Zygnematales by Borge, which, both as regards text and illustration, was altogether too scanty. On the whole, however, one can have nothing but praise for the care that has been bestowed upon the text, whilst the majority of the volumes are excellently illustrated, nearly every species being figured. Of particular value are the early volumes on Flagellatæ by Pascher and that dealing with Heterokontæ and the Red and Brown Algæ just published, which contain a mass of information here collected together for the first time.

Although ostensibly a freshwater flora of Central Europe, several of the algal groups are treated almost *in extenso*, all the genera and a great majority of the species being mentioned, even such as are at present only known from regions quite remote from Central Europe. In this respect, however, there appears to be no uniform plan, and the result is somewhat incongruous. Especially in some of the volumes more care might have been expended on the preparation of the index, which is of special importance in a taxonomic work. The price of the different volumes (averaging about four shillings) is very reasonable.

As the above was passing through the press, a thick volume on Cyanophyceæ by Geitler has been published. Algologists will welcome the detailed systematic treatment of this difficult group. The only defect is a tendency to multiply genera rather unnecessarily, whilst the introductory matter is based on a somewhat one-sided consideration of the literature.

F. E. FRITCH.

Biology and Human Life. By Benjamin C. Gruenberg. Pp. xiv + 592 + xi. (Boston, New York and London: Ginn and Co., 1925.) 7s. 6d. net.

IN Great Britain, biology is taught in schools, usually only in secondary schools, mainly from the examination point of view, to pupils who intend to pursue the subject further at a university or are preparing for a medical career. The majority of pupils, and particularly those in elementary schools, receive little if any

instruction in biology. The author of this book is convinced of the importance of a knowledge of biology to every member of the community, and no biologist at least would controvert his statement that "boys and girls who look forward to an early entrance upon occupational activities and the responsibilities of earning and spending money have as much need for the study of biology as have those who plan to go to college or the professional schools." This book is designed to meet this pressing need, and, if somewhat novel in its treatment of the subject, is so planned as to make it a living and vital one by special emphasis on the applications of biology to human affairs at all points.

After a brief introduction, all too brief we fear, to general biology, the main part of the book is divided into two sections headed the Biology of Health and the Biology of Wealth. In the first of these sections the author gives what is practically an introduction to human physiology, public health, hygiene, and the biology of disease, treating man first as an individual and then as a member of the community. The second section is a short survey of the field of economic zoology and botany with special reference to those animals and plants which are of importance to the general economics of the human race. The book is written in an almost breezy style, and the interest of both pupil and teacher constantly stimulated by questions designed to emphasise or enlarge on the special points of each chapter. The general plan of the book can be recommended as a good one for use by teachers in elementary schools, for, presented in this way, the pupil cannot fail to realise the fundamental importance of biology to himself personally and individually, and consequently to every member of the community in which he lives.

Geology in its Relation to Landscape. By Prof. Junius Henderson. Pp. vii + 152 + 30 plates. (Boston, Mass.: The Stratford Co., 1925.) 2.50 dollars.

PROF. HENDERSON has enriched the literature of a picturesque subject by his attractive and almost romantic treatment. His book is informal, and though it will teach the geologist nothing new, it is of the inspiring kind that, falling into the right hands, will make new geologists. Any one of ordinary education, and an interest in scenery, will be able to follow these pages with ease and pleasure. The book is beautifully printed and illustrated, and the author amplifies his own literary gifts with numerous poetical quotations.

After five introductory chapters dealing with geological processes and structures, there follow longer chapters devoted in turn to rivers, waterfalls, lakes, the oceans, glaciers, mountains, and volcanoes. The final chapters are concerned with geology in relation to vegetation, animal life and civilisation, and these will perhaps be of most interest to readers already familiar with the physical evolution of landscape, for they show, with many a light and happy touch, how geological factors have controlled man's environment, and how they have been turned to his service. The book may be warmly recommended, in particular to teachers and students of geography, and in general to the wider public who find in scenery one of the leading attractions of a holiday.

The National Physical Laboratory. Collected Researches. Vol. 18, 1924. Pp. iv + 456. (London: H.M. Stationery Office, 1925.) 17s. 6d. net.

THIS volume is a reprint of twenty-one electrical papers which have issued from the National Physical Laboratory and been published in the proceedings of scientific societies or in the technical press during the years 1919-24. About half of them deal with problems which have arisen in some branch of the electrical industry, and the other half with improvements in the methods and instruments used in standard measurements. In the first category are investigations on the magnetic properties of silicon irons, the behaviour of intervalve transformers, the electrical resistance of overlapping joints in conductors, the rating of cables for intermittent loads, the improvement of carbons for searchlights, and the use of a cube whitened inside in the photometry of electric lights. In the latter group are investigations of new methods of calculating self and mutual inductances of coils; on the effects of eddy currents on measuring instruments, on the best methods of measuring the intensities of radio signals, on the properties of the triode valve, on the measurement of the earth's field by an electrical method, and on an electrostatic voltmeter for accurate measurement. Many of these investigations have been carried out for Government Departments the consent of which has had to be obtained before the results could be made public. The whole add to the credit of the Laboratory and its staff, and make one wonder how the electrical industry managed to advance at all in the days before the National Physical Laboratory came into existence.

The Nature of Enzyme Action. By Sir W. M. Bayliss. (Monographs on Biochemistry.) Fifth edition. Pp. viii + 200. (London: Longmans, Green and Co., 1925.) 9s. net.

THE fact that the monograph has reached its fifth edition shows that it occupies a definite place in modern biochemical literature, and it seems almost superfluous to state that it presents an excellent account of our knowledge of the nature of enzyme action. Its very excellence, however, makes us realise the loss which science has suffered in the death of Sir William Bayliss. The manuscript was brought up-to-date by the author before he was overtaken by his illness, and has been prepared for the press by his son, without any attempt to include the work of the last two years. The earlier chapters consider the physical and chemical properties of enzymes and their methods of preparation and investigation, the central connecting thread being that enzymes act in the same way as catalysts of known chemical constitution. After a chapter on the velocity of reaction, the author passes on to consider their mode of action, and shows himself to be an advocate of the view that enzymes act by adsorption of their substrates so that the reacting substances are brought into a state favourable for the rapid progress of the reaction; the arguments for this view are fully and clearly presented. In succeeding chapters, co-enzymes, antienzymes, and zymogens are considered, and a short account is given of oxidation processes: doubt is thrown upon the existence of a number of so-called "antienzymes." The work is concluded by an extensive bibliography.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Blindness of Cave-Animals.

PROF. MACBRIDE has contributed a chapter to a volume of essays published by Messrs. Blackie and Son which professes to treat of evolution "in the light of modern knowledge." Prof. MacBride's chapter is headed "Zoology" and sets forth a statement of older as well as novel observations and experiments made by other workers which lead him to conclude that the evolution of organic form in plants and animals has been caused—mainly if not entirely—by "use and disuse," as held by Lamarck—not in the light of modern knowledge—but more than one hundred years ago.

Prof. MacBride cites the experiments and records of others. Consequently his paper has not the significance it would have, were he relating his own researches. I submit that judgment should be suspended with regard to Kammerer's results as to salamanders and toads until they have been repeated: for as Mr. J. B. S. Haldane points out (in his valuable article, "The Causes of Evolution," in the Annual of the Rationalist Press Association, 1926, p. 56), in the majority of similar cases brought forward in the past, critical repetition has proved fatal to the conclusions drawn from them.

It is especially in regard to the reduction of the eyes of certain cave-dwelling animals to vestiges, a process accepted by Prof. MacBride (as by Darwin in 1859) as due to the "disuse" of these organs consequent upon the absence of light from their environment, that I wish to make some criticism. Certain cave-animals are known, as he states, to be allied closely to normal species which live outside the caves at no great distance. The cave species living in the dark are either devoid of eyes altogether or have their eyes reduced to vestiges. Darwin, as stated by Prof. MacBride, assumed that the eyes of animals living in darkness failed to grow to their proper size owing to lack of use, and that this diminution in size was heritable—in short, that the effects of disuse were inherited. Without more ado, Prof. MacBride accepts this conclusion, declaring that other explanations of this phenomenon, which he does not cite with one exception, were "amazing." The exception is Weismann's theory of "panmixia," which he discusses and rejects.

I wish now to point out two important defects in "the disuse theory" of blind cave-animals as stated by Prof. MacBride, which seem to me to render his position untenable.

(1) We have no record of experimental work showing that the eyes of animals bred in the dark are reduced in size as compared with the eyes of the same species bred in normal conditions. Nor have we any records of the exact changes, if any, in size or character of the various parts of the eye when an individual animal or a series of successive generations has been born and reared in the dark as an experiment. No such experiment has been recorded in regard to any one species of vertebrate, nor in regard to any insect, crustacean, mollusc, or jelly-fish—in each of which peculiar and elaborately constructed eyes are found. Nor, again, do we possess any extensive and well-considered account of "congenital defects" of the visual organs in any one animal or in representative animals from different classes to which

we can refer for comparison, except in the records of human pathology. Again, our knowledge is very defective, especially as to microscopic details, in regard to the actual condition of the eye in blind cave-animals, as also in regard to that of the eye of blind deep-sea fishes and crustacea. Darwin seems to have regarded diminution in the size of the eye as the important matter; but such things as the condition of the retina and of the lens-like transparent structures, and again of focussing and light-screening parts of the eye, must each have its own decisive importance.

The absence of experiment in the matter has recently to some extent been removed by the American observer Payne (quoted by Mr. J. B. S. Haldane, *loc. cit.*). "Mr. Payne bred *Drosophila*, a fly which tends to move towards light, for seventy-five generations in darkness. At the end of that time no visible change had occurred in the eyes, and when 1000 such flies were given the opportunity of moving towards a light no change was found from the normal either in the proportion which moved within a minute, or in the average rate at which they moved." The majority of the experiments on the inheritance of the effects of use and disuse lead, writes Mr. Haldane, to equally negative results. Apparently the American observers have not yet had time to go into the question of the production of any departure from the normal in the minute structure of the eye as distinct from its physiological activity. In the actual state of knowledge we are not warranted in assuming that "darkness-disuse" produces a permanent change of structure in the disused eye.

(2) I now come to my second objection to Prof. MacBride's assumption of the truth of the disuse-theory of the blindness of cave-animals. It is this: we are not compelled to assume the inheritance of the effects of disuse in this case as the only probable explanation of the facts, since the theory of natural selection sufficiently accounts for the production of blind species of cave animals. Mr. Darwin in co-operation with Mr. Wollaston ("Origin of Species," chapter v.) pointed out that the wingless beetles of Madeira owe their relatively great abundance there (and in other sea-girt islands) to the fact that beetles with normal wings and normal powers of flight are continually caught when flying by the heavy winds and blown out to sea and destroyed. Those individuals with congenitally defective wings—a defect known to occur normally in a certain proportion of beetles of various species—will lie close to the ground and thus escape the fate of those caught by the winds when flying and consequently blown to sea. Thus by natural selection the beetles with defective wings will be favoured and preserved in the island so as to breed their like and establish wingless races or species. Darwin did not himself apply this parallel to the case of blind animals in caves. But many years ago, in the course of a discussion in one of the reviews, on the probable history of blind animals in caves (and in the deep sea), I ventured to do so. As it seems to have escaped attention in the interval, I submit this suggestion for consideration at the present juncture. Supposing, whether by gradual wandering into caverns (many of which are of vast extent) or swept in by swollen streams or floods, a considerable population of animals become the more or less well-established occupants of caverns. Then there will always be a tendency for those possessing normal eyes to follow up any gleams of light which they may encounter in their exploratory wanderings. They will follow up the light to some passage by which it enters the cavern, and gradually year by year escape in considerable numbers to the sun-lit surface. Those

with defective eyes will not thus escape, but remain and breed in the cave, establishing a series of races or species with defective eyes. The tendency of this process will be to favour the escape of those in every generation with normal eyes or with definite though feeble light-sensibility. These will include many born in the cave from parents with partially defective eyes. Thus constantly, year by year, the cave-dwelling blind forms will become purified from admixture with those possessing eyes of even minimal efficiency as organs of vision. The blind races remaining in the cave will develop in some cases organs of touch of special efficiency, and become established as blind cave-dwelling species.

No doubt further details as to the structure and functional qualities of the eyes of cave-dwelling animals are needed for fuller consideration of this matter, as well as an understanding of the malformations and congenital variations of eyes and of the essential optical mechanisms of eyes of all kinds. It seems to be a legitimate hypothesis that the modification of the organs of vision and their accessory parts in deep-sea fishes and deep-sea crustacea is brought about by photo-taxis migration similar to that affecting cave-dwellers, though at present this is merely a suggestion. The very curious modifications of structure in the eye-stalks of several deep-sea decapod crustaceans which have lost the power of vision have been described and figured by G. O. Sars. I have described and figured such modifications in species of the deep-sea crab, *Cymonomus*, and reproduced for comparison some of the figures given by Sars (see "On the modification of the eye peduncles in crabs of the genus *Cymonomus*," in *Quart. Journal Microsc. Sci.*, vol. 47, p. 439, and Plates 33 and 34). Histological details in regard to the changed and dwindled organs of sight in deep-sea animals have not yet been ascertained, nor is the process of change and degeneration as yet interpreted in relation to known morphological generalisations.

E. RAY LANKESTER.

November 1.

Choice of the Striking Point in the Pianoforte.

In his interesting letter dealing with the above subject in *NATURE* for October 17, p. 575, Mr. R. N. Ghosh appears to suggest that there is disagreement between S. K. Datta's results and my own. This apparent disagreement is due to a difference in the relative masses of the hammers used. Quantitative experimental results so far published are:

Position of Impact (a/l) giving Maximum Amplitude of Fundamental.	Relative Mass of Hammer (m/M)
$1/4$	$1/2.53$
$1/5.56$	$1/1.18$
$1/6.82$	1.0
$1/7$	1.687 (Datta)
$1/28.6$	9.625

where a = distance of struck point from nearer bridge, l = length of string, m = "mass" of hammer, and M = mass of string. From this table it is clear that as the relative mass of the hammer increases, the position of the impact giving the greatest maximum amplitude of the fundamental moves nearer to the bridge. There are other maxima and minima which become fewer and less pronounced as the relative mass of

the hammer is reduced, until for the mass ratio $m/M = 1/2.53$ there is only one minimum and two maxima for the whole length of the string. The maxima are greater and the minima are less the nearer they are to a bridge. Reference is also made to the work of G. H. Berry, but in this case the mass of the hammer is not given.

The statement that the duration of the impact is about *one-half* the fundamental period of the string when the amplitude of the fundamental is a maximum would appear to be true only for some particular mass ratio. S. K. Datta (*Ind. Ass. Proc.*, vol. 8, p. 116, 1923) finds a duration of nearly *three-quarters* the period of the string for a maximum when $m/M = 1.687$. The treatment of the problem from the point of view of the duration of the impact presents great difficulties, for on the modern general theories this quantity cannot be derived analytically. Moreover, Prof. Raman has theoretically shown the interesting fact that the duration of the impact grows in a *fluctuating* manner as the position of the impact moves from a bridge to the mid-point of the string. This phenomenon has been verified experimentally by his own work and also incidentally by some of mine, where the conditions and method of measurement were quite different.

Influence of Energy Absorbed—The problem may be examined from another point of view. In using an instrument like the violin or the organ, energy is almost continuously given to the system so long as sound is needed, but whatever energy is to be given to a note of the piano has to be communicated in, say, $1/50$ to $1/5000$ sec., depending on the pitch of the note. It therefore seems of interest to examine the influence upon the energy given up to the string by the hammer, of such factors as the position of the impact, the mass and speed of the hammer, the nature of the hammer face, and the stiffness and tension of the string. The experimental work for this investigation is now being carried out at University College, Nottingham, by Mr. H. E. Beckett. We are able by the method in use to make absolute measurements correct to within perhaps 1 per cent of the energy absorbed, and it is hoped to have the work ready for publication by the end of the year.

There are several misprints in Mr. Ghosh's letter. Datta should read Datta; $1/91$ should read $1/7$ in the first place, and $1/9$ elsewhere where l = length of string. Also $1/71$ should read $1/7$.

The Zeeman Effect on the Helium Bands.

PROF. NICHOLSON has recently (*Phil. Mag.*, vol. 50, p. 650, 1925) pointed out the importance of investigating the effect of a magnetic field on the so-called "doublet bands" of helium. He gives reasons for expecting that these particular bands should be subject to a Zeeman effect of the same general character as in the case of atomic line series. Apart from this, such an investigation would be amply justified by the singularly interesting nature of these bands, both as regards their distribution in the spectrum according to a line-series law and the details of their structure (see Curtis and Long, *Roy. Soc. Proc. A*, vol. 108, p. 513, 1925). It happens that we had already completed the experimental part of such an investigation when Prof. Nicholson's paper appeared, and as the final results will not be ready for publication for some months, it may be of interest to describe their salient features at once.

A large electromagnet and the 7 ft. 9 in. concave grating in the Physics Branch of the Artillery College were very kindly placed at our disposal by Prof. Andrade, and helium tubes of design suitable for end-on observation in a direction perpendicular to the magnetic field were specially prepared at King's College. Fields up to 20,000 gauss were employed, and plates were taken simultaneously in the grating third order and in a Hilger constant deviation spectrograph in conjunction with a Fabry-Perot 1 cm. etalon. Only the strongest band, that near $\lambda 4650$, which is the first member of the Rydberg band-series, has been studied so far, although many other band lines between $\lambda 4380$ and 4720 appear on the plates, and it is hoped to extend the investigation to the second member of the Rydberg series, the band near $\lambda 3680$.

The band-lines exhibit no Zeeman effect of a "normal" order of magnitude except in the case of the first member of each of the three branches constituting the band, namely, $Q(1)$, $R'(1)$ and $P(2)$. These are broadened but not resolved into components, as are the neighbouring He lines $\lambda 4713$, 4471 , and 4388 , even when examined through a polarising prism; this appearance may, of course, be due to a structure more complex than the resolving power available is capable of revealing. It is noteworthy, however, that in $Q(1)$ and in $P(2)$ the component corresponding to vibrations parallel to the field is considerably broader than the "perpendicular" component, whereas the reverse is the case both in the "normal" and "anomalous" Zeeman effects in series lines. In the case of $R'(1)$ the difference is much less marked and is probably opposite in direction; that is, the "perpendicular" component is slightly the broader.

The magnitude of the effect is greatest in $Q(1)$, the extreme width of which in a field of about 20,000 gauss corresponds to a separation (presuming it to be an unresolved doublet) of about $0.27 \text{ \AA.U.}$, that is, roughly two-thirds of the "normal" Zeeman effect, which is shown by the nearest He line $\lambda 4713$ ($0.40 \text{ \AA.U.}$). It is appreciably smaller in $P(2)$ and in $R'(1)$. In each branch the effect diminishes rapidly with increase of order number of the lines, that is, rotational quantum number, but it is still appreciable on the interferometer plates down to the fifth or sixth member of each branch, where it amounts to a few hundredths of an Angstrom only. It is thus clear that the effect of the magnetic field on the molecule is largely determined by the state of rotation of the latter, being relatively small for the higher speeds of rotation.

It may be that these results, if of general validity, will be of use in the analysis of band spectra. Thus, for example, in the helium band spectrum itself there are, in the region covered by our present plates, a number of lines not yet arranged in series, a few of which show pronounced Zeeman effects of the nature described above, and would therefore be expected to be the first members of their branches. Similar considerations may possibly be helpful in the analysis of the secondary spectrum of hydrogen. Evidently it cannot be assumed that a line showing an appreciable Zeeman effect must belong to a line-series rather than to a band-series, or that an affected line is *ipso facto* disqualified from association with unaffected lines. In this connexion it would appear desirable that the Zeeman effect on the latter spectrum should be investigated over a much wider range of wave-lengths than was attempted by Dufour (*Jour de Phys.*, 8, p. 258, 1909).

Birth-Control among the New Zealand Maori.

IN NATURE of October 17, p. 575, Miss Ettie A. Rout has made some interesting remarks concerning sexual life and birth-control among the Maori of New Zealand. Anthropologists and students of social hygiene will be grateful to her for directing attention to facts which have previously received little notice—the value attached by the native to physical fitness, its importance as one of the criteria of marriage, and the consequent influence of this ideal upon the general physique of the race. At the same time, it should be recognised that such important social institutions as betrothal, marriage and family life were not regulated by physical fitness alone, as Miss Rout seems to imply. Despite my sympathy with her views, I cannot help wondering whether these have not unconsciously coloured her statements about Maori life.

We are told, for example, "before betrothal occurred there was medical examination of both parties by the parents of the young couple and by the doctors." That this was a pre-European practice is very much open to doubt. In any event, from reasons of personal friendship of the parents, or tribal policy, betrothal quite often took place in early childhood, even soon after birth. Preliminary "medical examination" at such a stage, however, would scarcely appear to possess any great virtue in establishing fitness for reproduction. Also, if Miss Rout's statement is to be taken as valid, it must occasionally have been a matter of some delicacy, inasmuch as we know that infants were sometimes *taumau* (betrothed) before birth with the expectation that they would later turn out to be of different sexes!

Now as to "doctors." To elevate the old-time *tohunga* (priestly expert)—who is apparently the person meant—to the style and dignity of a *doctor* is, quite unintentionally no doubt, to give to European readers a highly exaggerated notion of the medical knowledge and capabilities of these folk, who were far more learned in magical practices than in physiology or pathology.

Before marriage a great amount of sexual freedom was allowed to the young people among the Maori, but after marriage was concluded strict fidelity was demanded. In general, the marriage bond was highly respected. Liaisons, of course, occurred, but adultery was never condoned; on its discovery a *taua miru* or plundering party which stripped the offender of property, was the result, while for an erring wife death was by no means a rare punishment. With these indisputable facts at disposal, it is difficult to see why Miss Rout has come to the conclusion that a married woman was allowed to have her children "by whatever father she desired." Again, it is stated that a woman "if she preferred some other man to become the father of her child might allege that this lover's spirit visited her" and that this was "a recognised polite fiction." It is to be feared that a Maori of the old school would indeed label it a fiction, though not of a very polite order. Moreover, to the children of any illicit unions a great stigma attached—the term *pororo* (bastard) was a perpetual shame to the person concerned; such an illegitimate child might be killed by the woman's husband or father, and women resorted to abortion rather than give birth to such. It is somewhat difficult, then, to conjure up Miss Rout's picture of a Maori warrior, humbly acquiescent in his wife's intercourse with another man, his sole reaction being one of self-pity because she considered her paramour a better potential father for her offspring.

In her selection of a husband, the Maori woman was drawn by his handsome appearance, his excellence in the *haka* (posture dance), his powers in war, his skill as a food provider, rather than by exalted notions

as to his worthiness for the high office of producing children by her. In brief, marriage and family relations among the Maori were determined by many other social factors besides that of physical fitness.

In substantiation of my remarks I refer the reader to various papers by Best, Gudgeon and Dr. Goldie in the Transactions of the New Zealand Institute and Polynesian Journal, besides the writings of S Percy Smith, Judge Wilson and James Cowan, whose statements are fully confirmed by my personal knowledge of the natives in the Waikato and the Urewera districts.

Greenland or Polar Front?

No doubt the gravitational outflow of air from the ice-dome of Greenland is the source of a good deal of cold air to the cyclones of the North Atlantic, as upheld by Prof. Hobbs in his paper to the Geography Section of the British Association at Southampton, and printed in NATURE for October 3. But why, many meteorologists will ask, should he go to the extreme length, implied in the article, of disregarding other sources of cold air for the Bjerknesian mechanism of cyclonic circulation? Can Prof. Hobbs seriously intend that the sloping ice plateau of Greenland, so very limited by comparison in area, can supply all, or nearly all, the cold air for the cyclonic activity of the entire northern hemisphere, Pacific, as well as Atlantic, centre? The idea seems incompatible with the scale of operations, and the facts quoted by Prof. Hobbs himself, if rightly interpreted, show that it really is incompatible. Of course, if Greenland were denuded down to sea-level one spring in the mechanism would be removed, and doubtless important modifications would be imposed upon the characteristic circulation of the North Atlantic Ocean, for in the last resort the details of the atmospheric circulation and the perpetual transpositions of the Polar Front are dominated by geographical configuration, or in other words by continentality and oceanity relationships. But the facts do not warrant the contention that Greenland, in a sense an accidental feature in the circumpolar configuration, is the mainspring of the circulation in the northern hemisphere.

Take the very fact adduced by Prof. Hobbs of the mean barometric pressure over the north polar basin, as established by the late Prof. Mohn, not being inordinately high. This is of little consequence. What is of consequence is the fact that the mean polar pressure is higher than the Atlantic minimum near Iceland and the Pacific minimum in the Bering Sea. This mean or average distribution of pressure means, when translated into *day to day changes*, that just as warm, humid equatorial air commonly drifts northward, so will cold dry polar air frequently drain southward irrespective whether Greenland is there to reinforce the process or not. This statement is simply in accord with the known laws of wind and pressure distribution, and every modern weather forecaster is familiar with true polar air on his day-to-day charts.

Then we are told that the air of the polar basin "where rain and fog are common" is not of the right quality to form discontinuities and interact with the equatorial currents in accordance with the admitted Bjerknesian process. Yet what could be farther from the truth than this statement? The north polar basin or Arctic Ocean is in the winter months one of the three "poles of cold" in the northern hemisphere, with a

mean January temperature round the Pole, according to Mohn, of -40° F. or C., the other two being north-east Siberia and the Greenland ice-dome itself. This extremity of cold over the inner polar basin necessarily implies dry air, and all polar explorers have testified to the *sparkling dry* atmosphere of the long polar night. The rain and fog occur temporarily and locally in the thaw weather of summer (never in winter except occasionally near Spitsbergen where there is warm Atlantic water); but, even so, outflows of polar air are amply cold and dry enough to interact with the equatorial air to supply the milder cyclonic activity of summer.

It must not be forgotten, further, that in winter the frost-bound continents can constitute additional reservoirs of "polar" air; and this fact is one of the chief, if not the chief, cause of the terrific state of turmoil which the North Atlantic Ocean is commonly in during the months of December and January—when supplies of "polar" air, to interact with warm damp Atlantic equatorial air, may be drawn not only from the North Pole and Greenland, but also from North America and Europe.

Finally, it should be observed that "glacial anti-cyclones" of the Greenland or Antarctica type are really disembodied systems, and it would surely be better to speak of gravitational cataracts of cold air. But that is another story. L. C. W. BONACINA.

Relation of Language to Physiological Stimuli.

In examining a vocabulary of more than a thousand words (compiled from upwards of sixty languages) bearing directly or indirectly on the sense of smell, it becomes apparent how many words are vocalisations and articulations of simple reactions to olfactory stimuli. A few examples must suffice here. [ch = ch in *loch*, ch = tch.]

A common reaction to odours would be the syllables like *bu*, *pu*, *fu*, *hu*, *su*, *tu*, etc., expressing the idea of blowing, puffing, budding, bulging, etc., and we have, e.g. Persian *bu*, odour; Efik *bu*, to rot, and *bu-bere*, to blaze; Circassian *buà gim*, sense of smell; Efate *busi*, to blow; Malay *busuk*, putrid; Chinook *pu-piu*, to stink, also skunk; Tibetan *po*, incense; Tahiti *puha* and Hawaiian *puki*, to blow; Samoan *puaoa*, mist; Inca (Quichua) *puhuni*, to blow, *puhucuni*, to kindle, *hapuni*, to smoulder, *puhura*, feather, and *puyuu*, cloud; Melanesian *punu*, smoke; Japanese *punpun*, like a delicious perfume, Samoan *punapuna*, to ascend; Russian *puvchnut*, to puff, blaze, and *puch*, feather. We have the international expressions of disgust, e.g. *faugh*, *pfui*, *fi*, etc. We have *simus*, *fumus*, *foetid*, and so forth, the Efik word *fula*, to blow, Chinese *fu*, fragrance; Japanese *fuki*, to blow (*hanafuki* = handkerchief), and *shuki*, stench; Natick Indian *shuah*, to stink; Basque *su*, fire and nose; Latin *tus* and Gaelic *tus*, incense; Russian *tuman*, fog, Melanesian *tunga*, fire, Zulu *tunga*, smoke (cf. *dung*, *Dunger*, *tongue*, etc.); Basque *tusuri* and Tibetan *du*, devil; Ancient Egyptian *chua*, to rot; Chinese *cheu*, stink, and smoke; and Russian *chuyanne*, scenting, understanding. Of interest here, too, are the Tibetan *u*, breath, and Honorific Tibetan = head, Russian *um*, mind = reason; the Inca *uma*, head, and *umu*, priest, the German *Atem*, *Odem*, breath; *Odin*, and the sacred *OM*, Ancient Egyptian *utu*, flowers, unguent; Basque *usu*, pus; Micmac *un*, fog, etc.

Another natural vocal reaction to olfactory stimuli, and of course connected with breathing, is a combination of guttural and vowel sounds and words, perhaps sometimes vocalisation of hawking or vomiting. To

quote but a few examples we have the Danakil *haha*, air; Seneca *gahah*, wind, and *gaoh*, air (cf. *gas*); Tibetan *gak-pa*, to be choked, Inca *chahani*, to kindle; Persian *gand*, stink; Urdu *gandhak*, sulphur; Japanese *hana*, nose, flower, the first; the Ancient Egyptian *cha*, to enter, and *chen*, flowers; *Ka*, the eidolon or familiar; Gipsy *cannelo*, stinking, and *noh*, nose, Melanesian *guoko* and Eskimo *kenowk*, nose, Circassian *chassa*, to learn; Arabic *chassal*, sense of smell, Inca *chosni*, smoke, and *kumpi*, sweat, Chinook *hummi*, stunk (Ar. *shamm*, to smell, Russian, *shaman*, sorcerer; etc.); Inca, *chuncu*, stink; Yao *nunga*, smell; Suahili and Zulu *nuka*, Congo *nukana*, and Chinyanja *nunktsa*, to smell; Russian *nyuchal*, to smell (cf. *nauk*, science)

The significance of the combination of the nasal and guttural sounds in connexion with smell may be seen by means of the following, somewhat rough, expedient. Taking 100 words signifying *nose* from Asia, Europe, Africa, Australia, the South Sea Islands, and America, and analysing the sounds present, it was found that of the 235 consonants present, 102 were n, ng, h, k, ch, and q; 59 were s, z, sh, zh, j, tch, d, and t, 35 r and l, 20 b, p, f, v; and 19 m. Of the 224 vowel sounds represented 63 were u, w; 53 a, 47 i, y, 36 o, o, and 25 e, a. While this method does not commend itself to philologists, it may serve to indicate a new way of building up an international language, based on the physiological reactions to stimuli, and in any case affording food for thought and discussion. It must be borne in mind that the few examples quoted above do not necessarily indicate their ontogeny. Perhaps what has been said about the nose may suggest even a connexion with the Ankh, and may not the anchor perhaps suggest a nasal symbolism?

Could the Romans in Britain weld Iron?

INCREASING attention has, within the last few years, been devoted to Roman remains in Britain, and a great deal of interest centres round such metallic remains as have survived from this period. Iron was always manufactured by the so-called "direct" process, that is, iron ore was reduced with charcoal direct to the metal without the intermediate formation of pig iron. The method was very wasteful, and in the further working of the metal so much oxidation took place that frequently the whole of the metal disappeared, the finished article consisting almost entirely of the hard ferrosferic oxide, the remainder being slag or other impurity. This was the case with certain "iron" nails from the Roman villa at Folkestone which were forwarded to me by Mr S. E. Winbolt.

As the Roman method of heat treatment was so crude and resulted in so much oxidation, I have often wondered if it was possible for them to weld their iron. Through the kindness of Mr. Walter G. Klein, I have been able to examine specimens of Roman iron from the excavations at Richborough, and an account of these was laid before the autumn meeting of the Iron and Steel Institute by Mr. W. E. Thorneycroft and myself. One piece of iron, when sawn through, showed that it consisted of a bundle of about 8 rods which had apparently been hammered together to make them unite. But metal did not touch metal, for each rod was separated by a thick layer of impurity, containing 45.47 per cent. of iron and 24.54 per cent of insoluble material, mainly silica. The rods held together with surprising ten-

acity, but a heavy blow cracked the cementing material, when they readily fell apart.

An iron ring was examined from the same source, and we thought that this might indicate whether or not the Romans could weld. At first we thought we had a clue. There was a distinct crack visible under quite low magnification at one part of the ring. But on further grinding this disappeared and no further evidence of a weld was obtained. The ring might therefore have been made by driving a hole through a plate, for its external diameter was only 40 cm., the mean diameter of the metal being 0.75 cm.

A week or two ago I received from Mr Francis B. Andrews, secretary of the Birmingham Archaeological Society, a piece of Roman iron pipe from Uriconium. It was a ring of metal, not unlike a serviette ring, 4.3 cm in diameter and 1.5 cm deep. On grinding down it became evident that the ring had been made by bending over upon itself a piece of sheet iron and cementing or "soldering" the join with molten copper or copper alloy.

There has not yet been time to examine the specimen micrographically, or to determine the particular composition of the cupriferous "solder". A full description of these will, it is hoped, appear in due course.

Searching through the literature, I have been unable to find any reference to this kind of thing before, and it would be most interesting if any of the readers of NATURE could cite further examples.

One of the great difficulties of work of this kind lies in the fact that the antiquary naturally desires to preserve his "finds" and hesitates to allow objects of interest to be examined by any chemical or metallurgical process that may tend to destroy them. With this we all sympathise. Yet where specimens are not unique, but fairly common, it might be possible to hand some of these over to tried investigators in order that science might benefit by a further examination, even at the risk of spoiling for exhibition purposes these duplicated specimens.

My sincerest thanks are due to those gentlemen who have so generously placed at my disposal the material discussed in this note.

Weather Prediction from Observations of Cloudlets.

I do not think that the method described by Sir G. Archdall Reid in NATURE of November 7, p. 676, is at all of universal application. It certainly cannot be applied to cirro-cumulus; the cloudlets composing lenticular cirro-cumulus not only *may* wax at one end of the cloud and wane at the other, as mentioned by Sir G. Archdall Reid, but they always behave in this way. I do not think that any of the explanations he gives accounts for the phenomenon, but the point is not to account for it, but to decide whether the waxing or the waning of the cloudlets is to be taken account of in weather prediction. Again, a whole mass of cirro-cumulus cloudlets may form and disappear in a very short time, is the appearance or the disappearance to be reckoned with? The lower clouds seem to me to tell even more against the method, on almost every fine summer morning we may watch cloudlets waxing, but it by no means follows that rain will result, probably in nine cases out of ten it will not. I should imagine that there must be nearly a hundred days every year when the method is disproved by the waxing of cloudlets which will develop not into rain clouds, but into the cumulus of a fine day.

Stoner Hill, Petersfield, November 9.

Michel-Eugène Chevreul, 1786-1889.¹

By Prof. HENRY E. ARMSTRONG, F.R.S.

RECENTLY, in London, we celebrated the centenary of the discovery of benzene by Faraday and in so doing took occasion to proclaim Faraday's greatness as a chemist. The commemoration was remarkable, because it was held by the Royal Institution, where the discovery was made, in conjunction with three other associations: the Chemical Society, the Society of Chemical Industry and the Association of British Chemical Manufacturers. This was the first time these three bodies, which collectively represent all the interests of British chemistry, have shown themselves to be actuated by one purpose and have elected to work to a specific end, in harmonious, declared co-operation. In England, we regard the event as a happy presage of the union we have long sought to achieve—the union of our chemists into a single professional organisation.

Now, a further step is taken along the same path. I am charged by the Royal Society of London and the three bodies I have mentioned, which again act as one, with the honourable and most gratifying task of conveying to our French colleagues, their united warmest congratulations upon this occasion. We not only desire to join in paying homage to Chevreul's memory: we also desire both to carry on the work we began, with the powerful aid of French men of science, in London and to aid them in reminding their public of the inestimable value of genius and in enforcing upon the attention of the rising generation of students the value of the examples before them in the work of the famous men of the past.

The world of to-day is accustomed to take advantage of the work its leaders do for it, without in the least attempting to understand what leadership is and entails. Our need of leadership, the paucity of leaders, was never more obvious, perhaps never so great. We are too prone to think in terms of majorities—forgetting that evil may often, more easily than good, command a majority. We do not sufficiently realise how much the War has cost the nations in leadership. On such occasions as this, we do well to pose such problems before the public.

We have a remarkable series of English essays, too little read to-day, I fear, on "Hero-Worship," delivered by our great man of letters, Thomas Carlyle, the historian of the French Revolution. His heroes were: Odm and Mahomet; Dante and Shakespeare; Luther and Knox; Johnson, Rousseau and Burns; Cromwell and Napoleon: representing divinity, poet, priest, letters and king. Science was not considered: letters have yet to fathom its mystery, if indeed it be fathomable by the literary mind. Even Anatole France, though respectful, is fearful of us; he even goes so far as to say: "Our chemists and our professors of science are almost to a man anarchists." He probably failed to recognise, that the religion of the future, if indeed there be one, will be fashioned out of pure knowledge. Being, we are told, "liberated from religious belief, lacking the organ of superstition," he

was perhaps unable to realise that the true office of science is to create belief by destroying dogma: to govern by necessary commandments.

Meetings on such occasions as this serve to correct unjustified literary partiality and misreading of our character. We can rejoice in what Chevreul did for civilisation, not against it: he was a veritable torch-bearer: he not only made the torch a thing of beauty to the eye but also deprived it of all offence to the nose. In doing so, he liberated glycerol but it remained for Sobrero to convert this into an engine of war.

Were Carlyle writing to-day, he would perforce include science in his gallery of heroes. The choice of representatives would be difficult. Certainly, one of the first to consider would be Lavoisier, the greatest philosophic chemist of all time. Then would come Faraday, I think, especially on the grounds of his moral outlook. To France would fall another nomination, that of Pasteur, as a great humanitarian. Anatole France would never have classed us as ultimately dangerous had he studied such examples. It would have interested him to know that, in 1824, the celebrated home of Sir Walter Scott, at Abbotsford, was lit by oil-gas, made from material which his countryman Chevreul was the first to study, the "gas" from which Faraday, a year later, was to isolate benzene. Not to be outdone by the Church, at the recent celebration, in London, of Faraday's discovery, in the evening, at the banquet in the Hall of the Goldsmiths' Company, one of the private palaces of our City of London, no less a number was lit than 578 of the candles made possible by Chevreul's invention of 1825. In such manner was honour done to the coming of benzene, in such manner was the chemist's "open chain" connected with the "closed." The great hall in which we met is one of the few now illuminated in accordance with ancient custom—by burning oil-gas, *in situ*, as it is produced from Chevreul's candle with the aid of the "retort" patented by Cambacères in 1834. To-day, Chevreul and Faraday march arm in arm, illuminating the world—the one bearing the candle, the other the electric torch. Anatole France, doubtless, in his time, burnt many candles as midnight oil—how then could he call us anarchists, unless it were because of the support our work gave to his anticlericalism? Had it not been for the constitutional inability of the literary to understand the experimental mind, he must surely have treated us as the most lovable of brethren.

Working as chemists, Chevreul and Faraday between them, practically at the same time, laid the foundations of organic chemistry: Chevreul of its open or paraffinoid, Faraday of its closed or phenoid systems. In our inability to escape from ancient practice, motorists to-day, fire-worshippers as they are, finding it to their advantage to associate the two types of combustible, unconsciously, the world over, render their burnt offering to the memory of the scientific fathers that begat them.

Chevreul's has long been an honoured name in England. He was elected a foreign member of the Royal Society in 1826 and received the Copley Medal,

¹ Address delivered at the fifth Congress of Industrial Chemistry organised by the French Society of Chemical Industry, on October 11, at the centenary celebrations of Chevreul's work on fats.

its highest honour, in 1857. He was elected a foreign fellow of the Chemical Society in 1849.

In the obituary notice published by the Royal Society (1889), it was said :

He will be known for his researches on the contrast of colours but his great work was that by which he cleared up the constitution of the fixed oils and fats and established the theory of saponification. Few scientific men surviving were even born^a when this important research was commenced—a research in the course of which he laid the foundation of the method now universally followed in the study of organic compounds, by showing that an ultimate analysis by itself alone is quite insufficient and that it is necessary to study the substances obtained by the action of reagents on that primarily presented for investigation.

The notice given in the *Journal of the Chemical Society* (1890) is in similar terms. His investigations are said "to cover the whole of chemistry, branching out into physiological chemistry, hygiene and physics." In our survey we are carried far back, in the history of the development of the method of chemical inquiry, in considering Chevreul's early contributions. I have difficulty too in picturing his masterful activity—it was so ceaseless and varied. He thoroughly deserved the title he was accorded of "Encyclopédie vivante." To-day, students know him only as a chemist who lived to be more than a century old and was the discoverer of the higher fatty acids. Few will have seen the wonderful bibliography prepared, at the time of his centenary, by M. Godefroy Malloizel. The items catalogued number 506, including several comprehensive treatises. In our English Royal Society's *Catalogue of Scientific Papers*, 233 titles appear under his name, between the dates 1806 and 1884.

Born at Angers in 1786 and educated there, at the *École Centrale*, in 1803, at the age of seventeen, he went to Paris and was admitted by Vauquelin, the discoverer, in 1797, of the element chromium, to his chemical manufactory but soon became chief of the laboratory. In 1810, Vauquelin appointed him his assistant in his course of applied chemistry at the Museum of Natural History. In 1813 he obtained the chair of chemistry at the *Lycée Charlemagne*. In 1824 he became professor of special chemistry at the Gobelins tapestry factory and succeeded Roart as director of the dye works.

Chevreul began to publish in 1806. His early work was of a miscellaneous character. He began to study indigo in 1807 and was the first to recognise that it occurred naturally in "its lowest stage of oxidation" as indigo white. In 1811, he isolated the yellow colouring matter quercitrin. Morin and luteolin were discovered by him in later years. In 1815 he proved that diabetical sugar was identical with starch (grape) sugar. He began his studies of the saponification process in 1810 and recorded the results of his examination of the fats, in a series of papers, between 1813 and 1818. He discovered butyric, valerianic and caproic acids in 1818 and oleic acid in 1823. In 1832 he prepared kreatin from meat extract. He studied wool-fats in 1853. His attempt, in conjunction with Braconnot and Gay Lussac, to establish the stearin candle

industry receives notice at other hands. It is well known that the manufacture was not successful until after the introduction of Milly's improved process of saponifying with lime and the invention of the plated wick by Cambacères in 1834. In its early stages, the industry was largely developed in England by Price and Co. It has now reached colossal dimensions, though the hydrocarbon paraffin has largely taken the place of stearic acid.

Like Faraday, Chevreul was no mere laboratory worker: he was not only a philosopher but also a systematist and logician of the first order. His scientific writings are all models of clear and simple statement and a complete justification of the motto he adopted, from Malebranche, as his guiding principle, "On doit tendre avec effort à l'infailibilité sans y prétendre."

Recognising "les inconvénients d'exposer de nombreuses recherches sur un même sujet dans une suite de mémoires," in 1823, he published, in book form, a comprehensive account of his work on the fats—"Recherches chimiques sur les corps gras d'origine animale," which he dedicated to Vauquelin.

The point of view from which his work generally had been undertaken is clearly defined in the introduction to this volume, in the following terms :

On dit que la chimie se compose de faits, mais des faits seuls ne constituent pas cette science, car lorsqu'on donne des définitions générales, lorsqu'on forme des groupes de corps d'après des propriétés analogues et des propriétés différentes, il a fallu nécessairement interpréter des faits déjà observés pour établir les rapports qui les lient. Lorsqu'on définit, il y a donc des rapports établis et on reconnaît des propriétés de différent ordres, quant à l'importance qu'on attribue à chacune d'elles : dès lors il y a plus que des faits, quoique en dernier ressort toute interprétation, toute définition, doivent s'appuyer sur des faits bien observés. Priestley a découvert un grand nombre de corps importants, il a reconnu la plupart de leurs propriétés et certainement il a fourni à la science plus de faits proprement dits que Lavoisier, cependant, sans que nous ayons l'intention de diminuer en rien la gloire du savant anglais, nous pouvons dire, sans crainte d'être démenti, que la postérité a placé Lavoisier au-dessus de lui. Quelle en est la cause, si ce n'est pas la manière dont les faits ont été interprétés ? Ce qui est vrai pour les faits qui ont servi de base à la théorie antiphlogistique, doit l'être pour ceux qui restent à découvrir : nous pensons donc qu'au lieu de recueillir sur des sujets très différents des faits qui manquent de corrélation, il est préférable pour le progrès de la science de rassembler le plus possible des faits analogues, de les coordonner ensemble, afin d'en déduire les conséquences générales, qui seules peuvent imprimer à un ensemble de faits le caractère constitutif de la science.

Lorsque nous avons commencé l'étude des sciences physiques, nous avons été frappés du vague qui régnait alors dans la chimie organique, en même temps que nous avons aperçu l'étendue des applications qu'on peut faire de cette branche de la philosophie naturelle aux sciences physiologiques et anatomiques, à la médecine et à ces arts nombreux dont l'objet est de préparer avec la matière des corps organisés des substances utiles à l'homme. Tels sont les motifs qui nous ont engagés depuis longtemps à réfléchir sur tout ce qui se rattache aux connaissances chimiques des produits de l'organisation.

^a Chevreul was only eight years old when Lavoisier was executed.

Nous nous sommes appliqués à connaître les principes que l'on sépare immédiatement des végétaux et des animaux, parce que cette connaissance est la base de la chimie organique et de toutes ses applications.

In a second volume, published in 1824, "Considérations générales sur l'analyse organique immédiate et sur ses applications," Chevreul dealt more generally with the methods to be followed in examining natural products. The copy of this book that I have consulted came from Faraday's library; that dealing with the fats was a presentation copy to Mitscherlich. He not only discussed the use of solvents but also the mode of action of the various chemical agents. The following quotation will serve to illustrate the crude state of knowledge at the time: "M. Berzelius a dit que la fibrine du sang, l'albumine, la gélatine, éprouve sur l'influence de l'alcool et de l'éther une altération telle qu'une partie de leur matière est transformée en substance grasse adipocire."

After describing his experiments to test this statement, Chevreul concludes: "J'ai été ainsi conduit à reconnaître que les substances grasses contenues dans l'alcool et dans l'éther qui ont été mis en contact avec des tendons, etc., sont simplement extraites de ces substances et non produites aux dépens de leur éléments."

What Chevreul would have attempted, what he would have achieved, had he remained a chemist and a free lance, it is difficult to say. I venture to think that systematic inquiry in organic chemistry might have been made more *de règle* at a far earlier date than it was. The fates determined that he should be called off to deal with the problems of colour and of practice. No one has handled them more comprehensively, more logically, than he did, in his capacity of Director of Les Gobelins. Not satisfied with treating the subject as a chemist, he at once proceeded to inquire into the effect of contrast in colour—not only in tapestry fabrics but also in clothing, in house decoration and even gardening—including the planting of the dahlia, the now-fashionable flower. His great work "La Loi du contraste simultané des couleurs," first published in 1839, was long out of print. A new large quarto edition, with a preface by his son, was issued by l'Imprimerie Nationale in 1889. That he retained his interest in colour to the last is proved by his communication to the Institute, in 1884, in his ninety-eighth year, entitled "La Vision dans ses rapports avec les contrastes des couleurs."

Chevreul ranks alone as a student of the philosophy of the dyer's art apart from his craft. His works deserve renewed attention, at a time when colour plays so important a part in our civilisation. Judging from what I have seen at the Exposition Internationale des Arts Décoratifs, modern artists might consult them with advantage.³ The first to study indigo, the dyestuff

³ In Paris, we had many opportunities of appreciating the importance of Chevreul's efforts to direct the use of colour and of noting how great is the part to-day played by its glory. The public gardens, those of the Luxembourg especially, were ablaze with it, the Dahlia being the predominant factor in its production. At the Exhibition of Decorative Arts it was everywhere to the fore. Many most exquisite effects and contrasts were to be seen in jewellery. Striking beyond measure, however, was the wondrous exhibit of the Lyons silk manufacturers. The colour contrasts and patterns were not always such as Chevreul would have advised but marvellously effective, for the most part. To judge from the display at the Salon, in comparison with that at the Exhibition, painters are no longer mindful of the rainbow, seeking to attract rather by abrogating than by following the harmonies therein disclosed. The potters, too, are behind in evolving pleasing effects and the glass makers also seem to be lacking in

which still ranks before all others in importance, no one would have been better able to appreciate the extraordinary advance, within recent years, in our knowledge of colouring matters, both scientific and practical: he would have specially welcomed the discovery of the superlatively resistant indigo-like dyestuffs derived from anthracene and their appearance, in commerce, in the "lowest stage of oxidation," ready for application to the fibre by the dyer.

Some day, we may well compel the admiration of such achievement by the literary mind, even by the poet, if we can but paint the marvellous story in sufficiently simple terms and make clear what it is that has fired the heart of the chemist to match himself against Nature—even to her undoing. Chevreul was certainly one of the earliest and boldest among the conspirators and were he with us, to-day, would undoubtedly have sought to impress upon the public mind the marvellous development our art has undergone since he became its votary—within a single century.

Chevreul was greatly devoted to historical and philosophical study and deeply interested in making known the principles of scientific inquiry. In his "Histoire des connaissances chimiques," published in 1866, he speaks of his long friendship with Ampère and Frédéric Cuvier, begun forty-five years previously and refers to their frequent discussions on the classification of human knowledge. This work is full of sage reflexions. Let me quote one:

L'erreur prise pour vérité a encore le grave inconvénient de mettre obstacle au progrès de la science, parce que si une découverte véritable annoncée est contraire à cette erreur, il arrivera que les partisans de celle-ci repousseront la découverte, c'est-à-dire la vérité plus ou moins longtemps.

Telle est la raison sur laquelle je m'appuie pour réduire l'enseignement élémentaire et l'enseignement dit professionnel à ce qui est vrai et susceptible d'être facilement démontré tel. Car beaucoup de gens qui se disent partisans du progrès, ne voient pas que des erreurs promulguées par ces enseignements comme des vérités, sont autant de semences qui, en se développant dans de jeunes intelligences ou des intelligences d'adultes que nulle étude n'a préparés à les juger, deviennent des opinions erronées qui seront un jour les plus grands obstacles à la propagation de la vérité, c'est-à-dire à ce même progrès que l'on veut favoriser.

L'importance que j'attache à la destruction de l'erreur explique mon ardeur à propager la méthode.

We may well take such admonition to heart, in these days of unchecked hypothesis. If "l'enseignement

true feeling. In fact, the appreciation of colour seems now to have passed mainly into the charge of the textile workers, who not only have an endless gamut of tones at their disposal but are also able to produce varied effects of surface texture, unknown in Chevreul's day, which greatly enhance their power to please.

A happy accident gave us also an opportunity of appraising the value of pure natural colour. Lunching at Foyot's, we were opposite a lady wearing a most becoming "hat" of expensively simple design, a neutral light-brown in colour, who was sitting with her back turned to a window through which the brilliant rays of a midday sun came streaming in, these were evidently caught by a prismatic wedge, for ever now and then, as she moved forwards and backwards, a complete spectrum hung upon her brow and the curved edge of the bonnet—the decorative effect was exquisite, one producible by no conscious art.

A greater opportunity was to come. In the interval, in sunshine and shower, we have explored our English Lakeland region and seen the full glory of the bow resting upon the brows of the fells and upon wondrously sculptured slopes clothed with harmonies of wetted autumnal colour—colour of indescribable, inconceivable beauty, yet mostly traceable to Faraday's benzene and to contrasts beyond compare in which Chevreul especially would have gloried.

dit professionnel" were reduced "à ce qui est vrai et susceptible d'être facilement démontré tel," how much higher would be the task of the teacher and how much more competent the pupil as student and worker.

That philosophical subjects continued to fill his mind is clear from his communication to the Institute, in 1883 (*C. R.* 96, 1521): "Considérations générales sur les méthodes scientifiques et applications à la méthode *a posteriori* de Newton et à la méthode *a priori* de Leibnitz," in which he discussed the diametrically opposite methods of the two philosophers. It would be to the advantage of students, if a complete edition of Chevreul's works could be published at a cheap price. They would be of great value, if only as examples of style.

Like Faraday, Chevreul turned his attention to occult phenomena and dealt specially with certain aspects of occultism, as member of a Commission of three appointed by the Academy, in 1853, to examine a memoir by M. Riondet "sur la baguette divinatoire employée à la recherche des eaux souterraines"; also a letter, by M. Koepelin, "sur les tables tournantes." His report was published in book form under the title "De la baguette divinatoire, du pendule dit explorateur et des tables tournantes." I have had at my disposal the autograph copy of this book presented by Chevreul to the Royal Society of London. He was prepared to undertake the task, having twenty years before addressed a letter to his friend Ampère "Sur une classe particulière de mouvements musculaires," discussing experiments which he had made in 1812 to test the statement: "Qu'un pendule formé d'un corps lourd et d'un fil flexible oscille lorsqu'on le tient à la main au-dessus de certains corps, quoique le bras soit immobile." Like all who have discussed such subjects critically and exactly, he came to the conclusion that the manifestations were to be referred to no "faculté surnaturelle," but to "unconscious cerebration."

Chevreul's work on the fats was limited to the recognition of their proximate constituents. A long series of workers has since laid bare their molecular structure: of these Dumas and Boullay, Gerhardt, Würtz and Berthelot, not forgetting Schorlemmer, were among the first. The story is the story of the development of structural chemistry—a colossal work of the human intellect which is too little appreciated, even in scientific circles.

It is noteworthy that, at this early date, he discussed the possibility of preparing organic substances by artificial means and definitely decided that it is likely that they would be so produced. Four years later, Wohler was to make urea, thus breaking down for ever the barrier between Nature and our art. To-day the Badische Co. is counting upon a production of 20,000 tons per annum and urea may well become the sole artificial nitrogenous fertiliser used by agriculturists. Indigo, Chevreul's early love, is fast being displaced by synthetic indigotin, the world production of which is already rated at 9000 tons (dry weight) per annum. The other natural dye-stuffs he studied are all but unused—the fats alone still carry the bloom of their natural origin, though, taught by Sabatier, we are now accustomed to pale the fresh complexion of those that are oils with hydrogen.

Our art has thus gone far in copying Nature but she

still defies us to read and understand her purpose. We have also done much to alleviate man's ailments and are vastly more powerful. Nevertheless we are no happier nor better attuned to her beauty and goodness. Our art is not yet true art. Would Chevreul have been satisfied with our slavish worship of mere measurement, great as was his devotion to accuracy? Would he not have deprecated our insatiate desire to manufacture everything—our attempts to waive aside Nature's activity in every possible way? Would he not have asked for a less academic and broader treatment—for a greater display of humanity, for more reverence for the great scheme we presume to dissect? No one was more alive to the frailty of the human spirit but no one more conscious of its powers when rationally used. True science is dangerously far from the public ken and we need to recognise the duty that is upon us to bring home to all the infinite possibilities it affords of a future worship of abstract truth.

Chevreul, to-day, would be astounded at the lengths to which we have been carried by application of the philosophical methods of study of which he was so stalwart an advocate throughout his life. We know the structure of the diamond, thanks to the confirmation X-rays have afforded of the chemist's conception of the carbon atom, built upon the foundations laid by Frankland and Kekulé, by Biot, Pasteur, Le Bel and van't Hoff and established by the labours of a vast army of patient students of organic structure. We can, in fact, assert, that the diamond is made up of individual units—carbon atoms—commanding tetrahedral domains. The contiguous units are arranged alternately, as tetrahedra may be, base downwards and base upwards, lines between their centres forming a zigzag and meeting at an angle of 109° , the tetrahedral angle. Recent measurements, made by Dr. Muller, at the Royal Institution, of exceptionally good crystals of stearic acid, show that the carbon atoms in this compound meet at this same angle. In fact, the saturated fatty acids are simple rods of carbon atoms, clothed with hydrogen atoms along their length, their acidity being determined by the presence of a terminal group in which Lavoisier's oxygen is substituted for hydrogen.

This is a strange structure in comparison with that of Faraday's benzene, which may also be pictured as being hewn straight out of the diamond but as consisting of compact hexagonal blocks of six carbon atoms.

Why Nature, in making the fats, should build such extraordinary scaffold-pole like molecules is passing strange. The field is full of problems: it is surprising that so little attention has been given to it (see E. Frankland Armstrong, Presidential Address, Society of Chemical Industry, Liverpool, 1924). I have here a solid model of the geometrical structure of the fatty acids which I owe to Mr. William Barlow, F.R.S. It is a veritable *bougie stéarique*, built, not wastefully, in cylindrical form but so that the individual units interlock to fill space. Mr. Barlow and I believe this model to be worthy of special attention, as it has features which serve to represent peculiarities hitherto unexplained in the chemical behaviour of the fats and paraffinoid compounds generally. If the hydrogen atoms were arranged around the carbon atoms tetrahedrally, they would serve to isolate them in space and the formation of crystalline masses from such units

would seem to be "impossible"; moreover, such compounds would be chemically neutral, assuming hydrogen to lose all affinity when it unites with carbon. In the model before you, as in that of benzene, the unit of affinity and, therefore, the hydrogen atom is a regular dodecahedron. Four such dodecahedra arranged in a pyramid represent the carbon unit: consequently, the dodecahedral units are distributed in two layers. The hydrogen atoms, in the fatty acids, are all brought down, as they are in the model of benzene, into these two layers: therefore, an upper and a lower face in the model are free carbon surfaces. The models can, in consequence, be superimposed at these faces and also interlocked at the sides. Verily, we have done well to use the name *paraffin*, not *sinaffin*. They can be joined, in the same plane, at the carboxylic ends and at the sides. To join them at the hydrocarbon ends, the models must be stepped, so as to raise one a layer above the other: this mode of packing is commonly met with in benzene derivatives. The attachment of the hydrogen units is peculiar, different from that adopted in our printed formulae, in that, although they occur in pairs, alternate carbon units carrying each a pair, both are on either one or the other margin of the model. These models, therefore, portray a new method of geometrical analysis, more powerful and intimate perhaps than any yet devised. It is further noteworthy, that although carbon surfaces are exposed, no complete carbon unit of affinity comes to the surface: whereas, in the model of benzene, there are three such affinities on each face.

From the measurements made by Langmuir and by Adam, we are led to conclude that the molecules of a fatty acid spread out upon water in single layers, so arranged that they stand upright, the carboxyl tip

dipping into the water, each upright molecule being closely fitted against its neighbours. The measured thickness of the thinnest black soap film is such that it may well be supposed to consist of two such layers, held upon a belt of water very few molecules thick, one standing upon the upper, the other depending from the lower face of the belt. Interpreting the film in this way, there is no reason to believe in the existence of a complex unit or micelle.

I can overlook sixty of the hundred years since Chevreul's invention. When I first studied chemistry, we were not entirely persuaded of the existence of atoms and were only beginning to form clear conceptions of molecular structure. We did not venture even to dream that we should ever be able to measure and speak with a close approach to certainty of the actual distances between atomic centres, which we now rate at little more than an Ångström unit, one hundred-millionth of a millimetre. Well might Chevreul say: "On doit tendre avec effort à l'infailibilité sans y prétendre": We seem to be near reaching it: though we can still make no claim to infallibility, we are probably far nearer to certainty than Chevreul ever thought possible. The methods which he did so much to make known and appreciated are the methods to which progress is due. As a result, the *bougie stéarique* is no mere illuminant to-day but something at which we can greatly marvel. The chemist can see massed in it wondrously built, tall staircases of atoms, up which the imagination may climb to infinite heights, seeing

..... successive zones
Of several wonder open on some spirit
Flying secure and glad from heaven to heaven.
Paracelsus.

Does the Solar Heat Stream Vary?¹

FIVE notable contributions to the literature of the "solar constant" have come recently from the United States: three, published by the Smithsonian Institution, give the evidence for variation in solar radiations and for the influence of that variation on terrestrial weather; the other two, appearing in the *Monthly Weather Review*, the organ of the Weather Bureau of the United States, contain critical analyses of the radiation statistics.

The first of these papers is an apologia by Prof. C. G. Abbot. He realises that critics have not been convinced hitherto that the fluctuations in the Smithsonian determinations of the "solar constant" represent real variations in the radiation received by the earth, and he sets out to marshal the evidence for variation in the most convincing way.

As a preliminary he narrows discussion by throwing over the earlier observations as too rough for the purpose in view. The paragraph is of such importance that it must be quoted in full:

¹ Washington, Smithsonian Miscellaneous Collections, vol. 77 (1925), No. 5: "Solar Variation and Forecasting," by C. G. Abbot; No. 6: "Solar Radiation and Weather or Forecasting Weather from Observations of the Sun," by H. H. Clayton; No. 7: "Solar Radiation and the Weekly Weather Forecast of the Argentine Meteorological Service," by Guillermo Hornmark. Washington. *Monthly Weather Review*, July 1925. "On the Question of Day-to-day Fluctuations in the Derived Values of the Solar Constant," by C. F. Marvin. *Smithsonian Solar-constant Values*, by W. W. Kimball.

Some writers mention our data for the past 10 or 15 years as if all were of equal value. Really, to speak in a figure, the Washington data of 1902 to 1907 were prehistoric. As for Mount Wilson results of 1905 to 1908, inclusive, before the invention of the silver disk pyrheliometer, or Fowle's method for estimating total atmospheric humidity... this work is ancient. Excluding altogether July and August 1912, the year of the eruption of the Katmai volcano, all Mount Wilson work of 1909 to 1920 can be classed as medieval. We had then but one station, operating only in summer. We obtained only one determination per day, subject to error from changes of sky transparency and also to errors of computing in the enormous multiplicity of computations used in the reduction of results by Langley's fundamental method. The period from January 1919 to the present is of another order of accuracy and represents the modern period.

It will be seen that it is only the comparatively short series of observations, those since January 1919, made mostly at Harqua Hala in Arizona, and of Mt. Montezumá in Chile, that need be taken seriously as evidence for rapid variations in the solar heat stream. Data for the greater part of this period, August 1920 to November 1924, have been published in a convenient form by the Smithsonian Institution (Misc. Collections, vol. 77, No. 3, Feb. 1925).

The average value of the solar constant is about 1.945 in terms of the unit in general use for this study, the gram calorie per square centimetre per minute. In other words, if the heat were all absorbed by a layer of water one centimetre deep, the temperature of the water would be raised 1.945° C. per minute.

In his discussion Abbot states that the average daily difference Harqua Hala minus Montezuma is only 0.011 units. This agreement has been attained, however, by an adjustment of the original readings by a process which has not been explained yet in print. It is clear that this process is calculated to minimise discrepancies between the stations.

Knowing the average difference between the approximately simultaneous observations, and assuming tacitly a Gaussian distribution, Abbot finds that the probable error of the daily measurement at either station is 0.0065 units. He proceeds to discuss the deviations from average in the estimates. These deviations are, it is true, of the same order of magnitude as the probable error. In the case of 398 estimates, each based on nearly simultaneous measurements at the two stations, the probable error is $0.0065/\sqrt{2}$ or 0.0046, and the number of such deviations exceeding 0.0046 is 214. The natural deduction would seem to be that the results show just as much consistency as would be expected if the solar heat stream really were constant and the deviations were due to errors of observation. There are, however, a few cases in which the deviations of the estimated radiation from the average are comparatively large. There are 6 deviations greater than 0.0245 units. With a Gaussian distribution of errors, the proportion of such large deviations would have been only 1 in 4000. Dr. Abbot seizes on this as strong evidence of real fluctuations in solar radiation. He suggests that the contrast between the extreme estimates and the ordinary run is comparable with that between the Washington Monument and the blades of grass around it. Dr. Kimball's remark that the determinations on which the extreme estimates are based are generally in the lowest grade of the Smithsonian classification, and mainly observations from one station only, seems more to the point. By a pair of telling diagrams Kimball shows that such correlation as exists between Montezuma and Harqua Hala values is due, not to any agreement in the variations during short periods, but to the large drop in the solar constant at one epoch. For October 1920 to March 1922 the average estimate at each station was 1.945, and for April 1922 to November 1924 it was 1.922. This contrast naturally dominates the situation when the observations of the four years are treated as a single group.

Thus the direct evidence for day to day variations in solar radiation is decidedly weak. Dr. Abbot supports his case, however, by evidence for an association of changes in radiation with the appearance of sunspots and faculae on the sun.

As to sunspots, this evidence is given in graphical form by Clayton. During the years 1918-1924 there were large sunspots, and the average values of the solar constant, reckoned for each of the 6 days before a spot passed the central meridian of the sun to 22 days after, fluctuate between 1.944 and 1.936. If the days are numbered -6 to +22, 0 being the day the

spot was on the meridian, it so happens that days 0, 1, and 12 are on the lower of these limits; days 9, 16, and 22 on the higher. The probable error of a single determination of the "constant" is supposed to be 0.0065 in the years for 1921 onwards. The earlier observations for 1918-1920 had much larger fluctuations. The probable error would average for the whole period at least 0.01. For a mean of 114 determinations the probable error would be about 0.001, so that variations for the mean up to 0.004 are scarcely significant. Moreover, Clayton's figures show no regular sequence. If they are accepted at their face value they indicate that a sunspot causes as violent fluctuations in radiation when it is on the far side of the sun as on the near side. We are forced to the conclusion that the analysis is worthless as evidence for the phenomenon Mr. Clayton wishes to establish, an association between the Smithsonian "solar constant" and sunspots.

Dr. Abbot and his colleagues have not been content to work at the improvement of their sunshine measurements. With the generous aid of Mr. J. A. Roebling, they have investigated the possibility of forecasting the weather by referring its changes to solar variations. The greater part of Mr. Clayton's paper is devoted to tables, graphs, and maps showing the average of pressure and temperature at various places so many days after high or low values of the solar constant. There is no attempt to show that the results are not attributable to chance, and indeed the general run of the graphs is in accordance with the hypothesis that they are.

Having reached this conclusion, how are we to explain the fact that Mr. Clayton can claim a considerable measure of success in forecasting temperature in New York several days in advance? Judging the forecasts by the departure of the mean temperature from normal, we see that when the forecast was "above normal" the average departure was actually nearly +1° F., and when the forecast was "below normal" the average departure was -1.28° F. The system of forecasting was based largely on the observation of sunspots and faculae: from these observations the solar constant was estimated and the subsequent pressure and temperature changes foretold. But Mr. Clayton did not trust to solar observations alone. "These were supplemented by the temperatures observed at Seattle, Withston, and Chicago, in order to ascertain to what extent the temperatures at American stations were responding to solar changes." Mr. Clayton will forgive us for thinking that his forecasts would have been equally successful if he had trusted to the weather telegrams and ignored the sunspots.

In Mr. Hoxmark's paper we have some account of the method adopted in the preparation of the forecasts which have been published at Buenos Aires for at least two or three years. The forecast published on a Wednesday gives the anticipated temperature at 8 A.M. and 8 P.M. for each day of the following week. As a sample of the results the paper includes a table showing the temperatures forecasted and observed for 12 weeks in the middle of 1924. If the reader takes the trouble to plot these figures he will find little correlation between forecasts and sequel. Calculations give 0.25 as the correlation coefficient in the case of 8 A.M. temperatures. As the standard value of a correlation

coefficient computed from the values of correlated variables is about 0.11, no importance can be attached to 0.25. For this particular period the forecasts must be regarded as a failure.

Mr. Hoxmark's own method of judging the points of his results is to find a correlation coefficient for each week. Of 131 weeks, 87 had positive coefficients and 44 negative. This disproportion must be counted as a point in favour of the forecasts. On the other hand, the fact that more than sixty per cent. of the week's forecasted yield correlation coefficients exceeding 0.3 is in no wise remarkable. Let it be noted that a correlation coefficient formed from seven pairs of samples is likely to be large even when samples are taken quite at random. The standard value of the coefficient derived from such samples is $1/\sqrt{6}$ or 0.41. In spite of the enthusiasm with which the results are recorded, we are left with the impression that these forecasts are not of practical value.

Thus the contention of Dr. Abbot and his collaborators that day-to-day estimates of solar radiation can already be used efficiently in weather forecasting would seem to fail. We have already seen that the reality of the fluctuations in solar radiation is itself highly problematical.

There is, it appears, a much stronger case for large

swings in the value of the solar constant, such as was found in 1922. The measurements show a notable reduction of so much as 1 per cent. in the radiating power of the sun as between 1920, 1921, and 1923, 1924. The possibility that such a change may be due to a failure to make complete allowance for some change in the earth's atmosphere is not to be overlooked. Prof. Marvin has brought out how difficult it is to be sure that the atmospheric effects have been eliminated. It is interesting to learn from Dr. Abbot that the solar changes are localised in short wave-lengths. The energy in the green, yellow, red, and infra-red was not affected by the 1922 drop; the effect was confined to the blue, violet, and ultra-violet. It is an obvious comment that this adds to the difficulty of accurate determination, atmospheric scattering being more serious with the short wave-lengths. To Dr. Abbot, a change, such as took place in 1922, indicates a reduction in the effective solar temperature, attending lessened solar activity, and the effects should be larger for shorter wave-lengths.

Let us accept this doctrine as a working hypothesis and look to its verification in the course of the sunspot cycle. At present most of the evidence available dates from the "medieval" era and therefore requires confirmation.

F. J. W. W.

Obituary.

PROF. WILFRID KILIAN.

CHARLES CONSTANT WILFRID KILIAN, whose death is announced at sixty-three years of age, was one of the most eminent of French geologists. For thirty-three years professor at the University of Grenoble, he was a man of enormous industry, his published papers and memoirs numbering nearly a thousand. The range of his work was very wide, but he is best known by his classic researches into the stratigraphy and tectonic structure of the French Alps, and by his palaeontological work, dealing chiefly with the Lower Cretaceous Cephalopoda; on this group he was acknowledged to be the leading authority.

Born at Schiltgenheim, in Alsace, in 1862, Kilian was educated at Strasbourg and at the Alsatian School in Paris, proceeding finally to the Sorbonne, where he was a contemporary of his lifelong friend and collaborator, Émile Haug. Here he was especially influenced by the teaching of Marcel Bertrand, and in 1885 served his apprenticeship in the field as assistant to this great Alpine geologist, on the expedition sent by the Paris Academy of Sciences to investigate the geology of Andalusia, following the great earthquake there. Three years later he presented as his thesis for a doctorate the "Monographie de la Montagne de Lure," a stratigraphical and palaeontological study which stamped him as a worker of great promise. The next year found him in charge of the school of geology at Grenoble, and from this time onwards his field-work was devoted entirely to the French Alps, where he toiled with untiring enthusiasm. Spending each summer vacation in the mountains, he can almost be said to have explored every inch from Provence to Mont Blanc, discovering many fossil localities, and bringing precise evidence to bear on the age and stratigraphical

relations of the rocks of this intensely complicated region. So enormous was the total of facts recorded by him that the titles of his papers occupy 25 pages of small text in the "Bibliographie géologique du sud-est de la France" compiled by him and a collaborator in 1922.

But never did the call of his field-work in the mountains detract from the care and accuracy of his palaeontological studies in his laboratory at Grenoble. Kilian's work on the phylogeny and ontogeny, and on the faunal succession, of Lower Cretaceous ammonites will always be considered classical, and his unique collection at Grenoble is one which many palaeontologists of the future will go there to see. In his rôle as ammonite specialist he was frequently called upon to report upon collections from other countries also, and so acquired an unrivalled knowledge of Lower Cretaceous stratigraphy. In the volume contributed by him to "Lethaea Geognostica" he attempted to bring this knowledge together into a comprehensive study. Three parts were published in 1907, 1910, and 1913, but the War intervened, and the work has remained unfinished.

Notwithstanding his immense scientific labours, Kilian never allowed himself to become too pre-occupied to fulfil thoroughly his duties as a university teacher. Under his influence the school of geology at Grenoble has become one of outstanding importance, and already some of his pupils rank among France's leading geologists. Many were the awards made to him in recognition of his services to science; finally, in 1921, he received the Gaudry Medal, the highest honour that can be awarded by the Société Géologique de France; and so, after a short and sudden illness, has passed away one whose name will always occupy an honoured place in the history of French geology.

L. R. C.

DR. J. R. HENDERSON.

DR. JOHN ROBERTSON HENDERSON, C.I.E., who died in a nursing home in Edinburgh on October 26, was an example of that "brotherhood between medicine and natural history in its widest sense" which has been a conspicuous product of the University of Edinburgh.

Born in Melrose in 1863, and educated at Dulwich College and Dollar Academy, Dr. Henderson graduated in medicine at the University of Edinburgh, and, influenced by the teaching of Sir Wyville Thomson, turned at once to those studies of marine animals which engaged his attention during the remainder of his life. He was one of the distinguished band of naturalists (which included Hugh Robert Mill, J. T. Cunningham, W. A. Herdman, and W. E. Hoyle) associated with Sir John Murray's oceanographical investigations after the return of the *Challenger*, first on *The Ark*, a canal barge anchored as a floating marine laboratory near Granton on the Firth of Forth, and later, on the steam yacht *Medusa* on the west of Scotland.

In 1886 Henderson was elected professor of zoology in Madras Christian College and relinquished that post in 1911, having, on the retirement of Mr. Edgar Thurston in 1909, been appointed Superintendent of the Madras Museum and Connemara Public Library and Keeper of the Marine Aquarium. On his retirement under the age limit a few years ago, he returned to Edinburgh and at once took part in the scientific activity of the city. At his death he was a fellow of the Royal Society of Edinburgh, and a member of council of both the Royal Physical and Scottish Zoological Societies. His experience in conducting and transforming the well-known Madras aquarium was of much service in the adjustment of the final arrangements of the large aquarium now being erected by the latter Society at the Scottish Zoological Park.

Henderson's zoological researches were almost entirely confined to marine invertebrates. As a result of his early years on the Forth and the Clyde, he made many contributions to the faunal lists of zoophytes, mollusca, echinoderms and crustacea of these areas, mainly published in the Proceedings of the Royal Physical Society. He was responsible for the account of the Anomura in the *Challenger* Reports, and continuing in India his work on crustacea, he described the Paguridæ collected by the *Investigator*. His most important work there, however, lay in the impetus he gave, by teaching and example, by his extension and development of the natural history section of the museum and of the aquarium, to the study of animal life in the laboratory, in the schools, and in the field.

Henderson was a man of wide interests; he wrote an excellent catalogue of the coins of Tipu Sultan, and his goodwill and the geniality which never flagged under the burden of ill-health gained him many appreciative friends in India and at home.

J. R.

DR. R. A. JOYNER.

DR. R. A. JOYNER lost his life as the result of an accident on Wednesday, October 7, through an explosion in the research laboratories of Messrs. Nobel's Explosives Co., Ltd. Dr. Joyner studied at University College, Bristol, taking a London degree with honours in

chemistry in 1909, followed by the M.Sc. degree of the newly founded University of Bristol in 1910. His work during this period is recorded in three papers on amalgams of silver and tin published in the Journal of the Chemical Society. These exhibit his careful and thorough experimentation and stand unaltered. They form the accepted basis of the treatment of dental amalgams in modern courses on dental metallurgy.

Joyner proceeded as an 1851 Exhibition Scholar to Zürich and afterwards followed Bredig to the Technische Hochschule, Karlsruhe, where he qualified for the degree of doctor of engineering, which has seldom been obtained by students from abroad. His exceptional ability and independent judgment were recognised by Bredig. He published two very pretty experimental papers, one on the affinity constant of hydrogen peroxide, the other on the catalysis of camphorcarbonic acids by bases in various solvents which further elucidated the remarkable parallelism between ordinary reactions and life processes, showing a mechanism through which optical activity may play its well-known rôle.

For twelve years Dr. Joyner served on the research staff of Messrs. Nobel's at Ardeer, and most of the important work which he carried out on such War-time problems as mustard gas and explosives is of course not available for publication, but an estimate of his unusual experimental skill and scientific acumen may be obtained from a study of the paper which he published in the Journal of the Chemical Society on the viscosity of solutions of cuprammonium.

Those who came in contact with Joyner must have realised that few scientific workers showed such wholehearted devotion and enthusiasm. He had many other interests, having been versatile in athletics and being a keen Territorial officer for many years. His straightforward and unassuming personality gained him not only esteem but also affection from all who knew him. In spite of the tragedy of his loss at the age of thirty-eight years, his widow and three children can look back with pride on his devoted work in the cause of science.

WE regret to announce the following deaths:

Sir Alfred Woodley Croft, K.C.I.E., president in 1892-93 of the Asiatic Society of Bengal and sometime trustee of the Indian Museum and Vice-Chancellor of the University of Calcutta, on October 29, aged eighty-four years.

Dr. Theodor Fuchs, corresponding member of the Vienna Academy of Sciences and honorary director of the geological and palæontological section of the Natural History Museums in Vienna, on October 5.

Dr. Carl Kupelwieser, honorary member of the Vienna Academy of Sciences, and a founder of the Institute for Radium Research at Vienna and of the Biological Station at Lunz, on September 16.

Mr. H. B. Mullen, Director of Museums and Libraries, Salford, and formerly an assistant in the Art and Ethnographical Department, National Museum of Ireland, on October 26, aged sixty-three years.

Mr. M. J. Nicoll, formerly assistant in the Zoological Gardens at Cairo, the author of numerous ornithological papers published chiefly in the *Ibis*, on October 31, aged forty-five years.

Dr. Henry H. Robinson, superintendent of the Connecticut Geological and Natural History Survey since 1920, on October 20, aged fifty-two years.

Current Topics and Events.

ON Thursday, November 12, a small company gathered in the entrance hall of the Royal Institution of Great Britain to witness the unveiling of the memorial to Sir James Dewar, who for forty-six years was director of the Institution. Mr. H. Munro Ross, chairman of the memorial fund committee, described the inception of the fund, and stated that although Dewar himself wished for no memorial, it was felt that a commemorative plaque in the Royal Institution, his home for so many years, and the scene of some of his best work, would meet with general approval. Mr. Munro Ross then asked the president of the Royal

spectacular demonstrations. In Sir Joseph's view, Dewar's greatest achievements were the liquefaction of gases on a large scale, thus making possible their use as physical agents, and the use of charcoal cooled by liquid air for the production of high vacua. This work has proved to be of fundamental importance in experimental research on the structure of matter.

THE recent visit of Sir Ernest Rutherford to Melbourne, at the instance of the University authorities there, is described in news-cuttings from the Melbourne *Argus* which have reached us. We understand that the Melbourne visit was part of a programme organised jointly by more than one of the Australian universities, and that Sir Ernest had already visited Adelaide, and was proceeding to Sydney, thence going on to New Zealand, his native country. The immediate purpose of the invitation was to enable serious students, researchers, and teachers in physical science to meet and to hear—in some cases, for the first time—one of the prime movers of their own work; and it is evident, from the clearly reported meetings and lectures described in the news-cuttings, that this object was attained so successfully that it cannot fail to yield valuable fruits, directly and indirectly. At the same time, as members of the British Association who travelled to Australia eleven years ago will not need to be told, warm hospitality was shown to the president-elect of the Royal Society, even outside academic circles; and he also came into touch with those concerned in radio transmission, and with medical radiologists.

THE great stimulus of personal intercourse with the comparatively few living pioneers in science is one which comes fairly easily and frequently to the members of British universities, who may thus tend to forget what an extraordinary encouragement and impulse is brought by each such occasion. It will be interesting, therefore, to learn whether the Australian institutions which have arranged this fruitful visit of Sir Ernest Rutherford meditate any plan of making such invitations at regular intervals. High though the cost of a visit is, it would not fall heavily if divided between several universities of the Dominion at intervals of a year or two. To be selected as the "Dominion Lecturer for 19—" would become an honour, for which even the busiest of the most eminent leaders should willingly devote time and energy. The English long vacation falls in the term-time of the Southern Hemisphere, and the necessary additional month or so of leave should present little difficulty. We do not see why such a scheme need be restricted to the branches of science, for historians, economists, and others would no less benefit. It seems certain that a plan of this kind would form a real network of thought and action among British universities and would lead to valuable interchanges of all sorts.

THE Stockholm correspondent of the *Times* has telegraphed that the Nobel Prize in Physics for 1924 has been awarded to Prof. K. M. G. Siegbahn, of the

Institution, His Grace the Duke of Northumberland, to accept the plaque as a perpetual memorial to Sir James Dewar and his work at the Institution, and to unveil it. The Duke of Northumberland acknowledged the gift on behalf of the Royal Institution and performed the unveiling ceremony, revealing the relief here illustrated of Sir James Dewar seated before his laboratory bench. Thus Dewar is added to the group of notable men of science connected with the Royal Institution whose memorials grace its entrance hall, and its position, on the main staircase opposite the entrance, ensures that all comers will see the likeness of one who was not the least of those who have directed its activities. After the unveiling ceremony, Sir J. J. Thomson gave a brief address on Dewar and his work. He referred to the originality and forcefulness which were characteristic of Dewar's methods, and also spoke of his genius for devising

University of Upsala, for his work on spectrum analysis. The Prize in Physics for 1925 has been reserved, while the Prizes in Chemistry for both 1924 and 1925 have also been reserved. As the Prize in Chemistry for 1924 has thus remained unawarded for two years, the money must either be added to capital or used to form a special fund for promoting scientific research, independently of the annual prizes. Accordingly the 1924 Prize has been assigned to the reserve fund of the chemical section of the Nobel Institute.

ALL who are interested in the trend of modern atomic theory will welcome the announcement that the Nobel prize for physics for 1924 has been awarded to Prof. Manne Siegbahn of Upsala. When the prize was instituted it was intended as a recognition of outstanding experimental work, and Prof. Siegbahn is, first and foremost, an experimentalist. His most notable researches, and those for which the award has been made, have been in X-ray spectroscopy. Since Moseley's first measurements, the technique has been improved to such an extent that it is now possible to measure wave-lengths in this region of the spectrum to six significant figures. This advance is due, almost entirely, to the work of Prof. Siegbahn. In addition to these high precision measurements, he has made an exhaustive study of the soft radiations which lie between the ultra-violet and the ordinary X-ray region. These researches have made possible the theoretical work on which practically all our knowledge of the distribution and energy properties of the electrons in the atoms is based. The complete and accurate data now available have led to the identification of three new elements, hafnium and the two eka-manganeses, while another application which originated and is being pursued in the Upsala laboratories is the investigation of the effect on the X-ray spectrum of an atom of its different states of chemical combination. This work promises to throw much light on the distribution of the electrons in the molecule. It is certainly fitting that experiments which have led to such an important increase in our knowledge should receive recognition, and the new Nobel laureate is to be congratulated on a well-deserved honour.

THE long-awaited particulars of the projected re-organisation of the British Dyestuffs Corporation, Limited, were announced on Saturday, November 14, in an official communication to the shareholders. As anticipated, Government control is to be abolished and the capital of the company is to be drastically reduced. The company states that experience has proved that the restrictions imposed by the Government seriously militated against the successful conduct of business, and the Government has agreed to withdraw its veto and control provided that the company purchases its share interest of 1,700,001*l.* for the sum of 600,000*l.* in cash, communicates to the Government all necessary information concerning technical matters and research, and that the old restriction of not issuing more than 25 per cent of the company's shares to foreigners, remains in force. The proposals, which are to be submitted to a meeting

of shareholders on November 25, also include the writing off of nearly one-half the issued capital to cover depreciated assets, and the conversion of the three classes of shares into a single denomination. The authorised capital is to remain at 10,000,000*l.*, but not more than 6,000,000*l.* will be issued unless by resolution of the shareholders. If the proposals are accepted, the issued capital will be 4,775,580*l.*, all of which will be in the form of ordinary shares, and the sum of 1,667,185*l.* will be available as working capital. The accounts for the period of 17 months to March 31, 1925, show a profit of 88,674*l.*, after providing 437,832*l.* for depreciation. In view of the preponderance of plant capacity over consumption in all dye-producing countries, it is interesting to note that the board proposes to engage in the manufacture of "other products."

DR. KNUD RASMUSSEN, in an address to the Royal Geographical Society on November 9, gave an account of his travels from Greenland along the north coast of Canada to Alaska and across Bering Strait to Siberia. In the course of this journey of three and a half years' duration, he had opportunities to explore fully the routes of migration and the culture of various tribes of Eskimos. On the shore of Lake Yathkied, about three hundred miles south-west of Chesterfield Inlet he discovered an unknown inland tribe of Eskimos, ignorant of the coast life of tribes farther north and living in primitive conditions which suggested that they may be a remainder of the aboriginal Eskimos. In places along the north coast of Canada, Dr. Rasmussen found other Eskimos still using bows and arrows and in a state of isolation so complete that no word of the War had ever reached them. As a rule they were very shy of white men, and turned out fully armed to meet the explorers. In several of the tribes it is the custom to put to death nearly all girls at birth, but in other respects they are kindly and well-disposed. Dr. Rasmussen came on traces of the Franklin expedition of 1845-48. He met an Eskimo whose father had seen several of Franklin's men and had visited his deserted ships at King William Island. The bones of two of Franklin's men were found, one in King William Island, the other at Starvation Cove in Adelaide Peninsula. These were men who had fallen in the retreat towards the Great Fish River.

A SPECIAL meeting of the Institution of Chemical Engineers was held on Thursday, November 12, for the discussion of the report of the British Science Guild on "Scientific Research Workers and Industry," referred to in our columns on September 26. The president, Sir Frederic Nathan, took the chair, and the Hon. H. Fletcher Moulton opened the discussion and pointed out that although the proportion of science students in Great Britain has increased above the 1914 standard by 60 per cent, it is still only equal to the pre-War proportion for the United States and Germany. In spite of this, many research workers are unable to find posts. There is also an unfortunate tendency to belittle technical research in favour of fundamental research. The great problem is to combine efficiently university training with

factory work at some early period of a student's career. In the discussion which followed, a number of interesting points were brought out. For achieving the desired combination of practical experience and theoretical knowledge, it was suggested that the scheme followed by the Chemical Engineering School of the Boston "Tec," in which training classes under a responsible teacher are regularly held in several works for six months at a time, might be adopted. The importance of good industrial experience as part of the lecturer's qualification was also discussed. Many research workers are, indeed, really more suited for the works laboratory than for the more academic type of research. The discussion of the activities of research associations revealed the fact that the average cost to a firm of belonging to a research association is about the price of one office boy. In spite of the excellent results obtained, however, successful research associations tend to break down by the large firms forming their own research departments.

Two Chadwick public lectures on "The Control of the Food Supply" were delivered by Dr. William Howarth at the Royal Sanitary Institute on October 30 and November 6. In the first lecture, statistics were given illustrating the enormous amount of food imported into Great Britain, and the general principles controlling the supervision of imported food were reviewed. The importance of refrigeration in relation to food supply was emphasised, and it was suggested that local authorities ought to be vested with certain powers of control over cold-storage. Recent regulations designed to ensure greater cleanliness in the handling of meat, etc., will probably fulfil their aim, though the control of stores and shops presents difficulties not easy of solution. As regards the milk supply, considerable improvement might be effected. The control of pasteurised milk is unsatisfactory, as the official term "pasteurised milk" may be used only under licence, but this fact does not deter unlicensed persons treating milk by pasteurisation or sterilisation and selling it in bottles either as "milk" or as "heat-treated milk," or by any other designation so long as it is not an official one. Publicity may have given the impression that the food supply is deplorably unhygienic, but in Dr. Howarth's opinion this is not so, and the position in general is one that may be regarded as reasonably satisfactory, with room for improvement in certain directions. In the second lecture, the subject of milk was further considered. Dr. Howarth pointed out that the definition of cream in the "Preservatives Order" is unsatisfactory, and that cheese is another produce for which no declaration of composition is required, unless it is margarine cheese, with the result that remarkable variations in the fat content occur. The manufacture of canned foods was explained, as well as the method of inspection and sampling applied to them. Other subjects dealt with were eggs, ice, ice-creams, and the use of preservatives in food-stuffs. As regards the last-named, reference was made to the difference of opinion existing as to the harmfulness of such substances as boric acid, and

Dr. Howarth expressed a doubt as to whether benzoic acid would prove to be an efficient substitute for boric acid.

We have received from the Central School of Science and Technology, Stoke-upon-Trent, a catalogue of its ceramic library, which includes the well-known collection of the late L. M. E. Solon. Solon was for thirty years in the service of Messrs. Minton, and was an indefatigable collector of ceramic literature. Since his death the collection has been acquired by a gift of 2000*l.* from the Carnegie United Kingdom Trust, and its deficiencies made good by a further gift from the same quarter—the Trust stipulating that the Library should be regarded as a national institution and that its contents should be available (under proper safeguards) to other than the inhabitants of the district. The printing of a catalogue of the collection thus became a necessity. The catalogue is an author catalogue with appendices of (a) catalogues and (b) periodicals, but this arrangement the student is left to discover for himself. Moreover, the classification is not strictly carried out. Catalogues of books, for example, will be found in all three sections. In other respects the cataloguing methods adopted are not satisfactory. The grouping of anonymous works under the general heading ANON is contrary to accepted practice. Biographical references are not appended to author headings. Hence the student must examine each entry in the author section if he wishes to consult the literature which has appeared around the names of Palussy, Tinworth or Wedgwood. The work, however, is well printed and will, no doubt, be useful to those interested in the literature of ceramics and glass.

In the course of a lecture to the students of the Royal Academy of Arts, London, on Wednesday, November 18, on the selection of stone for building, Prof. A. P. Laurie divided the stones which are used for building into two groups—sandstones and limestones. The most serious cause of weathering to-day is the attack on the stone of the acid oxidised products of sulphur, and this is not confined to the towns. The action of the sulphur acids results in the formation in the case of limestones, and in the case of sandstones, which contain calcite, of calcium sulphate, which is slightly soluble in water. The most serious effect of calcium sulphate is its crystallisation within the stone, resulting in the stone being mechanically broken up. Some sandstones are practically free from calcite, and these should be used in modern cities. Limestones differ considerably in susceptibility to attack and in tendency to break up, owing to the crystallisation of the sulphate of lime. Apparently one of the conditions is that there should be free and rapid evaporation from the stone after wetting, so as to draw the sulphate of lime to the surface and prevent it from crystallising inside the stone. This raises the question as to whether the hosing of buildings during hot weather would not be of advantage. Further research is required in these directions, but in the meantime it was quite possible to guide the architect in the selection of sandstones and lime-

stones by chemical analysis and by experiments on the rate of attack of acid vapours upon samples of the stones

It is precisely one hundred years ago since the *Memoirs of Samuel Pepys*, F.R.S., Clerk of the Acts, were first edited by Lord Braybrooke, from a version of the shorthand manuscript in Magdalene College, Cambridge, which had been deciphered by the Rev. John Smith of St John's College. The private thoughts and confidences of few persons have been more widely read and quoted than those of the versatile Mr. Pepys. He has illustrated the actions, feelings and sentiments of his contemporaries with such a wealth of detail that it is difficult to believe that the diary only covers the years 1659-1669, but as those ten years cover the period of the foundation of the Royal Society, it is very pleasant to receive a reminder of the scientific side of the great diarist, "a great cherisher of learned men," in the form of an article in the October issue of the *Quarterly Review*, from the genial pen of Sir Arthur Shipley. It is surprising to learn that Pepys had had no early preliminary education such as we now expect of a man of science. He reached his thirtieth year before beginning to learn the first four rules of arithmetic, but then an hour on a July morning sufficed for a good beginning with the multiplication table, an accomplishment which he afterwards used to distract and instruct his wife. By associating with the leading men of science of the day he became a scientific amateur of the best type. Always receptive, always interested, unspoiled by over-education, he did a vast amount of good by encouraging others.

An organisation for encouraging the study of natural history in China was formed at a meeting held on September 21, in the lecture room of the department of anatomy, China Medical Board, Peking. In his opening remarks Dr. A. W. Grabau, who was the enthusiastic promoter of the movement, enumerated the existing scientific organisations in China, and stated that he felt that there was a need for a new natural history society. Dr. W. H. Wong, Mr. R. Chapman Andrews, and Mr. Walter Granger also spoke in hearty approval of the organisation of the proposed society. Following a brief discussion, it was decided to adopt the name, "The Peking Society of Natural History." The object of the society is the promotion of the study of, and the spread of interest in, the natural history of China. The following officers have been elected for the coming year: *President*, Dr. G. D. Wilder; *Vice-Presidents*, Dr. W. H. Wong and Mr. Sohtsu G. King; *Secretary-Treasurer*, Mr. N. Gist Gee; *Council*, Dr. A. W. Grabau, Prof. S. C. Lee, Dr. R. K. S. Lim, Dr. H. H. Tan, Dr. Davidson Black and Mr. K. K. Chung. Upon the completion of the organisation of the society, Dr. Wilder addressed the meeting upon the subject "Some Common Birds of Peking." Dr. Wilder had a number of mounted specimens of Chinese birds, and coloured plates of closely related American birds. An interesting feature of the illustrations was some copies by Mr. Kungpah King

of ancient Chinese paintings of birds. These were so accurate that in many instances the birds can be identified from them.

MR. L. C. M. S. AMERY, Colonial Secretary, has written to Sir William Thiselton-Dyer congratulating him upon the completion of the "Flora Capensis." An account was given of the inception of this work and the conditions under which it has gradually advanced to completion, in *NATURE* of September 26, p. 474.

At the annual general meeting of the Cambridge Philosophical Society, held on Monday, October 26, the following officers for the session 1925-1926 were elected:—*President*, Prof. J. T. Wilson; *Vice-Presidents*, Mr. C. T. Heycock, Dr. G. T. Bennett, Mr. G. Udny Yule; *Treasurer*, Mr. F. A. Potts; *Secretaries*, Mr. J. Gray, Mr. F. P. White, Mr. R. H. Fowler, *New Members of Council*, Prof. G. H. F. Nuttall, Dr. J. Chadwick, Mr. H. Munro Fox, Mr. W. B. R. King, and Mr. P. M. S. Blackett.

At the annual general meeting of the London Mathematical Society held on November 12, the following officers for the session 1925-1926 were elected:—*President*, Prof. A. L. Dixon; *Vice-Presidents*, Prof. S. Chapman, Mr. J. E. Littlewood, and Mr. H. W. Richmond; *Treasurer*, Dr. A. E. Western; *Librarian*, Prof. H. Hilton, D.Sc.; *Secretaries*, Prof. G. H. Hardy and Prof. G. N. Watson; *New Members of Council*, Dr. W. E. H. Berwick, Mr. R. H. Fowler, and Mr. E. C. Titchmarsh.

At the annual general meeting of the Junior Institution of Engineers held on November 13, the following officers were elected:—*Chairman*, Mr. A. J. Simpson; *Vice-Chairmen*, Messrs. R. L. Kirlew and C. E. Atkinson; *Hon. Treasurer*, Mr. C. O. Hourant; *Hon. Librarian*, Mr. T. W. P. Mullings; *Members of Council*, The Master of Sempill, and Messrs. S. Dunlop, E. D. Gill, and D. B. Skinner.

THE Peterborough Natural History and Archaeological Society has acquired for its Museum the collection of fossils made by the late Mr. P. J. Phillips from the Oxford Clay of the neighbourhood. When Mr. Alfred N. Leeds died in 1917, Mr. Phillips continued his work in collecting fossil reptiles and fishes, but he was much handicapped by the introduction of steam diggers in the brickfields. Under difficult conditions he obtained several fine specimens, including a unique example of the rare ganoid fish *Heterostrophus*.

THE fifth International Congress on Genetics will be held in Berlin during the latter half of September 1927. Those who attended the fourth Conference in Paris, 1911, will remember that a meeting in Berlin was then planned for 1916. The invitation, which now comes from the German Society for the Study of Heredity, has been unanimously accepted by the six surviving members of the International Committee appointed by the Paris Conference. The arrangements are in the hands of Prof. E. Baur, president of the German Society, with whom are associated Profs. Correns, Goldschmidt, Hartmann, and Nachtsheim.

SIR ARBUTHNOT LANE directs attention in the *Fortnightly Review* for November to the importance of good health and the prevention of disease to the nation as well as to the individual. It is estimated that sickness imposes a burden of 500,000,000l per annum upon Britain in the form of lost earnings alone. Sir Arbuthnot Lane ascribes much ill-health to wrong feeding by the use of over-refined and over-manipulated foods. In order to renew the health of the nation, some medical and non-medical men have founded "The New Health Society," which proposes to begin a nation-wide campaign, and all those who are able and willing to help are requested to communicate with the Secretary at Sentinel House, Southampton Row, W.C.1.

At the annual general meeting of the Philosophical Society of the University of Durham, the following officers and committee were elected.—*President*, The Chancellor of the University; *Vice-Presidents*, Sir Theodore Morison, Sir Chas. A. Parsons, Dr Irvine Masson, Dr A. Robinson, Prof. Havelock, and Mr Wilfred Hall; *Secretaries*, Mr. J. W. Bullerwell and Dr. G. C. Leith; *Editor*, Dr. G. W. Todd; *Librarian*, Dr. F. Bradshaw; *Chairmen and Secretaries of Sections*. (Chemistry and Physics) Mr. P. L. Robinson and Mr. Clarkson; (Geology and Biology) Dr. K. B. Blackburn and Dr. Allan; (Mathematics) Mr. J. L. Burchinal and Mr. Colbourne; (Archæology) Dr. J. Wight Duff and Dr. J. L. Morison; (Applied Science) Dr. Morrow and Dr. Baker; (Philosophy) Prof. Ferguson and Mrs. Alderson.

We learn that the London Mathematical Society intends to publish, in addition to its *Proceedings*, a second periodical entitled *The Journal of the London Mathematical Society*, which will be issued in four

quarterly parts of about 64 pages each, and will be sent free to members. There can be no question that there is room for such a journal, for there is little periodical literature available in the field of mathematics. The new *Journal* is therefore assured of a wide welcome. Its contents will, in the main, consist of original contributions to knowledge, but the papers printed in it will be short and will be selected, so far as possible, from those most likely to appeal to a wide circle of readers. The *Journal* will also contain records of proceedings at meetings, abstracts of papers, obituary notices, and other matters of interest to members. The first part will be published in January next. All business communications should be addressed to the publisher, Mr. Francis Hodgson, 89 Farringdon Street, London, E.C.4.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Two investigators under the Safety in Mines Research Board for research work in connexion with wire ropes used in coal mines—Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (November 27). A temporary advisory officer on farm economics under the Board of Agriculture for Scotland—Secretary, Board of Agriculture for Scotland, York Buildings, Queen Street, Edinburgh (November 30). A professor of philosophy in the University of Bristol—Registrar (February 1). A glassblower at the University of Birmingham—The Professor of Chemistry, The University, Edgbaston, Birmingham. A chief mechanic and instrument maker for the chemical department, University College, Gower Street, W.C.1—The Secretary.

Our Astronomical Column.

A THEORY OF STELLAR EVOLUTION.—Dr. J. H. Jeans contributes a further paper on this subject to the Monthly Notices of the Roy. Ast. Soc. (vol. 85, No. 9). It is concerned with the question of stability, and the directions in which it may break down. In the case of the hottest stars a limit of output of energy is reached when, say, 99 per cent. of the nuclei are stripped of all their electrons. A limit on the side of smaller temperature is fixed in the case of the giants by the development under certain conditions of very large pulsations, such as are conjectured to be present in Betelgeux. In the case of the dwarfs it is concluded that at a certain point in their cooling, rapid contraction occurs, and they end their stellar career in a state like that of the companion of Sirius. But Dr. Jeans notes that unless these stars have very slow initial rotations, the acceleration of rotation that accompanies contraction will cause fission, accompanied by a rise of surface temperature. The end may thus be postponed for a season, but it is only delayed. A geographical analogy is used which enables some of the results of the paper to be stated very concisely. The stars are plotted with ordinate denoting absolute magnitude and abscissa spectral type. They group themselves over an area shaped something like North and South America, but with a widened isthmus of Panama. The giants are in North America, the Pacific coast being the line where 99 per cent. of the electrons have been stripped from the nuclei. The

Plaskett star is appropriately located near the Victoria Observatory. The Canadian Atlantic coast is occupied by the M giants like Antares, the red dwarfs being much lower down.

The masses of the stars are indicated by graphs that are very nearly parallel to the lines of equal absolute magnitude, showing that Dr. Jeans now regards the law of dependence of absolute magnitude on mass as being a fairly close approximation to the truth.

THE NEW 200-INCH MAP OF THE MOON.—This large map of our satellite will be issued, as stated in NATURE of June 13, in sections measuring 22 by 30 inches. The following will be available for distribution by about the end of December, at a price of 4s. per section: Copernicus Region, Tycho R., Mare Crisium, Sinus Iridum, Clavius R., Pitatus R., M. Australe and Plato R. Copies of these, and also of the 60-inch map already published, may be obtained of the author, Mr. H. Percy Wilkins, 46 James Street, Llanelly, South Wales. It is intended that the map shall include every known object on the lunar surface, and the details have been represented with a very careful regard to accuracy. Selenographical literature has been ransacked for details, and every effort made to ensure correctness. The Mount Wilson photos have also been consulted, and the author himself has made a number of telescopic observations which have supplied useful evidence as to certain formations.

Research Items.

MAORI ROCK CARVINGS.—An interesting discovery which will probably prove of some importance in Polynesian ethnology is announced by the Wellington (New Zealand) correspondent of the *Times* in the issue of November 11. Two members of the State Forest Service have discovered a series of rock carvings in a shallow cave 4 ft to 12 ft. deep, 7 ft. high, and extending for a distance of about 80 ft. along the base of the cliff at the edge of the Kaingaroa Plains near Rotorua. Rough bas-reliefs of canoes, some thirty in all, grouped in fours or singly, were found on the back wall of the caves. The canoes vary from 3 ft to 8 ft. in length. A point of considerable interest in them is that while they have high stern frames, the bows differ entirely from the Maori form of canoe in having a beak on the waterline, and a high boarding platform. A further point of difference is that the carving on the sides is in the form of a double spiral instead of the single spiral of Maori art. Dr. Buck, the well-known Maori authority, apparently does not regard this difference as necessarily of fundamental significance, and thinks that the people who made the carvings were at least related to the Maoris. So far, the evidence of human habitation in the caves is confined to the stones of a primitive oven and a stone pestle used for pounding fern-root. It is suggested that this cave may have served as a refuge for the Ngatihotu tribe who inhabited the wide central area of North Island and were dispersed some time after the Maori immigration of the fourteenth century.

THE NORSEMEN—In the *Dalhousie Review* for October, an article by Mr. Victor Plarr surveys some of the evidence for the extension of Norse influence in the tenth and eleventh centuries A.D. A much-disputed question in this connexion is that of the identity of "Vinland," colonised from Greenland by Torfinn Karlsefne in 1003. In the year 1000 A.D. (a year to which Mr. Plarr erroneously assigns the coronation of Charlemagne), Leif, son of Erik the Red, the coloniser of Greenland in 982 A.D., had already reached the mainland of America. Torfinn's colony soon came to an end, possibly, owing to the attacks of natives, the "Skraelings." Mr. Plarr accepts the view that identifies Vinland with Nova Scotia, the "grapes," which the Norsemen are said to have found being, it is suggested, mountain cranberries. He also agrees that the natives with broad faces and ugly hair were Eskimo. This description might equally well apply to some of the Indian tribes, now extinct, who inhabited this part of North America. Mr. Plarr refers briefly to the subsequent history of the Colony of Greenland which died out, the Norsemen being either exterminated by the Eskimo or more probably, he holds, absorbed by them through intermixture. Mr. Plarr, however, does not refer to the very interesting discoveries made in the course of excavations in the graveyard of the Church at Herjolfsnes and described by Nørlund, Hansen, and Jónson in *Meddelelser om Grønland*, vol. 67, 1924, which throw considerable light on Norse culture in Greenland. They included arms, clothes, and personal ornaments, as well as skeletal remains, and a remarkable collection of small crosses in very large numbers.

SNAILS OF THE GENUS PARTULA.—In a publication by the Carnegie Institution of Washington (Publication No. 228a, March 1925), Dr. H. E. Crampton gives the results of a close study of the variation, distribution, and evolution of the genus *Partula*, in the Mariana Islands, Guam and Saipan. This is the

second memoir by the author: the first, published in 1917, dealt with the species of Tahiti. The present volume is illustrated with fourteen plates, four of which consist of beautiful coloured illustrations of the four species inhabiting the islands. The work contains important observations on the ecological characteristics of the Mariana Islands. Though the researches are biological in character, the author discusses the pertinent geological problem as to the prior existence of a great land-mass, or group of land-masses, in the western and southern Pacific Oceans, and from his present studies of the genus *Partula* he concludes that subsidence has been the general process by which an ancient land-mass with a widespread parental stock has been converted into lesser disconnected areas upon which occur the isolated daughter stocks. Some interesting details are given concerning the geological nature of the habitats and the breeding habits of the snails. *Partula salifana* (a new form from Mount Salifan in Guam) has a remarkably heavy shell, though it occurs in a region where no limestone exists. Conversely, *P. fragilis*, which lives in the northern part of Guam, in a calcareous region, possesses an extraordinarily thin and diaphanous shell. From these and other instances it is clearly evident that character of soil is not a factor influencing the density of the shell. *Partula fragilis* also produces eggs before the flaring lip of the aperture (the conventional sign of maturity) is constructed. Further, in contrast with its associates of the Mariana Islands, its egg-capsules are fully impregnated with calcareous salts. The eggs are also remarkable for their great size relative to the size of the parent shell.

MIOCENE SHELLS FROM TRINIDAD.—The object of Mr. W. C. Mansfield in a recently published paper (Proc. U.S. Nat. Mus., 66, Art. 2) is to describe some inadequately known Miocene Gastropoda and Scaphopoda from Trinidad, and to fix the exact geological horizons of the localities whence they were procured. Out of some 92 species considered, 58 are described as new, while 13 remain indeterminate. The ten plates in illustration of 72 of the species are exceedingly well done.

EXTINCT PROBOSCIDEA—In the Proceedings of the American Philosophical Society for 1925 will be found Prof. H. F. Osborn's "Final conclusions on the evolution, phylogeny and classification of the Proboscidea." These conclusions Prof. Osborn himself describes as "very startling and novel to those conservatives who would embrace all the two hundred and ninety odd species described from all parts of the world in two genera, namely, *Mastodon* and *Elephas*." He divides them into twenty-eight genera, which are arranged in polyphyletic lines. In a pamphlet of twenty-eight pages it is not to be expected that the author should enter into detailed reasons for his views, and palaeontologists will await with interest Prof. Osborn's forthcoming monograph on the group.

RAISED CORAL REEFS OF THE RIUKIU ISLANDS AND TAIWAN (FORMOSA).—Coral reefs raised to heights of from 10 to 684 feet above sea-level are found extensively in these islands of Japan. They are nearly horizontal and rest unconformably on Palaeozoic or Tertiary sediments or on igneous rocks. The age of these reefs is discussed by H. Yabe and S. Hanzawa (Science Rep. Tôhoku University, Sendai, ser. 2 (Geol.), 7, 2, 1925). The fossils include numerous species of Foraminifera, Polyzoa, Brachiopoda and Mollusca. The Foraminifera, of which the more important forms are described and figured in this

memoir, differ considerably from those now living in the adjacent seas and suggest that the reefs are of Pleistocene or earlier date; but they are not likely to have been formed during the Glacial Period, since, according to Daly, even so far south as the Hawaiian Islands, the temperature was then too low for reef-building corals to flourish. The evidence at present available suggests that these reefs are either of late Pliocene or early Pleistocene age.

SWEDISH METEOROLOGY—Among recent publications of the Statens Meteorologisk-Hydrografiska Anstalt is Part 4 of the *Arsbok* containing the meteorological observations taken at Swedish stations during 1922, including data collected at several lighthouses. Altogether there are about two hundred meteorological stations. The data from twenty of these are given in full, from some forty the monthly and annual means are given, and from the remainder the monthly and annual temperature means alone. Another annual Swedish publication of interest is *Observations Météorologiques à Abisko en 1916*. For this station in lat $68^{\circ} 20' N$ the observations are given in full. A further contribution to the hydrographic survey of Sweden is contained in Dr G. Wersén's paper on the Lulälven in the series entitled *De Svenska Vattendragens Arealförhållanden*.

THE PASSAGE OF ELECTRONS THROUGH CRYSTALS.—An investigation of the Hall effect produced by applying a magnetic field at right angles to the direction of the photoelectric primary current in diamond and zincblende is described by Dr H. Lenz in the *Annalen der Physik* for September. Two small electrodes touched opposite edges of the elongated crystal through which the current passed, and the magnetic field was at right angles to the broader faces. The sign of the difference of potential between these electrodes caused by the magnetic field was in the case of diamond that demanded by the theory of electronic deflexion. With zinc sulphide it was often reversed and a number of experiments were made in an endeavour to discover the reason, but neither the orientation of the crystal nor want of uniformity in the illumination accounted for the anomalous results. A theory is developed for the normal effect by means of which it is possible to calculate the free path λ and velocity v of the electrons. In one observation with a field intensity of 4000 volts and a magnetic field of 4000 gauss, the Hall effect was 62 volts; this gave $\lambda = 3.4 \times 10^{-8}$ cm. and $v = 6 \times 10^8$ cm./sec. for diamond. The lattice cell of this substance is of the order of 10^{-8} cm., so that the electron does not move from one molecule to the neighbouring one but through a greater distance. Values for normal observations with zinc sulphide are of the same order of magnitude. Observations were made with part of the crystal kept dark, and it was shown that the small current which passed through the dark parts was not caused by diffuse reflected light. No alteration in the diamagnetism of diamond was found when it was illuminated, as seemed possible theoretically. Experiments were made as to the production of conductivity by shooting electrons into the crystal, and others on the photoelectric current at the temperature of liquid air.

THE RAYLEIGH SEISMIC WAVE—In a paper in Part 5 of Vol. 2 of the *Japanese Journal of Astronomy and Geophysics*, H. Nakano discusses the effect of a seismic disturbance in the interior of an elastic solid bounded by a plane face and otherwise extending to infinity. The problem, which is treated in two dimensions only, is an extension of Prof. Lamb's classical investigation of the disturbance arising from a surface pressure. Reference was made to the paper

in NATURE of July 4, p. 27, and, as was remarked there, it is shown that the Rayleigh wave does not appear in the neighbourhood of the epicentre, and at no place is marked by a sudden beginning. At greater distances, the time at which it becomes prominent corresponds to the time taken to traverse the distance measured from the epicentre (and not from the focus). The following further details are of interest. When the initial disturbance is such as would give rise to both compressional and distortional waves, two systems of Rayleigh waves are formed. If the velocities of these three kinds of wave are respectively V_1, V_2, V_3 , the disturbance of the first system is not appreciable at epicentral distances less than $V_3 f / (V_1^2 - V_3^2)^{1/2}$, where f is the depth of focus, the other system first becomes important at distances greater than $V_2 f / (V_2^2 - V_3^2)^{1/2}$. At distances less than this latter, the separation of an L phase from P and S phases will be almost impossible, as at distances between these values the Rayleigh wave (of the first system) arrives between the P and S waves. When this result has been extended to three dimensions, a comparison of records obtained near the epicentre may throw some light on the question of the depths of earthquake foci, but the problem will be greatly complicated by the existence of the granitic layer, which necessitates taking into account the formation of Love waves.

URINARY ANTISEPSIS—The problem of the destruction of harmful micro-organisms in living tissues can only be satisfactorily solved with the discovery of substances which are germicidal when acting in the tissues of the body and at the same time are quite innocuous to the latter. The majority of known antiseptics also injure or destroy the tissues in certain dilutions, so that attention has been directed to the finding of compounds which will exert a specific effect on the organisms in concentrations far removed from those which are toxic. A further complication has arisen from the fact that many substances which are bactericidal in watery solutions lose much of their activity when acting in media containing proteins, such as the body fluids. Moreover, for efficient action in the body, it is frequently necessary for the compound to be conveyed to the site of action by the bloodstream, so that to be of any general use it should be capable of administration by the mouth, being subsequently absorbed in the intestine. In the case of the urinary tract, where, especially in the upper parts, the local application of antiseptics is not easy, the compound must also be one which is excreted through the kidneys. Hexamine, given by mouth, produces formaldehyde in acid urine, but effective concentrations tend to be irritating to the mucosa. V. Leonard (*Jour. Amer. Med. Ass.*, 1924, vol. 83, p. 2005) has been investigating the antiseptic properties of a series of alkyl derivatives of resorcinol and has found that the hexyl compound is forty-five times as efficient an antiseptic as phenol, and yet is comparatively non-toxic. When administered by mouth, it is absorbed in the intestine and excreted in the urine, chiefly in conjugation with some other substance, but also in small quantities unchanged; the urine acquires definite bactericidal properties. When tested clinically in cases of chronic urinary tract infection, it was found to destroy organisms such as the *Staphylococcus* and *B. coli*, and, except in cases with heavy infections of the latter, the urine became sterile after a variable period. The real value of the substance can only be determined after prolonged clinical trial; but the early results suggest that a useful urinary antiseptic has been discovered. Hexyl resorcinol has been put on the market by The British Drug Houses, Ltd., under the name of "Caprokol."

Engineering in Steel Works and Collieries.

THE presidential address of Sir William Henry Ellis, delivered at the Institution of Civil Engineers on November 3, was devoted to a survey of the varied and difficult problems arising in steel works and collieries connected with the great development in mechanical engineering which has taken place during the last forty years. In the early part of this period, steel works engineering was in the hands of good practical men who could only with difficulty move with the times, owing to their lack of knowledge of the technical side of engineering. Low pressure steam was supplied to distant mill and machine shop engines with inevitable waste. Electricity probably did not exist in any of the large steel works. High-speed tool steel was unknown, except Mushet steel, used more for its power of dealing with unexpectedly hard material than as high-speed steel is now used. There was, therefore, a great opportunity for young engineers who had received a combined technical and practical training to share in the work of introducing improved machinery. Economic production was not then so important, and there was comparatively little foreign competition.

The introduction of much higher steam pressures with water-tube boilers, and the advent of electricity, have been the two factors of the greatest help to steel-works engineers. To illustrate the advance—thirty years ago a large machine shop, with its inefficient driving and steam generation and distribution, was converting 15 per cent of the total energy of the coal into useful work. Now, by taking power from one of the latest and most efficient super power-stations in Great Britain, the shop can convert 17.38 per cent of the thermal energy of the coal into useful work. This represents less than one-fifth of the energy available, and hence engineers cannot yet feel satisfied.

Developments in marine engineering caused the introduction of hollow rolling. Up to the time of the *ss Lusitania* turbine drums had been nearly all welded. Sir William was able to apply a process of punching and hollow rolling to the production of drums, in some cases more than thirty tons in weight. The process has revolutionised this important industry, and the results have been entirely satisfactory. What has always been wanted for this purpose has been a satisfactory ingot, cast hollow. At present Sir William and his colleagues are interested in experiments in this direction by means of centrifugal

casting, this point being mentioned as an instance of the importance of the metallurgist and engineer co-operating in the closest possible way.

The physical properties of steel begin to change at temperatures at which steam is now used—750° F and higher, and Sir William is carrying out a research on this point, with his metallurgical colleague Dr W. H. Hatfield. The results of the series of tests being made will be useful to engineers who have to deal with the very high steam pressures employed. If still higher pressures with their corresponding temperatures are introduced, it may be necessary to use alloy steels, the physical properties of which are only affected at much higher temperatures.

No engineers are more definitely entrusted with the lives of their subordinates than mining engineers. Such engineers must possess an extremely varied knowledge, and it is very difficult for the mining engineer of a large colliery to be conversant with all the modern developments in mechanical engineering. Immense progress has been made in recent years in colliery engineering, but much remains to be done, and Sir William urges the desirability of the mining engineer having well-trained mechanical engineers on his staff. Such could render very great assistance to their chief.

Electricity has as yet been introduced into collieries only to a limited extent. No doubt electrical engineers may aid its use by further reducing the liability to sparking. Oil-immersed switches in closed boxes are a considerable safeguard, and the well-thought-out designs of main cables now in use appear to afford great security against risk of short-circuiting in cases of falls of roof. Electric haulage in the workings has largely replaced the practice of surface engines with haulage ropes in boxes down the shafts. Electric winding has been introduced, and is making considerable progress.

Reference was also made to the work of the British Engineering Standards Association, which has now 475 committees and 2300 members. Engineers have shown great public spirit in giving time and attention to this great work—entirely on an honorary basis. Engineers and steel firms throughout Great Britain have generously supported the work by contributions to the funds, but this is a severe tax on industry in the present state of things, and it is earnestly hoped that some measure of Government help may be forthcoming.

The Ignition of Gases.

MANY of the difficulties connected with the ignition of gases are still unfathomed, although the subject has been investigated in one way or another from the time of Davy's well-known researches connected with safety in mines. Measurements of the rate of combustion were first attempted by Bunsen, but it was left to Berthelot, to Le Chatelier, and to Dixon to lay down the methods by which the propagation of combustion in gases could be satisfactorily studied. A further impetus to such investigations came with the development of the internal combustion engine. The recent work of Bone, which indicates that nitrogen plays a considerable part in the process of combustion, is particularly interesting and links the subject with the fixation of nitrogen. It was apt, therefore, that a discussion on the subject should have taken place at the meeting of the British Association at Southampton between the Chemistry and the Engineering Sections.

Prof. H. B. Dixon opened the discussion with a historical survey of the subject. He described Berthelot's discovery of the detonation wave and Le Chatelier's experiments on the same subject at the same date. Le Chatelier discovered three stages of combustion, the stage of uniform propagation, developing into a vibratory type of combustion which precedes the last stage, the initiation of the detonation wave. Prof. Dixon illustrated his remarks by some of his beautiful photographs of the propagation of explosions in mixtures of oxygen with cyanogen, acetylene, and other gases. The explosion wave travels with uniform velocity at the speed at which sound would travel in the gas, taking into account its high temperature and state of compression due to the combustion. Experiments on the measurement of ignition temperatures, which he has recently carried out by two different methods, were described. Tizard and Pye have shown that the delay which

may occur before ignition when a combustible mixture is suddenly compressed adiabatically, depends on the temperature coefficient of the gaseous reaction. Ignition occurs when the heat evolved by the ignition of a gas just exceeds that lost to the surroundings. For the purpose of their experiments, Tizard and Pye used a variable compression machine with a piston which could be stopped by a toggle joint as soon as the gas had been compressed to the desired amount. Prof. Dixon described a similar arrangement by means of which the ignition point of electrolytic gas has been found to be continuously lowered as oxygen is added, in agreement with Le Chatelier's earlier experiments. With methane-air mixtures there is first a lowering, then a rise of the ignition point. It may be mentioned that Tizard and Pye, on the other hand, have found that for heptane-air mixtures the ignition temperature is only changed some 8°C when the heptane-to-air ratio is increased from 1 to 10. Prof. Dixon showed some interesting photographs of explosions occurring in gases compressed by his falling weight method, the combustion does not proceed from a point, but spreads out from an undefined region of luminosity.

The second method used by Dixon for the determination of ignition points depends on allowing a stream of inflammable gas to meet a stream of oxygen or air heated to the same temperature. This is effected by means of two concentric tubes surrounded by electric heating arrangements and so arranged that the gases can be introduced under high pressure or at reduced pressures. So long as the temperature is above a certain point, the gases on meeting ignite at a certain distance from the orifice of the tube. Increase of pressure as a rule decreases the temperature of ignition, but in the case of hydrogen, decrease of pressure also lowers the ignition temperature, even down to a pressure of one-tenth of an atmosphere.

Prof. David described his work on the effect of radiation on the rate of combustion of gas mixtures in a closed vessel. He finds the radiation which is effective is that which is absorbed by the combustible gas, but that no speeding up occurs if there is no nitrogen present. The radiation 4.4μ is absorbed by carbon monoxide and speeds up the combustion of carbon monoxide, oxygen, and nitrogen, while 3.2μ radiation is absorbed by methane and speeds up the combustion of methane, nitrogen, and oxygen mixtures. If the nitrogen is replaced by argon, oxygen, or carbon dioxide, no speeding up occurs. The rate of rise of pressure measured by means of an optical indicator determines the amount of the speeding up. The effect of radiation is shown not to be due to the inhibition of formation of oxides of nitrogen. Prof. David suggests that the radiation

tends to inhibit the temporary association between the nitrogen and the combustible gas, which normally occurs according to his view. Bone has found that nitrogen plays a considerable part in combustions at high pressures, the rate of combustion being much slower when nitrogen is present, the effect being attributed to "activation" of the nitrogen. There result considerably greater amounts of oxides of nitrogen than otherwise would be expected.

When ignition of a combustible mixture occurs in a closed vessel, the rate at which the flame spreads depends on the rate of communication of ignition from layer to layer of the gas and the rate at which the mixture moves under the expansive force of the burning gas. Dr. O. C. Ellis described the method by which he has studied this phase of the subject; work which has been undertaken for the Safety in Mines Research Board. A mechanically controlled camera is arranged to take a series of photographs of the advancing flame, the final photograph has the appearance of being divided into alternate dark and light zones, the exposures being intermittent. For weak mixtures—mixtures near the limit of ignitibility—the lightness of the burning portion compared with the surrounding unburnt gas together with the convection currents which outrun the flame and return upon it, determine the propagation and spread of the flame. For stronger mixtures, burning first occurs at nearly constant pressure; in this case the effect of the enclosure makes itself manifest and the flame moves to the more open space. If there is an opening the flame will move towards it. In a spherical vessel with central ignition, the flame would spread as if to reach all parts of the wall at the same time, but if convection currents have time to influence the combustion, the spread will be quicker in the upward than in the downward direction.

A glow has been found to occur in the flame products and lasts longer than the time taken for the primary flame to spread throughout the vessel. The duration of the afterglow appears to vary with the amount of water present; the glow is greater when argon is used as a diluent rather than when excess of carbon monoxide or nitrogen is present. The glow appears to be due to burning of combustible gas which has escaped the passage of the flame. It is not mainly due to oxidation of carbon monoxide, because in mixtures of oxygen and excess of cyanogen, brilliant periods of residual burning are found.

The incompleteness of combustion and the continuance of processes of combustion after passage of the flame was one of the points brought out by this discussion. Another point, which will no doubt repay further investigation, was the very considerable part played by nitrogen in processes of combustion.

Ornithologists at Berlin.

THE seventy-fifth anniversary of the German Ornithological Society was celebrated in Berlin on October 3-7. The meeting was more like a congress, nearly two hundred members attending, including representatives of eight different countries, in addition to those from all parts of Germany. The programme was full and varied.

On the first evening of the celebrations, an opening address was given by the president, Dr. von Lucanus, and the addresses and congratulations from the ornithological societies of other countries were read and presented. Dr. Ernst Hartert and Mr. Gregory M. Mathews represented the British Ornithologists' Union. Dr. Stresemann compared the status of

ornithology in 1850 and 1925. The lectures referred chiefly to Mediterranean and African ornithology. Lonnberg (Stockholm), on the influence of periods of climate on the African ornith. Spatz (Berlin), on Crete, Hartert (Tring), on Atlas and Sahara, Reiser (Vienna), on the present knowledge of the ornith. of the Balkans; Koenig (Bonn), on the White Nile; Heck and Neumann (Berlin), on Abyssinia, and so on. Other lectures were concerned with bird-migration. Geyr von Schweppenburg (Munden), Drost (Heligoland), Drescher (Ellguth), especially the results of ringing, with systematic studies and distribution: Kleinschmidt, Freiherr von Berlepsch and others, and ecology. Heyder (Oederan). Most interesting

and valuable were Dr. Heinroth's reports on the rearing of many species of birds from eggs, illustrated by lantern pictures. The rest referred chiefly to local German ornithology (Schlott and others).

Many wonderful nature-photographs and films were shown on the screen, among the latter the remarkable "Ufa" films of bird life in Brazil (humming-birds nesting, taken by Baron Dungern), in Abyssinia, East Africa, on the Kurische Nehrung (the ornithological station at Rossitten), and on bird migration, also the medieval method of catching thrushes on migration, which is almost extinct now, only lingering in one place in Westphalia. A striking figure among the ornithologists attending was the ex-King Ferdinand of Bulgaria, whose wide and varied knowledge astonished all those who did not know him. Dinners and luncheons concluded the meeting, as well as inspections of the Zoological Gardens and the Aquarium, the model from which the larger London Aquarium has been built. Last but not least, a flight in aeroplanes took place over the forests and swamps of the Mark Brandenburg, Dr and Mrs. Heinroth explaining where rare birds, such as cranes, various species of *Locustella*, and others, were breeding. E.-H

University and Educational Intelligence.

CAMBRIDGE.—The School of Biochemistry built by means of funds from the trustees of the late Sir William Dunn has during the last few years found difficulty in maintaining itself on its endowments. The demands of biochemical research are bound to be somewhat extensive in material, and its materials are expensive in character. The same trustees recently gave 2000*l* per annum to the Medical Research Council for the next five years; the Council has investigated the accounts of the Biochemical Department, and as a result has forwarded 500*l* towards the maintenance fund of the School.

An extension of the Fitzwilliam Museum is proposed, this extension has been rendered possible by the generosity of two anonymous benefactors who have provided 50,000*l*.

LONDON—Two free public lectures on "The Efficiency of the Heart and its Measurement" will be given by Prof. Y. Henderson, of Yale University, at University College on November 30 and December 1, at 4.30. On December 4, at 5 o'clock, at St. Thomas's Hospital, Prof. F. G. Parsons will give a free public lecture on "The Earlier Inhabitants of London."

MANCHESTER.—Mr. William Myers, formerly Director of Weaving, has been appointed professor of textile technology in succession to Prof. F. P. Slater, who has resigned.

The Council has received the resignation of Dr. Henry Stephen, senior lecturer in chemistry, on his appointment to the chair of organic chemistry in the University of the Witwatersrand, Johannesburg.

The following have been elected Honorary Research Fellows: Ann Bishop, in zoology; Anthony Claassen (Amsterdam), in physics; Dr. H. Raymond Ing, in chemistry; J. N. Ray (Calcutta), in chemistry; Dr. J. C. Smith, in chemistry.

The Knight Travelling Scholarship in Psychological Medicine has been awarded to Mr. L. C. F. Chevens

THE East London College gives particulars in its Calendar for 1925-26 of the School of Dramatic Study and Research recently established by the College Council. The Faculty of Engineering offers, in addition to the usual civil, mechanical, and electrical engineering courses leading to the B.Sc. degree of the Uni-

versity of London, a three-years' course in aeronautical engineering.

WE learn from *Science* that the will of the late James B. Duke, former president of the American Tobacco Co., provides 8,000,000*l* for Duke University, Durham, N.C., 800,000*l* of which is to be used for the establishment of a medical school and hospital. This amount is in addition to the 8,000,000*l* given to Duke University last December by Mr. Duke, to which reference was made in these columns (*NATURE*, December 20, 1924, p. 916).

THE Board of Architectural Education, which, under the Council of the Royal Institute of British Architects, controls education in architecture through the Institute's examinations, has recently been reconstituted in order to make it fully representative of all such educational interests throughout the British Empire. The R.I.B.A. is already in very complete touch with all architectural problems through its allied societies, which represent the profession in specific areas embracing the whole of Great Britain. The Board proposes to delegate executive powers to three committees concerned with schools, examinations, and prizes and scholarships respectively, confining its own work to matters of policy and principle. In addition, there will be a small body of moderators who will deal with the details of the examinations. The numerous schools of architecture and allied arts, polytechnics and art schools concerned, H.M. Board of Education, the Headmasters' Conference, the London County Council and several other bodies, will have seats on the board, which should thus form a very powerful and representative organisation able to stimulate the work of the schools by its visiting committees and to function in the best interests of students and the art and technique of architecture by securing a requisite uniformity in examination matters and educational policy.

THE University of British Columbia, which has long outgrown the quarters in Vancouver City in which it has carried on its work since its establishment in 1915, celebrated on October 16 the opening of its new buildings on the magnificent site, comprising 548 acres on the headland which forms the western extremity of the Point Grey Peninsula, granted for the purpose by the provincial government in 1911. The ceremony was presided over by Sir Arthur Currie, Principal of McGill University, to which Vancouver College, the nucleus of the University of British Columbia, was affiliated from 1899 until 1915. The new buildings, which have cost nearly two million dollars, consist of three permanent units—the science block, library, and power house—and nine semi-permanent, designed for a life of forty years. Among the latter are an applied science building for departments of geology, botany, zoology, forestry, and civil engineering, an agriculture building accommodating departments of agronomy, animal husbandry, dairying, horticulture and poultry, a mechanical and electrical engineering, a mining and metallurgy, and a forest products building. There are at present but three faculties—Arts and Science, Applied Science, and Agriculture. The number of students enrolled in 1924-25 was 1451. The University is in the fullest sense a State institution. It is an integral part of the public educational system of the province, and its policy is "to promote education in general, and in particular to serve its constituency through three channels—teaching, research, and extension work." A principal aim of the extension work is to inform the people of the province of the results of special work by the staff. Last year the provincial legislature granted 480,000 dollars for the upkeep of the University.

Early Science at Oxford.

November 22, 1687. Some letters were read from Mr Cluner with Mr President's answers concerning the squaring the Circle, and Parabola. Some moulds of old coins were communicated by Mr Musgrave sent by Mr. Hughs out of Somersetshire. Some stones communicated by Mr Musgrave taken out of the ureters of a man, being 7 small ones, and one very larg being an inch long, and above an inch round. An account of the dissection of Mr. Castillion who dyed of a universal Tabes, and cancer of the Stomach, was also communicated by Mr. Musgrave.

November 23, 1683. Mr Piggot informs ye Company, that filing takes off ye attraction of iron; as, he says, was found true by a late experiment; but this was afterwards found to be true, onely when ye Iron was filed *all over*. Dr Plot tells us farther, that of 22 sorts of Iron-ores, which were dug in Sussex, and he has by him, not one applies to ye magnet. It was ordered to be tried whether a peice of this ore will apply after a very great Calcination? as also whether a magnet, and peice of iron, being put into Mr Boyle's Pump, and ye air exhausted, will draw one ye other? A Catalogue of Bodies Electricall was ordered to be brought in. 'Twas ordered to be tried, whether electricall bodies will operate, as such, in vacuo. Severall of ye stones belonging to Mr Ashmole's Musæum, were examined, as to their Electricity; A sapphire, a Bohemian granate, a spinall ruby, a balass ruby, and a hyacinth were observ'd to be electricall.

Dr Pit was pleased to promise, that ye next time we met, he would give an account of some experiments relating to Digestion.

November 23, 1686. Mr R P, vicar of Kildwick in Yorkshyre, sent an account of a strange *eruption of waters*, June 1686, in Craven.

An account was communicated from one Tho. Wells in Oxford who cures himself of the *Gout* by drinking Beer, wherein mustard-seed has been Steeped.

He likewise gives us an account of the great *herring fishing* trade lately begun in Summersetshire, by ye coming of the Herrings up the Severn which was not known before this year.

All things were prepared by Mr Caswell for observing ye Eclipse on the Friday night, but the cloudinesse of the night hindred him from makeing any observations.

Dr. Plot communicated an account of a monstrous *Cucumber* growing in the garden of Dr Wm Jacob at Canterbury. Ye length was 3 foot ten inches and a quarter, ye girth circumference 9 inches.

November 24, 1685. An Experiment was tried before ye Society which shewed, that 12 ounces of water was enough to buoy up a vessell of more than two pounds weight, so that ye vessel did plainly swim. This experiment was made use of to confirm ye 10th Prop: of ye 4th book of Stevinus's Staticks concerning ye different pressure of ye same quantity of water in vessells differently shaped.

A Description of a new sort of Pump was read. The contriver of it has made some tryall of it, and thinks it will be usefull, where there is occasion to pump much water, and especially in deep pits.

Dr Plot shewed us ye *Corallum Album Fistulosum* of Ferrante Imperato; and another Corall with fine small threads of a dark red not described by any, that we know of. He also shewed us an egge of the Sea-Tortoise, which was somewhat bruised, but seemed to have been exactly globular, and a piece of whitish substance very light, called cream of Soap, said to be made by ye nuns of Prussia.

Societies and Academies.

LONDON

Royal Society, November 12.—Sir William Bragg and R. E. Gibbs: The structure of α and β quartz. The original investigations upon α quartz left four unknown parameters, namely, the distance of the silicon atoms from the trigonal axis and the spatial relations of the oxygen to the silicon atoms. One parameter could be estimated from the results of intensity measurements, but more data were required. At 573°, α quartz undergoes a transition to the β hexagonal variety, probably with little structural change. If, therefore, the β structure could be determined, that of the α would become nearer solution. The evidence of theoretical calculations and of X-ray rotation photographs of quartz above its transition point shows that in the β structure the oxygens surround the silicon atoms tetrahedrally, and that the spirals parallel to the principal axis are formed by alternate atoms of silicon and oxygen. Atomic dimensions are consistent with the normal values, and the structure agrees with requirements. The structure is consistent with the development of pyro- and piezo-electricity and compatible with the theory of electrical conductivity.—Lord Rayleigh: The light of the night sky: its intensity variations when analysed by colour filters. (i.) The observations now extend over nearly 2½ years. The intensities of the various chromatic components of the light undergo important variations when measured against a fixed terrestrial standard, and the components also undergo considerable relative variations when measured against one another. Attention is primarily concentrated on the spectral region transmitted by a screen designed to isolate the green auroral line as nearly as possible. Notwithstanding the definite relative variations, this auroral intensity is highly correlated with the intensity in the orange-red region, not so highly with the blue region, and still less with the photographic region centred near $\lambda 4300$. The values found for the correlation coefficients are: Aurora-red, 0.70, Aurora-blue, 0.66, Aurora-photographic, 0.44. On the other hand, the auroral intensity is not correlated appreciably with the degree of magnetic disturbance or the height of the barometer. The connexion with the sun-spots, if any, is not yet apparent. The intensity does not vary measurably with the sun's distance below the horizon, within the limits, evening and morning, when twilight is excluded. Parallel observations of the auroral intensity at Pasadena, and at Mt. Wilson, California, are, in the mean, more than double those prevailing in England.—W. A. Bone and G. W. Andrew: Studies upon catalytic combustion. Pt. 1. The rate of combination of a (moist) theoretical mixture of carbon monoxide and oxygen ($2\text{CO} + \text{O}_2$) in contact with a gold surface in a "normal" state of activity at 300° C or thereabouts is always proportional to its pressure. The "normal" catalysing power of the surface at such a temperature can be (a) greatly diminished by either keeping it at the room temperature for some days or prolonged evacuation of it at 300° C, or (b) highly stimulated by previous exposure to either of the two reacting gases at 300° C. Whenever, starting with the surface in a state of "normal" activity, either one or other of the two reacting gases is present in excess, the subsequent rate of combination, which rapidly becomes "supernormal," is always proportional to the partial pressure of the carbon monoxide. It is considered that an "activation" occurs of both of the combining gases of the surface, which is not confined to superficially "adsorbed" gas-films of monomolecular thickness, but extends also to more deeply occluded gases.—O. W. Richardson

and F. C. Chalklin: The excitation of soft X-rays. When the curves between efficiency of X-ray emission and primary voltage using a photo-electric method are plotted, a number of abrupt changes of slope are observed. Within the range 40-600 volts, four such discontinuities, of which the lowest one is complex, have been observed for carbon, 13 for tungsten, 10 to 13 for nickel, and 15 for iron. Some of these discontinuities are due to the excitation of characteristic X-rays and allied phenomena. The total X-radiation per electron impact is approximately proportional to the square root of the atomic number, for the target elements tested, and to the square of the energy of the impinging electrons.—R. Campbell Thompson: On the chemistry of the ancient Assyrians. Ashurbanipal's library of clay tablets inscribed in cuneiform in the seventh century B.C., excavated at Nineveh and now preserved in the British Museum, included tablets now in 24 fragments, giving the native Assyrian receipts for making glazes, glass, and their colours. The first section of these chemical texts describes the furnace for the glass, the magical formulae necessary, and the fuel of *Styrax-logs. The next few sections detail the ingredients for making the celebrated blue glaze, first with a frit of 10 parts sand, 15 alkali, and $1\frac{1}{2}$ *Styrax-gum, followed by copper-scale, prepared by heating, and the subsequent directions for its admixture. Glasses were of three kinds: *surcu* (60 parts sand, 180 alkali, 5 salt(petre), 2 chalk); *dushu* (crystal) (60 sand, 180 alkali, 6 salt(petre), $\frac{1}{2}$ chalk, 3 oxide of tin (?), 3/10 oyster shell (?)), and *zuku* (components mutilated). The most interesting receipt is to make 'bahrā'-stone (red coral (?)), approximately 7200 parts of *zuku*-glass, 32 oxide of tin (?), 20 antimony, some salt(petre), and 1 part of gold, which suggests the well-known Purple of Cassius.—J. E. Lennard-Jones: On the forces between atoms and ions. The repulsive fields of 20 atoms and ions have been determined. Applications of the results are made to evaluate the interatomic distances of 32 crystals, including 16 alkaline halogens. In the case of the latter, the calculated values are found to lie, with one exception, within 1 or 2 per cent of the observed distances.—F. G. Mann and Sir William Pope: β , β' , β'' triaminotriethylamine and its complex metallic derivatives. The preparation of triaminotriethylamine hydrochloride from bromethylphthalimide has been improved. This amine acts as a tetra- or as a tri-acidic base, according as the tertiary nitrogen atom exerts or fails to exert its basicity. Consequently, two distinct series of aurichlorides, platinumchlorides, and rhodochlorides have been prepared. Co-ordinated derivatives of the base with divalent and tetravalent metals have been prepared: in all these compounds the amine acts as a tetracidic base, and satisfies four co-ordination valencies of the metallic complex.—K. R. Ramana-than: The structure of molecules in relation to their optical anisotropy. Pt. II.—E. V. Appleton and M. A. F. Barnett: On some direct evidence for downward atmospheric reflection of electric rays. In a study of signal variations at short distances (18-100 miles) from a short-wave transmitter, by changing the wave-length of the transmitter continuously through a small range, interference phenomena were observed, indicating the existence of two or more rays. Experiments made at Cambridge on the signals from London (2LO) have shown that the signal variations are greater on a loop antenna than on a vertical aerial, the ratio of the variations indicating that the direction of propagation of the down-coming waves makes an angle of 65°-70° with the ground. The existence of down-coming waves has been demonstrated at distances of 18 miles from a transmitter, which indicates that the ionised layer reflects waves at almost

normal incidence. The rays returned from the upper atmosphere are of complex polarisation, as is to be expected according to the magneto-ionic theory of wave propagation, and are of sufficient intensity to be responsible for the directional errors experienced in short-distance transmission. An inferior limit for the number of electrons per cubic centimetre in the ionised layer is 10^6 .

Royal Microscopical Society, October 21.—R. J. Ludford. Short osmic acid methods for the demonstration of the cytoplasmic inclusions of cells. After a number of experiments carried out with the view of shortening the technique previously described, shorter methods have been worked out, which give quite as satisfactory results. The tissue is fixed in corrosive-osmic, and the osmication is carried out with 2 per cent. osmic acid at 30° C., for three days, followed by water at the same temperature for another day, to complete the reduction of the acid. An alternative method is to begin the osmication in 2 per cent. osmic acid at 35° C., and dilute daily with an equal quantity of distilled water. At the end of the third day transfer to water also at 35° C. After sections have been cut, mitochondria can be stained by the modified acid-fuchsin method already described.

Physical Society, October 23.—H. E. Smith: The influence of strain on the Thomson effect. For piano-forte steel, charcoal iron, constantan and nickel, the Thomson coefficient numerically decreases with tension until the elastic limit is reached, after which it increases. With removal and restoration of tension a new definite cycle is followed. The Thomson effect in tungsten, here measured for the first time, increases with tension and also follows a cycle. No change is noticed in brass or German silver. Heterogeneity was not present in the specimens investigated.—W. Mandell: The measurement of temperature by thermocouples in unequally heated enclosures. In doing this, the recorded temperature depends upon the thickness of the couple, the nature of the walls of the enclosure and the nature of the gas. An explanation is suggested based upon the fact that the amount of radiation received and emitted by a couple depends upon its position in the enclosure, and that the amount of energy transferred to it by molecular impact varies with the nature of the gas.—W. Clarkson. On the flashing of certain types of argon-nitrogen discharge tubes. Discharge tubes having various types of electrodes, and in which the filling gas, a mixture of argon and nitrogen, had a wide pressure range, were used. At higher pressures the discharge is no longer of the "glow" type, but takes place between definite points on the electrodes.

Royal Anthropological Institute (Indian Section), October 27.—S. M. Edwards: The population of Bombay City. remarks on its origin and growth. The history of the City falls into five well-defined periods, each of which contributed certain distinct elements of population. During the first four periods Bombay consisted of seven separate islets, which were welded together during the fifth or English period. The prehistoric period contributed the fishing-population of Kolis and their aboriginal goddess, whose title has given the name Bombay to the city and western presidency. The second or Hindu period, which lasted until A.D. 1300, witnessed the arrival of the Parsis and Beni-Israel in Western India, as well as the mixed Mohammedan population, resulting from the union of Arab traders and refugees with Hindu women of the coast. The rule of the local Silahara chiefs was responsible for the immigration of various castes of Hindus, notably the Pathars, Prabhus and Panchkalshis, and probably also, the

Bhandaris, who cultivate and tap the liquor of the coco-nut palm. During Mohammedan rule the famous shrine of the Saint at Mahrin was established, while under the dominion of the Portuguese (A.D. 1524-1661) the Bombay population was considerably reduced and dispersed by the proselytising tyranny of the Portuguese religious orders, their only contribution to the population being the native Christian and Indo-Portuguese or "Topass" elements. The customs of some of these converts present an interesting study. The real growth of population commences with the arrival of the English in Bombay, and can be traced to certain definite political and domestic events, including the steady reclamation of the island from the sea, and the foundation of the local textile industry. In A.D. 1660 the population was said to be 10,000, to-day it numbers more than one million, including persons from all parts of India and Asia, Europe, Africa, and America.

CAMBRIDGE

Philosophical Society, October 26.—Sir Ernest Rutherford and W. A. Wooster. The natural X-ray spectrum of radium B—C. D. Ellis and W. A. Wooster: (1) The atomic number of a radioactive element at the moment of emission of the γ -rays. The atomic number found in the case of radium B (82) is 83, and in the case of radium C (83) is 84. Since both these bodies disintegrate by emitting an electron from the nucleus, these results show that the γ -ray emission occurs after the actual disintegration. (2) The β -ray type of disintegration. In a β -ray disintegration the γ -rays are emitted after the electron has left the nucleus. This result is discussed and a general picture given of the β -ray type of disintegration.—D. H. Black. The analysis of the β -ray spectrum due to the natural L-radiation of radium B—D. R. Hartree: Doublet and triplet separations in optical spectra as evidence whether orbits penetrate into the core. The separations of terms of all available doublet and triplet spectra are compared with Landé's formula, which is derived on the assumption that the orbit of the series electron penetrates into the core. If in any actual case the orbit does not penetrate, no agreement is to be expected. The results agree in most cases with the assignment of quantum numbers proposed by Bohr; except for lithium-like atoms, all p -terms correspond to penetrating orbits.—H. F. Baker. On the reciprocation of one quadric into another—P. A. MacMahon. The enumeration of the partitions of multipartite numbers—R. H. Fowler. Assemblies of imperfect gases by the method of partition functions. Theorems of statistical mechanics in a mathematically simple form, applying to assemblies of isolated systems, such as perfect gases or single crystals, are extended to imperfect gases, where the free atoms and molecules continue to act on one another with forces of short but not negligible range, and again with long range forces obeying the inverse square law. We thus recover in a new setting the usual results of the theory of van der Waals, and examine the basis of the important combined use of Boltzmann's and Poisson's equations.—J. P. Gabbatt. Note on the pedal locus.—L. H. Thomas. An extended form of Kronecker's theorem, with an application which shows that Burgers' theorem on adiabatic invariants is statistically true for an assembly.—W. F. Sedgwick. On the series of forms of Jacobi's rotating liquid ellipsoid.

DUBLIN.

Royal Irish Academy, November 9.—Kenneth C. Bailey: The estimation of aldehyde in alcoholic liquors by means of Schiff's reagent. The estimation,

as usually performed, often gives very inaccurate results. The development of a colour from Schiff's reagent and alcohol, which is apparently not due to aldehyde originally present, is noted, and possible explanations suggested. A reliable technique for the estimation is proposed.

LEEDS.

Philosophical and Literary Society, November 3.—C. K. Ingold. Structural relations of natural terpenes. Utilising the principle that gem-dialkyl and allied groupings appear in natural compounds only in such positions that they stabilise the structure, the number of possible natural terpene structures is shown to be limited and to conform to all recorded observations, except one—the alleged occurrence in Nature of sylvestrene.—J. Ewles. The luminescence of solids. The lines along which the theory of luminescence of solids is being developed are indicated. It is suggested that the slight trace of impurity necessary for luminescence enters into the crystal lattice of the substance in the form of solid solution. The impurity nuclei, with their linked solvent atoms, are supposed to act as the radiating system.—G. F. Brett. The photographic effect of slow electrons. For slow electrons ordinary films and plates are unsuitable and a method is described in which a fluorescent substance in the form of a thin layer of special grease is applied to the film. By this method, electrons having speeds of at least 65 volts and upwards can be registered photographically.—H. M. Dawson and J. S. Carter: A contribution to the study of the ionisation of strong electrolytes. The solubility of iodine in sodium chloride solutions of widely varying concentration shows that the halogen combining capacity of the salt is independent of its concentration. The condition of the dissolved salt thus appears to be unaffected by change of concentration in agreement with the theory that strong electrolytes are almost completely ionised.—E. Rhodes and R. M. Woodman: The fatty substances of the plant growing point. Data are supplied as to the fats present at the growing apices of root and shoot of the broad bean at different stages of growth. These are supplemented by data as to the fats formed in excised root tips kept growing in culture media under sterile conditions.—J. H. Priestley and G. Redington. The effect of diurnal periodicity upon fibre production. Plants have been grown under artificial light, some remaining continuously illuminated, other being removed to a dark chamber for 8 or 16 hours each day. A diurnal periodicity in illumination greatly favours the production of sclerenchyma.—W. T. David, S. G. Richardson, and W. Davies: The effect of infra-red radiation upon combustion of gaseous mixtures containing nitrogen. The rate of combustion of inflammable gaseous mixtures contained in a closed vessel is increased by introducing radiation into the reacting system provided that (1) the radiation is of the type which is absorbed by the combustible gas, and (2) that nitrogen is present in the mixture.

SHEFFIELD

Society of Glass Technology, October 21.—T. C. Moorshead. (Presidential Address) The glass bottle industry and its future developments. The last quarter of a century saw practically a revolution in the manufacture of glass containers. About 1900, two ideas, totally different in principle, suddenly blossomed forth. One was Homer Brooke's idea of feeding a machine with a stream of glass flowing by gravity from the furnace—the other was the application of the suction principle in feeding the machine, a process developed by M. J. Owens. From this

time progress in the development of mechanical devices for glass manufacture has been rapid. To-day many bottle manufacturing plants are mechanically operated practically throughout. In the firm belief in the feasibility of the principle of feeding and melting the batch at the same time, and with the view of blazing the trail for future and more extensive research work, the United Glass Bottle Manufacturers, Limited, are arranging to finance some experimental work based on the principles outlined by Mr. Alex. Ferguson, and described to the Society of Glass Technology in May 1923. The theoretical advantages claimed for the new process are: (1) Smaller radiating surface per ton of furnace melting capacity, the ratio being approximately 2 to 1. (2) More intimate contact between the flame and the constituents of the batch. The first mentioned, however, depends upon (a) the feasibility of melting the batch, when pulverised and fed into the furnace in fine powder, in the short time of passage through the flame; (b) the corrosive effects of the stream of melted glass on the side walls of the funnel-shaped melting chamber, as well as the effect on the glass itself.

PARIS

Academy of Sciences, October 5.—Maurice Hamy: Study of the photography of stars in full daylight.—H. Deslandres: Complementary researches on the structure and distribution of band spectra. Further considerations regarding the formula giving the frequency as a multiple of the universal constant 1062.5.—R. Szilard: A new method of distinguishing culture pearls. The method is based on the difference in the densities of natural and cultivated pearls. The pearls are placed in a tube with methylene iodide, and bromonaphthalene added drop by drop, with shaking. For a certain mixture, some float at different heights, others go to the bottom of the tube: the latter are the culture pearls. This test is not applicable to 'blue' pearls.—R. H. Gernay: The cycles of periodic integrals infinitely near partial differential equations of the first order.—A. Dufour: Michelson's experiment. A correction of an earlier communication.—Mlle. Anastasie Anargyros: Colloidal oxide of manganese. Potassium permanganate, reduced in the presence of sodium protobate, gives stable colloid solutions of manganese dioxide. After purification by prolonged dialysis, the colloid exhibits Brownian motion, is electronegative, and remains unchanged for a month.—Alfred Schoep: Buttgenbachite, a new mineral. This mineral was found adhering to cuprite from the Belgian Congo, and has the composition $18 \text{ CuO} \cdot 3 \text{ Cl} \cdot \text{N}_2\text{O}_5 \cdot 19 \text{ H}_2\text{O}$.—R. Weil: The synthesis of cristobalite in the wet way. Precipitated silica and sodium silicate solution, heated in a steel tube at $650^\circ\text{--}750^\circ \text{C}$. for seven to fifteen hours, gave crystals of quartz and cristobalite.—G. Georgalas and N. Liatsikas: The new eruption of the volcano of Santorin (August 1925). Details of observations made during the eruption, July 28–August 23.—Henry Hubert: The seasonal clouds of the rains in western Africa.—L. Petitjean: The distribution of the forces in the neighbourhood of a discontinuity.—Jacques Pellegrin: The presence in Morocco of *Pelobates caltripes*.—Armand Dehorne: Observations on *Lagis Koreni*: hermaphroditism, paramyelinic formations in the ovule; nephridian cells with capsules containing a central body.—G. Mouriquand and Leulier: Avitaminosis C (with or without tuberculosis) and cholesterol of the blood and suprarenals. It is shown that both chronic and acute avitaminosis C is accompanied by profound changes in the metabolism of the

cholesterol of the suprarenal capsules. The trouble is aggravated when associated with tuberculosis.—A. Gruvel and B. Conseil: Remarks on the biology of *Orcinus alalonga* in the sea near the Antilles.—S. Métalnikov and Rapkine: Phagocytosis and immunity in the blastula and gastrula of sea urchins. The larva of sea urchins, even in the blastula and gastrula stages, possesses a marked immunity against *Bact. tumefaciens* and *Contacuzène's* micro-organism. On the other hand, it is very sensitive to the cholera bacillus. It is shown that the immunity against the first two organisms is due to phagocytes detached from the summit of the primitive intestine.—E. Grynfeldt and H. J. Guibert: The alterative lesions of the lamellar tissue in the course of experimental inflammation.—Léon Binet and René Fabre: The elimination of camphor and oil, after experimental injection of camphorated oil. The camphor is rapidly eliminated, mainly through the kidneys. The oil remains for some weeks at the place of injection, and is slowly absorbed by leucocytic action.

CAPE TOWN.

Royal Society of South Africa, September 30.—James Moir: Colour and chemical constitution. Pt. xxi.: An astronomical orbit theory of colour with special reference to the dicyclic azo dyes. In the monocyclics, colour is built up from one ring by adding a hapton; in the dicyclics colour is built down by bending the chain. The mathematical theory in the paper does not supplant the author's earlier factorial theory, but endeavours to give it a physical basis.—C. Pijper: Note on witchcraft in Europe: the case of Anne Boleyn. The motive for the execution is considered to have been the belief that Anne Boleyn was an adherent of the witch-cult. The author bases his study on the work of M. A. Murray.—Ernest George: (1) The preparation of umbelliferone.—(2) Some phthalein analogues.—T. R. Sim: The Bryophyta of South Africa.

SYDNEY.

Linnean Society of New South Wales, August 26.—E. C. Chisholm: The Comboyne Plateau: its general conformation and flora. In this paper the flora of the Plateau is briefly dealt with from an ecological or economic point of view; and a list is given of the plants collected on the Plateau arranged in botanical sequence.—John R. Eyer: A comparison of the male genitalia of the Palæosetidae with those of other Lepidoptera Homoneura. From a tabulation of the archaic characters of the genitalia, it is shown that the male genitalia of Palæosetids possess certain structures quite similar to those in Prototheoridae and Hepialidae. They retain more archaic characters than these two families and stand intermediate between Prototheoridae and Micropterygidae, the latter family having the greatest number of archaic genitalia characters among the Lepidoptera Homoneura.—Rev. H. M. R. Rupp: Notes on species of *Pterostylis*. Of the forty-three known species of *Pterostylis* the author has obtained thirty-two and has made extensive field notes regarding their character, habit and geographical distribution. One of the finest species, *P. baptista*, was originally found in a peaty swamp near Fivedock and was thought to be rare but has been found to be fairly abundant at Bulladelah.—Prof. M. Bezzi: On the tachinid genus *Euthera*, with descriptions of new species from Australia, Africa and South America. A key is given for the determination of the seven known species of *Euthera*, four of which are described as new.

Diary of Societies.

SATURDAY, NOVEMBER 21.

BRITISH MYCOLOGICAL SOCIETY (at University College), at 11 A.M.—S. Dickinson New Method of Isolating Single Spores.—W. J. Dowson Fall of Apples Associated with Core-rot due to *Sclerotinia Frustrigena*.—J. Ramebottom Fragmenta Mycologica IV.—A. Smith. Penicillium Diseases of Gladiolus and Narcissus.—A. Lorrain Smith Lichen Dyes.—E. M. Wakefield and W. Buddin: Life-history of a Fungus Parasitic on *Antirrhinum Majus*.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (jointly with Institute of Mining and Mechanical Engineers) (at Neville Hall, Newcastle-upon-Tyne), at 3.—R. Dowson: The Steam Turbine in the Electrical Industry.

MONDAY, NOVEMBER 23

NORTH STAFFORDSHIRE INSTITUTE OF MINING ENGINEERS (Annual Meeting) (at Central School of Science and Technology, Stoke-on-Trent), at 8.—Presidential Address.

INSTITUTE OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—E. E. Tasker and others Discussion on The Testing of Large Electric Plant.

INSTITUTE OF ELECTRICAL ENGINEERS (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—T. Carter The Engineer his Due and his Duty (Lecture).

ROYAL SOCIETY OF ARTS, at 8.—Dr R. Lessing Coal Ash and Clean Coal. I. (Cantor Lecture.)

ROYAL GEOGRAPHICAL SOCIETY (at Eolian Hall), at 8.30.—Dr. H. Gordon Thompson From Yunnan-Fu to Peking along the Tibetan and Mongolian Borders.

CHEMICAL INDUSTRY CLUB

TUESDAY, NOVEMBER 24.

ROYAL DUBLIN SOCIETY, at 4.15.—K. G. Bailey The Action of Radon on Mixtures containing Ammonia and an Oxide of Carbon.—P. A. Murphy and R. McKay Methods for Investigating the Vicious Diseases of the Potato, and some Results Obtained by their Use.—E. J. Sheehy An Examination of the Errors Introduced by the Various Approximate Methods used for Estimating the Total Quantities of Milk and Butter Fat Produced during a Lactation.

INSTITUTE OF AUTOMOBILE ENGINEERS (at 88 Pall Mall), at 6.30.—Discussion on Gradient Meters and Tire Pumps.

INSTITUTE OF MARINE ENGINEERS, at 6.30.—O. Brunler Internal Combustion Boilers.

INSTITUTE OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—F. Carter The Engineer his Due and his Duty (Lecture).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Capt. J. Noel: The Story of the Mount Everest Film and Slides.

ROYAL ANTHROPOLOGICAL INSTITUTE (at Royal Society), at 8.30.—Sir Arthur Evans: Early Nilotie, Libyan, and Egyptian Relations with Minoan Crete (Hurley Memorial Lecture).

WEDNESDAY, NOVEMBER 25.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at Neville Hall, Newcastle-upon-Tyne), at 7.15.—C. H. Cooke Lubrication.

INSTITUTE OF AUTOMOBILE ENGINEERS (North of England Centre) (at Houldsworth Hall, Dewsbury, Manchester), at 7.15.—Capt. R. K. Hubbard The Requirements of the Military Motor Vehicle.

SOCIETY OF CHEMICAL INDUSTRY (Nottingham Section) (at University College, Nottingham), at 7.15.—A. T. King Migration of Alkali (in Wool), or Indicator-dyed Wool.

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications Section), at 7.30.

ROYAL SOCIETY OF ARTS, at 8.—D. Greenhill Colour Printing.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (at 1 Wimpole Street), at 8.30.—Dr. E. Glover The Neurotic Character.

THURSDAY, NOVEMBER 26.

ROYAL AERONAUTICAL SOCIETY (at 7 Albemarle Street), at 5.30.—A. H. R. Fadden Installation Problems in Air-cooled Engines.

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section), at 5.30.—Dr. L. J. Llewellyn Diathesis (Presidential Address).

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Brig.-Gen. R. J. Keutish Playing-Fields for Children.

INSTITUTE OF STRUCTURAL ENGINEERS (Yorkshire Branch) (at Great Northern Hotel, Leeds), at 6.30.—E. C. Snelgrove Fieldwork in Central Africa.

INSTITUTE OF AUTOMOBILE ENGINEERS (Luton Graduates' Meeting) (at Luton), at 7.30.—W. B. Flint The Motor Omnibus as a Means of Public Transport.

INSTITUTE OF CHEMISTRY (Edinburgh and East of Scotland Section) (jointly with Society of Chemical Industry, Edinburgh and East of Scotland Section) (at 36 York Place, Edinburgh), at 7.30.—J. W. Mitchell Fuel.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Neville Hall, Newcastle-upon-Tyne), at 7.30.—G. S. Baker: Measured Mile Trials and other Ship Propulsion Data. Part II.

CHEMICAL SOCIETY, at 8.—Prof. R. Robinson Recent Researches on the Structural Relationships of some Plant Products (Informal Lecture).

INSTITUTE OF CHEMISTRY STUDENTS' ASSOCIATION (London), at 8.—Impromptu Debate.

FRIDAY, NOVEMBER 27

ROYAL SOCIETY OF MEDICINE (Balneology and Climatology Section, jointly with International Society of Medical Hydrology), at 10 A.M.—Discussion on The Treatment of Rheumatism in Industry.

INSTITUTE OF AUTOMOBILE ENGINEERS (at Olympia), at 11 A.M.—O. H. Macmillan The Installation of Small Marine Motors.—At 2.30.—Basil H. Joy The Advantages of Twin-Screw Installation for Motor Boats.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—R. G. Linnon Atomic Dimensions.—W. E. Benton On Edge Tones.—J. J. Manley The Spectroscopic Determination of Minute Quantities of Mercury.—Demonstration by G. R. Mather of an Instrument for Imitating the Eastward Motion of Bodies Dropped from a Great Height.

SOCIETY OF CHEMICAL INDUSTRY (Glasgow Section) (jointly with Institute of Chemistry) (at 29 Elmbank Crescent, Glasgow), at 7.—W. G. Hiscock The Heat Evolved during the Detonation of Explosives.

INSTITUTE OF ELECTRICAL ENGINEERS (London Students' Section), at 7.—A. P. Hill The Tungar Rectifier.

JUNIOR INSTITUTION OF ENGINEERS, at 7.—E. Granville-Smith The Engineer and his Relationship to the Traction Industry.

INSTITUTE OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—W. P. F. Fanghanel and others Discussion on The Work of the Mechanical Engineer in Non-Engineering Industries.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch, Graduate Section) (at Middlesbrough), at 7.30.—W. L. Rigby Steel Framed Structures.

SATURDAY, NOVEMBER 28.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Associates and Students' Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—S. L. Pepper Mining Royalties, with Special Reference to Surveying.—Papers open for further discussion.—Underground Efficiency in Collieries, with Special Relation to Labour, by H. R. Houston; Modernisation of Old Collieries, by H. P. Mould.

PUBLIC LECTURES.

SATURDAY, NOVEMBER 21

HORNIMAN MUSEUM (Forest Hill), at 3.30.—G. O. Robson Animal Life in the Depths of the Sea.

TUESDAY, NOVEMBER 24

KING'S COLLEGE, at 5.30.—Miss Hilda D. Oakley: The Philosophy of Aristotle: The Highest Good for Man: The Best and Actual States.

WEDNESDAY, NOVEMBER 25

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Dr. W. M. Willoughby Infection in Ships and the Prevention of spread therefrom.

CHEMICAL SOCIETY, at 5.30.—Dr. E. A. Koen The Physicist in Agriculture, with Special Reference to Soil Problems (Lecture in the series "Physics in Industry," given under the auspices of the Institute of Physics).

UNIVERSITY COLLEGE, at 5.30.—G. F. Barwick The British Museum for Research Purposes.

THURSDAY, NOVEMBER 26

KING'S COLLEGE, at 5.15.—E. L. Woodward Thomas Hobbes.—At 5.30.—M. Bera The Story of the Creation and the Flood in Roumanian Folklore (Succeeding Lecture on December 3.)

SATURDAY, NOVEMBER 28.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—E. Lovell The Luck of an Old Shoe.

SATURDAY, NOVEMBER 28, 1925.

Research in Mental Disorder.

WE welcome the address of the Earl of Birkenhead at the Royal Society of Medicine lately as evidence that it is at last appreciated by others, besides a very few specialists, that far graver and more urgent criticisms may be launched against the present lunacy administration than have yet reached public notice. So long as fault-finding was based solely on allegations of abuse of official power, entailing injustice or ill-treatment of individuals, it was clear to most people who had any understanding of the facts that agitation might be futile or mischievous, but it could do nothing to advance our methods of dealing with the vast problem of mental unfitness, either medically or socially.

Lord Birkenhead displayed a caution and moderation proper to a lay approach to a highly specialist problem when he "doubted whether medical science, medical care and nursing efficiency had made the advance in dealing, from the preventive point of view, with mental cases, that, even in his lifetime, they had made in almost every branch of medical and nursing science." So far as medical science is concerned, a unique combination of disastrous circumstances has conspired to restrain advance. More than 7,000,000¹ is expended annually upon the upkeep of mental hospitals in England and Wales alone, and this sum, large as it is, gives but a partial and uncertain indication of the economic importance of mental disorder, taking no account of the cost to society, from inefficiency, mistakes and crimes, of a multitude of sufferers, uncertified or uncertifiable, the existence of which has only recently been revealed through the establishment of a very few widely scattered out-patient clinics. Nor does it count the cost of congenital mental deficiency in most of its forms and degrees. It is merely one item in an account the true magnitude of which cannot be gauged. From the humane point of view, also, mental disorder deserves at least as much consideration as other disorders. Lunacy as a disease is not painless in any but the narrowest sense.

Lord Birkenhead spoke only a day or two after the publication of specialist opinions which deserve as wide attention as his. They were Dr. Bernard Hart's, that the actual state of affairs with regard to research and the early treatment of mental disorder were in Great Britain "little short of a scandal," and Dr. Mapother's, that "whether strictly between ourselves we may not admit that we have no definite information on the prevention of mental disorder."²

The phraseology of these criticisms would be mild if mental disorder were something new which had come

¹ 7,658,823 in 1922. The figure, 6,933,804, given in the Report of the Board of Control for 1924 is for County and Borough Mental Hospitals only.

² *Brit Med Jour*, Oct. 31, 1925.

upon our community suddenly. Its main features have been well known throughout historic times, and it is well over a hundred years since Gall laid the foundations of an extensive science of cerebral structure and function. Physiology has attained dimensions which would appear vast even to Huxley. Medicine, preventive and curative, has its victories. But of psychology and mental disease, nothing: even to say that they had baffled us would be dishonest, for that would imply a vigour of attack which is wholly lacking.

The responsibility for this remarkable situation may lie with the medical men who undertake the study of mental disease and the care of the insane; with the authorities, for the most part public, which employ them; or with the Board of Control which at present supervises the administration of the Lunacy Act. A discerning reading of the Board's recent reports, and particularly that just published,³ throws some light on this point, surely a vital one for future development. They certainly betray a confusion of mind which cannot fail to be reflected in asylum committees and through them in the administration of mental hospitals. It was not until 1922 that the Board's attention was diverted, probably with relief from pressing domestic matters, to the problem of research. It then found that "it has long been realised that there is an urgent necessity for co-ordinated research into the basal causes of mental disorder."

Trite remarks of this kind are inevitable from a body the natural course of which, if not a "neat rivulet of text in a meadow of margin," is a broader and correspondingly a shallower flood, for, so far as public asylums are concerned, the Board has no executive authority worth mentioning. In private institutions it can, and frequently does, indulge any fancy of the reforming zeal on pain of immediate closure; but elsewhere it can only hope without expectation and desire without hope. In consequence, the Reports of the Board are politely benevolent in tone, with a strong flavour of reminiscence and remoteness. These tendencies are clearly evident in the matter of research. What attracted the sudden interest of the Board was the inception of a scheme at Birmingham for research under the City and University jointly. The means were provided by private generosity. This appeared to be fortunate to the Board, which recalled the fact that in the absence of legislative permission local authorities "are precluded from collaborating with this object."⁴ No wonder that "it is our hope, and we shall do all in our power towards its fulfilment, that

similar or corresponding Research Centres will be instituted in connexion with each University." Three years later this hope has expanded slightly and we find (p. 106)—"We wish, too, to repeat our desire (see 9th Report, p. 55, and our last Report, p. 70) to see research centres (Schools of Psychiatry) established—one in connexion with each of the Universities—with each of which all the institutions at which mental cases are received in the neighbouring counties would be grouped and affiliated."

It may be argued that, while a Royal Commission is inquiring into the present administration, the Board of Control does wisely to mark time. But this phrase is not one which properly describes the Board's activities. They are directed towards a definite policy—the grouping of mental hospitals about central laboratories with a more or less ill-defined university association. This plan, at present in operation, is inadequate to the real need. But "it is with no small satisfaction" that the Board observes a tendency to develop along these lines. Then it plunges into an argument which reveals at once the hopeless confusion into which a problem may be thrown by special pleading in conjunction with irresponsibility. "Not less than 60 per cent of the [mental] hospitals possess a laboratory *in more or less active operation*, in 21 of which the work is *to some extent* linked with a teaching centre." (Eight universities and the Maudsley Hospital are named.) The position "though there is room for a good deal of improvement, . . . compares favourably with that which obtains outside mental hospitals, where, we gather from information kindly supplied from 8 general hospitals *exclusive of those which subserve a Medical School*, the proportion at which laboratory work is prosecuted is 46 per cent." Without information concerning the size and character of these hospitals comparison is impossible. Ninety-six mental hospitals average 1082 patients each. How many points of view are the following passages, found cheek by jowl in the same paragraph (p. 181), designed to meet?—

I. Sound training and skill in ordinary bedside examination are essential, and it would be a great mistake were it to be neglected or undue reliance placed upon laboratory reports. Nevertheless, a growing recognition of the important part played by certain bodily conditions—*e.g.* morbid states of the nose, throat, teeth, intestines, blood and other fluids—endocrine disturbance, the presence of the syphilitic virus, etc. . . . makes it imperative that every mental hospital should possess at least a small clinic laboratory, instead of relying on the present inadequate method of posting a selection of specimens for examination elsewhere. . . . *It is a waste of time for much of this work to be actually performed by a doctor*, and the medical staff should not be expected or encouraged to undertake it, the employment of a trained labor

³ The 11th Annual Report of the Board of Control, 1924 (London: H.M. Stationery Office, 1925) 12s 6d net.

⁴ In the case of London with its many hospitals this difficulty has not arisen. So long ago as 1895, Sir Frederick Mott was appointed by the L.C.C. to control a joint pathological laboratory at Claybury.

tory Assistant, who will work under their instructions, is therefore not only desirable but essential.

II. As to the medical staff, while it is an advantage if all can find time for at least some work or attendance in the laboratory, *the routine application of laboratory investigation in aid of bedside methods is likely to be more reliable and systematic if entrusted either to a resident or to a visiting pathologist*, the latter alternative being the manner in which the smaller hospitals probably can best meet these requirements. Even where there is a resident pathologist, however, unless he is allowed to undertake duties at a general hospital . . . it seems to us desirable that a pathologist should be appointed on the staff of Visiting Specialists. When the mental hospital is in the vicinity of a University, it would be an additional advantage were he a member of the University staff.

Surely the Board is aware of the difference between a laboratory assistant and a pathologist of university rank.

It has been the custom of the Board recently to publish an account of asylum laboratory work compiled from statements made to the Board by medical officers. This is headed in the present report "Scientific Research Work in Mental Hospitals in 1924." The returns are seventeen in all. They are not constructed upon any general plan, and to the uninitiated the information they contain is not presented in an easily assimilable form. Throughout, there is no effort to distinguish between the barest necessities of clinical investigation and research; between research into what may be termed "administrative" diseases—physical disorders affecting the administration of asylums, like dysentery—and research into mental disease; between research into treatment and research into "the basal causes of mental disorder." The reports which mean most are generally the shortest and convey least information; those which mean nothing are most painfully detailed—urines tested and throat swabs taken, with actual figures but no percentages of hospital population. All this is collected together, with serious work at Cardiff, in the north of England and at the Maudsley Hospital, to fill forty-one closely printed pages of "scientific research."

On other vital points, the Board is an adroit but scarcely a trustworthy guide.

"In our view, doctors who take up permanent resident posts in mental hospitals can fairly be expected to acquire a specialist's competency in psychological medicine; but it is unfair to them and to their patients to expect them, for instance, to undertake surgical operations or to possess a corresponding competency in other branches, which is nevertheless wanted for a proper elucidation of many cases." At some hospitals "it happens that one or more of the resident medical staff has special competency in some of these branches, and reliance is placed on his services; however great his competency, we think this policy is a mistake, as it

. . . must . . . cause the sacrifice of time which can ill be spared from his recognised duties."

If his recognised duties are partly administrative—and without actual experience few can realise how heavy this may be—and partly the care of a number of patients varying from 300 to 600. It is scarcely surprising that research reports are under suspicion.

What interest does it serve to disguise the facts of mental research or to present them in a garbled and unintelligible form? If there is no time for serious research, no facility, no guidance, why should not public authorities be told that they have made no provision for more than the detention and care of their insane patients? London, with 182,068 certified insane, has one qualified pathologist to whom are referred most of the more refined diagnostic questions of many hospitals and the intensive physiological investigation of the Maudsley patients. If all that is contemplated in that extraordinary paragraph quoted above about laboratory tests were referred to him, he would be utterly unable to deal with it. Similarly with the Birmingham laboratory. Last year this laboratory summarised its work as follows:

TOTAL SPECIMENS.

Total Bacteriological	1306
Total Wass, Sig., Colloidal gold	459
Total Serolog Agglutinations	375
Total Chemical Sundry	175
Total Basal Metabolic Determinations	60
Total Iodine in Thyroid Glands	60

Most of this is not research work but routine work, undertaken to persuade a parsimonious and pound-foolish public to allow the research worker to approach his subject in his spare moments.

It is by disguises and evasions of this kind that a situation has grown up which richly deserves the strictures of Dr. Bernard Hart and Dr. Mapother. The men upon whom falls the direct responsibility are the worst paid in the medical profession. They are in most cases on duty for ninety-five hours a week in circumstances which rigidly restrain enterprise and enthusiasm; and in addition they must struggle to adjust themselves to the atmosphere created by official short-sightedness. The prevailing affective tone is one of cynicism and discontent. Would it not be a simple expedient for the Government to appoint a single Commissioner to report upon the scientific aspects of mental disorder? It is one which, directly or indirectly, has been richly productive in other scientific questions of great public importance, and it need not conflict with the work of the present Royal Commission. But preferably he should be a man of science independent of the conflicting interests of the asylum world.

Recent German Work on Heredity and Evolution.

Die Abstammungslehre: Tatsachen, Theorien, Einwände und Folgerungen im kurzer Darstellung. Von Prof. Dr. Ludwig Plate. Zweite Auflage des "Leitfadens der Deszendenztheorie." Pp. vii + 172. (Jena: Gustav Fischer, 1925) 6 gold marks.

Pluripotenzerscheinungen: Synthetische Beiträge zur Vererbungs- und Abstammungslehre. Von Valentin Haecker. Pp. viii + 213. (Jena: Gustav Fischer, 1925.) 9 gold marks.

THESE two books contain some of the most recent German ideas on the subject of heredity and its bearing on theories of evolution.

(1) Prof. Plate's work is an ordinary treatise on evolution, embodying all the well-known arguments from embryology, morphology, and palæontology, and evidently intended more for the benefit of the intelligent outsider than for the special student of biology. It is beautifully illustrated, and on this account possesses a value of its own, whether we do or do not agree with Prof. Plate's conclusions; we may mention two views of an almost perfect Moustarian skull from the Berlin Museum on page 137; views of the male and female Bird of Paradise on page 31; views of the male of *Papilio memnon* of the three types of females belonging to this species on page 32.

When we come to the theoretical part of the treatise, we find that Prof. Plate, like St. Paul, endeavours to be all things to all men. He accepts "mutations" as the causes of evolution, and also reactions to changes of condition—which is essentially Lamarckism. He admits that the attempt to produce changes in animals which shall be inheritable has met with a considerable measure of success: he accepts as valid the results of experiments of exposing the pupæ of Lepidoptera to changes of temperature: these experiments produce changes of coloration not only in the imagines which emerge from the pupæ but also in the following generation. It seems to us, however, that Prof. Plate, like so many modern zoologists, thoroughly misunderstands Lamarck when he opposes natural selection, and the inheritance of acquired qualities, and when he rejects what he calls Lamarck's assumption of "psychic roots" for variation in Lamarck's phrase "the inner needs." Whether we accept Lamarckian ideas or not, there is no escape from natural selection. The logic that since the female cod produces nine million eggs a year, and that since on the average only two of her progeny reach maturity, all the rest must prematurely perish, is unanswerable. But the slaughter of the majority of the family does not in itself explain the qualities of those that survive.

In order that any change may be produced at all, there must be constant variation, and to find the causes of this is the real problem of the evolutionist. The great attractiveness of the Lamarckian doctrine is that it proposes an explanation of these variations; and therein it gets nearer to the root of the matter than Darwinism. Lamarck's assumption of "inner needs," by which he means the appetite or urge that spurs an animal to activity, is a piece of the most far-sighted philosophy. Modern research on animal behaviour—such as that of Jennings on the most primitive animal of all, *Amoeba*—has shown that it is utterly impossible to explain the activities of even the lowest form as a mechanically connected chain of automatic reflexes. All animal life is a striving to attain ends, and this striving is expressed in the activities of the animal, in a word, in its habits, and changes in habits lead to the use and disuse of organs.

Prof. Plate states that neither the Lamarckist nor the selectionist has been able to produce a crucial experiment in support of his views. We may predict that no Lamarckist will ever be able to adduce a proof which will satisfy his opponents so long as their minds are obsessed by the Weismannian complex. For of any account of experiments, however conclusive, they may say that they will not accept them but will wait until these have been repeated, and as such experiments require periods of from five to fifteen years for their accomplishment, and the objectors make no effort to repeat them, their entrenchments will be impregnable. Only as younger and more plastic minds succeed to those trained in the older philosophy will Lamarckism come to have justice done to it.

Prof. Plate concludes with a chapter on the relation of the doctrine of evolution to religion and education which throws an interesting light on post-War German psychology. He attacks in the most vigorous language "Haeckelismus," which we may translate as the "mechanist" view of life: he asserts that a monistic view of Nature with our present knowledge is impossible, and that matter, force, and spirit are incommensurables, which the theory of evolution does not aid us in connecting with one another. The efforts of Haeckel to alienate the people from the Church is deplored; since only on the central doctrines of the Church can a practical system of ethics be founded.

Prof. Plate then goes on to make an equally violent attack on what he terms the "Jewish" doctrines of democracy, universal peace, and the equality of the races of men. The fact that all life is the history of a struggle is emphasised, and the German youth is warned to beware of being deprived of the powers of self-defence through being misled by these ideas.

(2) The treatise on "Pluripotenz" by Dr. Haecker

is a book of quite a different character. It is an attempt to penetrate further into the causes of variation, by bringing together a large number of obscure phenomena. It is in our opinion a rather confused book, but it is a valuable testimony to the fact that thoughtful German opinion is beginning to be discontented with the fashionable theory of variation embodied in the terms "factors" and "genes." By "Pluripotenz" is meant the fact that the form which an animal or vegetable germ develops does not fully express its latent powers, that in other circumstances it can produce something quite different; so, for example, the skin in the shoulder-region of the tadpole normally produces only skin, but if the embryonic eye-vesicle be cut off from the brain and pushed along under this region, then the skin of the shoulder will develop into a lens. But in later chapters the conception of "Pluripotenz" is enlarged to include the fact that quite similar variations turn up independently in different strains of the same larger group; so, for example, the transformation of the molluscan mantle-chamber into a lung has occurred at least six times. "Petaloidy," or the transformation of stamens and carpels into petals, occurs independently in quite unrelated flowers. A blue colour crops up in the plumage of birds belonging to quite different families. A further application of the idea of "Pluripotenz" is to the effect of the sex-hormones on the growing bodies of many forms of animals, so that, as Zawadowsky has shown, it is possible to convert a hen into a cock with comb, spurs, hackles, tail feathers, and voice complete by first extirpating the ovary and then grafting on a testis. Then "Pluripotenz" is also stretched to cover cases where several so-called "mutations" occur, in some cases associated with one another and in other cases separately. So in human families "polydactyly," or supernumerary fingers, and "syndactyly," or a web of skin between the fingers, and "brachydactyly," or the fusion of two of the phalangeal bones in each finger, associated with a short thick shape, often occur together, but one of these characters may appear and be inherited specially.

Having thus stretched "Pluripotenz" like an overcoat which covers many defects, over a whole range of vaguely defined phenomena, Dr. Haecker endeavours to extract from these phenomena certain general ideas. He points out that if a large group of divergent genera, or even families, are descended from a single ancestor, they will have inherited from this ancestor a particular type of germinal substance, which in consequence will be specially liable to the same type of change in all the descendants of that ancestor. This is, in fact, "orthogenesis" in the sense in which Eimer used the word, though so-called orthogeneticists nowadays employ it in a very different sense. Dr. Haecker gives

a beautiful analysis of the causes of the blue colour in birds' feathers. The formation of yellow and brown pigment in the cortical cells is inhibited and the superficial cells of the medulla become hollow boxes the walls of which are pierced by pores. These pores exist in this situation in all feathers, but in these blue feathers they are enlarged. The deeper cells of the medulla develop dense black pigment, so that no light is reflected from them, and the light reflected or rather scattered from the "cloudy medium" constituted by the horn + air of the superficial cells of the medulla is blue.

When dealing with the various associated mutations in man and other mammals, Dr. Haecker puts forward the valuable idea of a definite "habitus" which manifests itself in more or fewer symptoms according to its intensity. We may translate "habitus" by "diathesis," and Dr. Haecker directs attention to the fact that all these symptoms are indications of "Entwicklungshemmung," which we may translate as "germ-weakness." Thus, polydactyly is often associated with hare-lip and mental defect. Even brachydactyly, which superficially regarded appears to be an insignificant aberration, is fatal when inherited from both sides of the house, for brachydactylous people when they marry with each other are childless.

Lastly, Dr. Haecker attacks the crude conception of the linear arrangement of the genes in the chromosome, and the idea of crossing over. He points out that Chambers has shown by micro-dissection of living cells that the chromosome in life is an elastic gelatinous rod, and the absurdity of supposing that such a rod would break in the complicated manner which Morgan assumes is obvious. He discounts all deductions from stained figures of chromosomes in which a pair appear to be spirally twisted around one another, stating that exactly the same figures can be seen in the vegetative division of nuclei in *Radiolaria*. Finally, he makes the significant remark that only in *Drosophila* has a correspondence between chromosomes and linkage-groups of genes been observed: the significance of this would have been still more evident had he been aware that in the pea, nine linkage groups have been demonstrated, and there only exist seven chromosomes.

It appears to us that in recent times nothing more disastrous to the real progress of biology has occurred than the spread of the idea of "genes" and crossing over; for it has induced many biologists to be content with pseudo-explanations, which consist in inventing new imaginary entities to fit all irregularities which turn up, and it has diverted research from seeking the real physiological bases of these mutations. Each particular group of animals, of course, requires special investigation, but Jansen in Holland, Törnier in Germany, and Sir Robert Jones in Great Britain have

shown that a whole host of mutations (many of which are "linked") which occur in man can be regarded as results of one cause, namely, amniotic pressure. Their linkage is not due to the ranging of genes in a chromosome, but they are manifold results of the same weakness. The embryo of the higher vertebrates is early covered by the amniotic fold: this at first clings closely to the embryo, but as growth proceeds it is forced away from it by the secretion of the amniotic fluid, and into this fluid the various members grow out. The secretion of this fluid is correlated with rocking movements of the embryo, as Foster and Balfour showed forty years ago. If then, owing to germ weakness, these movements are weakened, too little fluid is secreted and the amnion for a longer or shorter period clings too tightly and presses on growing members and inhibits their growth. "Polydactyly" and "brachydactyly" are both due to the pressure of the amnion on the growing rudiments of the fingers. In the first case the rudiment is split into two, and in the second case it is shortened. When the amniotic pressure sets in early it may interfere with the growth of the brain and produce mental defect, and in extreme cases it may inhibit the growth of the brain altogether and so prove to be what Morgan calls a "lethal factor." The childlessness of brachydactylous couples seems to be due to the lethal effect of a double dose of germ weakness.

We do not for a moment suggest that all manifestations of "Pluripotenz" are associations of symptoms due to a given grade of germ-weakness. The fact is that Dr. Haecker has grouped together things of totally different nature. The development of a lens, for example, from the skin of the shoulder in a tadpole means that all the nuclei of the embryo are potentially alike as their chromosome content shows, and in all the complete hereditary powers of the organism are latent; and it depends on the stimulus applied which of these powers are manifested. So in fowls, the male and female sex hormones are capable of producing on indifferent material (the ordinary cells of the body) quite different results.

Similar organs turning up independently as specific characters in quite different stocks of the same class are the reactions of similar constitutions to similar changes in the environment; so the independent production of a lung in different groups of the Gastropoda may be explained. Sometimes the similarity may be due to the atavistic reproduction of a long-lost organ which may be compared to the revival of an almost forgotten memory. Of this a marvellous example was recently given to the Zoological Society by Mr. Tate Regan, and with this we shall close. It is as certain as anything of the kind can be that the original dermal skeleton of fish consisted of scales like those now found in our

sharks and rays. Remnants of this "shagreen" exist in all the higher vertebrates in the form of teeth; for the scale of the elasmobranch fish is merely a dermal tooth. As time went on the bases of these dermal teeth became bound together by calcifications of the dermis beneath them; and thus bony scales came into existence which soon rendered the teeth superfluous, although in the bony gar-pike of N. America (*Lepidosteus*) microscopic representatives of these teeth can be found scattered around the periphery of the scales. When the first Teleostei appeared, which may be termed Jurassic herring, even these remnants had disappeared and the scales alone were left. Later, probably in Eocene times, the first invasion of the rivers by Teleostei took place, and thus were evolved the oldest teleostean fresh-water fish, the Characini of Africa and South America. These Characini are covered with smooth well-developed scales. In turn these gave rise to the cat-fish, most of which have naked skins, but some of their South American representatives have bony scutes, in the intervals between which typical dermal teeth are found exactly like those of an elasmobranch. No more wonderful recovery of long-lost organs is to be found in the animal kingdom.

E. W. MACBRIDE.

The Theory of Limits.

Elements of the Mathematical Theory of Limits. By Dr. J. G. Leathem. Pp. viii+288. (London: G. Bell and Sons, Ltd., 1925.) 14s. net.

PARTLY due to the fact that their knowledge of the subject is acquired piecemeal, most mathematical students show confusion of thought on questions relating to the theory of limits. On it rests the theory of the calculus, the subject above all others where accuracy of thought is needed in the training of a present-day mathematical specialist. For many years Dr. Leathem was known in Cambridge as one of the most genial exponents of the theory of limits: he introduced the arrow symbol for tendency to a limit in 1905. The MS. of the book before us was substantially complete before his death in March 1923. Profs. H. F. Baker and E. T. Whittaker have seen to its publication.

The volume develops the theory of limits in elementary mathematical analysis with lucidity and accuracy. Infinitesimals and infinities, and their orders, are adequately discussed, also elementary asymptotic expansions and the meaning of continuous functions and differentiation. The last section deals with infinite series and products, including the simpler tests for their convergence.

Dr. Leathem only assumes elementary mathematical knowledge on the part of his readers, but, as an intro-

duction to elementary calculus, the book is much too long and elaborate. Some readers (with analytical minds) will revel in the wealth of meaning assigned to the conceptions of infinity and continuity: others will think that all the salient features could have been presented more briefly. It is disappointing to find that so large a volume contains no reference to uniform convergence or to Riemann integration, which are now considered to be essential to the training of a young mathematical analyst. Only three pages are given to the integral calculus, but seven to the less-studied convergence of continued fractions.

The author's proof of the existence of a limit of a sequence of real numbers (when convergent) is made to depend on the one-one representation of real numbers by points on a straight line. Here he protects himself by a footnote saying that the existence of the limit is really postulated by the existence of the arithmetical continuum. It is practically impossible to say what is actually proved in the existence-theorems of Chap. xxii. The defence of Dr. Leathem's book is that it is for beginners, who must have the subject presented much as it would be in the seventeenth century.

Many able teachers of mathematics agree with the late Prof. F. Klein in advocating the use of intuitive methods before strictly logical ones, but it should never be suggested that the latter are unnecessary. From the strictly arithmetical point of view, a logical discussion of irrational numbers, such as Dedekind's or Cantor's, must necessarily precede any criterion for the convergence of a sequence of real numbers. Dr. Leathem's attitude on the matter is contained in his closing words.

"While we have dealt with the conceptions of limits and irrational numbers from the geometrical point of view, regarding it as incomparably the more useful way of presenting the subject to beginners, there is nevertheless the alternative arithmetical aspect, to be studied perhaps at a later stage. As regards these alternatives, the most ardent partisan of either can scarcely claim that a choice between them is a choice between right and wrong; one may doubt if it is a choice between better and worse. As there are mathematicians who find the keenest intellectual pleasure in geometry, so there are others who would approach all subjects, geometry included, by arithmetical methods. The difference is one of temperament and taste, such as cannot be finally disposed of by argument."

This, however, is not the only possible view on the question at stake. Another quite defensible attitude is to say that a choice between the arithmetical and geometrical arguments is not a matter of disposition at all. Every one uses geometry as far as it will go, but geometry is bound to break down due to passing beyond the threshold (*Schwelle*) of intuition; and then the geometry itself must be buttressed by Dedekind's axiom.

W. E. H. B.

The Destructive Distillation of Wood.

The Technology of Wood Distillation: with Special Reference to the Methods of obtaining the Intermediate and Finished Products from the Primary Distillate. By M. Klar. Translated by Dr. Alexander Rule. With an additional Chapter by the Translator. Pp. xv + 496. (London: Chapman and Hall, Ltd., 1925.) 25s. net.

THE destructive distillation of wood is one of the earliest industries known to man. The need of charcoal for fuel and for the smelting of iron was the primary aim of the undertaking. Up to the beginning of the nineteenth century, the carbonisation of wood was carried on mainly with the object of furnishing sources of heat and light. At a somewhat later period the industry was in a precarious condition, for coke and tar from coal distillation successfully competed with the related products from wood.

With the rise of the organic chemical industry in the nineteenth century and the great demand for such products as acetic acid, methyl alcohol and acetone, the wood distillation process survived, but only, as M. Klar remarks, as a result of never-ceasing progress made by chemical research. With the gradually increasing difficulty in obtaining wood supplies, and with competition on every side, the struggle for its existence as an industry was a keen one. It was only by the fullest application of scientific methods, especially in the direction of improving the process of carbonisation and in the manner of working up the volatile products, that success was obtained. The striking features of a wood-distillation plant at the beginning of the twentieth century have been briefly described by M. Klar to include among other operations and processes the following: The use of large carbonising plant with mechanical charging and discharging apparatus; the use of producer gas for heating and the utilisation of waste heat for initial drying of the wood; preheating of the non-condensable gas on the regenerative principle before combustion; scrubbing the gas produced and using it for generating power; economic recovery of calcium acetate and its drying by a continuous process; preparation of pyroligneous acid free from tar, and the rectification of crude wood naphtha and production of pure methyl alcohol in one operation. M. Klar has dealt with all these subjects, and has done his work so well that the original has long been regarded as the German standard in this subject. There is no doubt that this translation will secure a similar position in English-speaking countries.

During the War period, according to M. Klar, the method of operation as carried out in Germany did not undergo such changes as to render a revision of

the book essential, and the third German edition (1920) is a simple reprint of the second (1909) edition with cost data and values of products at the 1909 period left unchanged. Dr. Rule has in the main translated without alteration, but some additional matter and new references have been added. The extra material deals especially with investigations which aim at increasing the yields of acetic acid and methyl alcohol. In many ways the translation has produced a book which excels the original, and Dr. Rule has made every effort to bring the material at his disposal up-to-date. He has certainly achieved his object in filling a gap in the literature of the subject available to English readers. Except for the excellent book by Bunbury, this branch of technology has not received close attention from English writers.

While the state of the industry was insecure twenty-five years ago, the present position is considerably more serious, especially in Europe. Much more valuable uses are now being found for surplus wood than mere destructive distillation. The securing of wood for the production of cellulose for paper and artificial silk, to mention but two requirements, makes an enormous demand on the gradually decreasing forest supplies. But the troubles of the wood carboniser do not end here. Recent progress in applied chemistry has shown that with the aid of electrical power, synthetic acetic acid can be produced in enormous quantities at a comparatively cheap rate. Again, the economic production of methyl alcohol from water gas is now claimed as a commercial proposition in Germany. The wasteful destruction of wood to give small yields of methyl alcohol or acetic acid may therefore before long be unnecessary. Modern practice inclines rather towards the utilisation of the cellulose molecule in the form in which Nature has carefully built it up rather than the wasteful breaking down of this complex to simpler substances. On the other hand, the chemist aims at the direct syntheses of substances such as acetic acid, methyl alcohol, acetone and formaldehyde, and in recent years much success has followed from such efforts. The main hope of the wood distiller in the future possibly lies in the direction of gas production from wood waste unsuitable for other purposes.

Apart from the actual distillation process, there is a considerable amount of very valuable information in this book which will be of great value to the technologist and analytical chemist. Such subjects as charcoal and its composition, wood naphtha, acetate of lime, acetone, acetic acid, formaldehyde, etc., receive detailed treatment. In addition, there is a first-rate analytical section comprising nearly one-fifth of the book, which will be of general use to the chemist in the works laboratory.

J. REILLY.

Our Bookshelf.

Memoirs of the Geological Survey of Great Britain. Palæontology. Vol. 2, Part V.: *Fossil Plants of the Carboniferous Rocks of Great Britain*. By Dr. Robert Kidston. Pp. 377-522 + plates 92-122. (Southampton: Ordnance Survey Office; London: Edward Stanford, Ltd., 1924.) 20s. net.

THE work on which the late Dr. Kidston was engaged at the time of his death is probably the most important contribution to our knowledge of the plants of the British Carboniferous rocks which has yet been printed. Whether regarded as a study of the distribution of species in our British coal seams, or as a critical systematic account of a fossil flora of scientific interest and economic importance, it ranks as a unique work. Unfortunately Kidston's sudden death occurred when only four parts had been published, and the present part is the first to appear since; but it is hoped that several more parts are in a condition sufficiently advanced to admit of their publication. It will be a catastrophe if the material collected for so many years by such an indefatigable worker is not made available by publication.

The present part, like those which have preceded it, deals with those varied and often perplexing fern-like plants which form such an important element in the Carboniferous flora. Some of the genera described and figured are rare and little-known forms, such as species of *Cyclothea*, *Unatheca*, *Anemites*, and *Alcicornopteris*, while others are common but polymorphic forms such as *Dactylothea*. The treatment of the fronds of the fern genus *Pecopteris* is commenced. The old group was a very large and artificial one, and a system of nomenclature is now proposed which will limit the artificial genus *Pecopteris* to a much smaller number of forms. The species which have been found in a fertile condition are removed to their appropriate natural genera, and we have seven of the more familiar species now described as species of the genus *Asterothea*. Some of the genera described, such as *Zeilleria*, *Telantrum*, and *Seftenbergia*, are of considerable botanical interest on account of the form of their reproductive structures. The records of the exact horizons and localities of each species in Britain are given, and this should prove of great value not only in the recognition of the horizons of coal seams, but also for the study of the evolution and distribution of the Carboniferous flora.

H. H. T.

The Pliocene Mollusca of Great Britain: being Supplementary to S. V. Wood's Monograph of the Crag Mollusca. By F. W. Harmer. Vol. 2, Part 4. (The Palæontographical Society: Volume for 1922.) Pp. xiv + 857-900 + 1 plate. (London: Printed for the Palæontographical Society, 1925.)

ALTHOUGH the preparation of this monograph was begun very late in life, the author lived to complete his work, but not to see the publication of the concluding portion. The first part was issued in 1914, and the author died in April 1923. Since the appearance of Searles V. Wood's great monograph on the "Crag Mollusca" (1848-57), with its Supplements (1872-82), there has been much progress in conchology and considerable additions have been made to the

already known rich fauna of the English Pliocene deposits, especially to that of the Waltonian Crag. Consequently, during his stratigraphical investigations F. W. Harmer found that a supplementary monograph was needed. The present memoir deals mainly with the gastropods and is illustrated by 65 excellent plates. The author's work on the stratigraphy of the Pliocene deposits of East Anglia and Western Europe, and his interesting conclusions concerning the physical conditions of the period, have been published in the Quarterly Journal of the Geological Society and elsewhere, but a few further points of general interest are given in this monograph, such as his discussion of the supposed Miocene age of the Lenham Beds.

[Sir Sidney Harmer informs us that he has a few copies of Vol. 2 of the above monograph, and he would be glad to hear from workers on Pliocene Mollusca who received copies of Vol. 1 but have not yet had Vol. 2.—ED.]

Evolution, Heredity, and Variation By D. Ward Cutler. Pp. 147. (London: Christophers, 1925.) 3s.

THE purpose of this book is, in the words of the preface, "to present, in as simple a manner as possible, some of the results of modern research on the great questions of evolution, variation, and heredity." The book is designed mainly for the use of schools in which biology receives a place in the curriculum, and for the general non-scientific reader who is interested in the bearings of these problems on questions of human sociology. It naturally contains nothing that is new, nor even a new viewpoint, and the author has had to make rigorous selection of available material in order to present the various aspects of the questions in as complete and impartial a manner as the exigencies of space would allow.

On the whole, Mr. Cutler has done his work well. It is almost inevitable in a book of this kind that the author should tend to be dogmatic, and this attitude is rather emphasised by the author's somewhat stilted and peremptory style. We should, for example, have preferred a less summary statement on the question of the inheritance of acquired characters, and a little fuller presentation of the more recent work on this baffling problem, especially in view of the reaction towards Lamarckianism, of which signs are not wanting, and of the grave importance of the matter in its bearings on human sociology. But this is, perhaps, a small point in an otherwise well-balanced book, which should be found very useful for the higher forms of schools where biology is taught for one or other of the school leaving certificates.

The Negro and his Songs: a Study of Typical Negro Songs in the South. By Prof. Howard W. Odum and Guy B. Johnson. Pp. ix+306. (Chapel Hill: University of North Carolina Press; London: Oxford University Press, 1925.) 13s. 6d. net.

THIS is the first volume of a series in which the story of the United States negro is to be presented. It comprises songs from Northern Mississippi, Northern Georgia, and a few others, chiefly from North Carolina and Tennessee. The types included are religious songs, social songs, and work songs, the last named being, perhaps, the most attractive from their purely rhyth-

mical effect. The two earlier classes are, however, the more instructive in the light they throw upon the mentality of the negro; and no one who reads through the whole of the social songs, with their peculiarly frank exhibition of the negro's attitude towards sexual feelings and relations, can fail to appreciate one side of the race problem in the United States. This, however, is not the whole story, and the religious songs show another side. Throughout there is ample evidence of the negro's gift of imagery, of graphic description, and above all of appreciation of dramatic effect. Amusing examples are given which illustrate the fact that the negro has not lost the gift of improvisation which other primitive singers have, or their impish delight in bringing into their songs any white man who may be present. The authors make an eloquent plea for the systematic study of negro culture, which readers of this volume will heartily support.

Le calcul des probabilités à la portée de tous Par Prof. Fréchet et Prof. Halbwachs. Pp. xi+297. (Paris: Libr. Dunod, 1924.) 18 francs.

TO mathematicians of the seventeenth and eighteenth centuries, the main interest of the theory of probability, then a new object of curiosity, lay in its application to games of chance. In more recent times this theory has developed in such a way as to occupy a central place in many theoretical and applied sciences, from astronomy and physical chemistry on one hand to biology and sociological science on the other. Probability is also the foundation of statistical work, which forms the basis of economics and of actuarial science.

Most treatises on probability, like Laplace's classical "Probabilités," involve some acquaintance with mathematics, and a reader without a working knowledge of the calculus usually finds them too formidable. In the volume before us, Profs. Fréchet and Halbwachs lucidly expound a variety of investigations in the subject which require no wider mathematical knowledge than that of elementary algebra. The questions discussed belong to a wide range of sciences, and the book will be a useful one to readers who are interested in the applications of probability but have only scanty mathematical attainments W. E. H. B.

A Treatise on Light. By Dr. R. A. Houstoun. Fourth edition. Pp. xi+486+2 plates. (London: Longmans, Green and Co., 1925.) 12s. 6d. net.

DR. HOUSTOUN has now remedied one rather serious defect in his well-known "Treatise on Light," namely, the out-of-date character of the section dealing with spectral series. That some modification was desirable will be apparent from the remark still to be found in the third edition (1923) that "all attempts to explain the origin of spectral series are regarded as unsuccessful." In the present edition a brief non-mathematical account of Bohr's theory is introduced, and some of its simpler applications, as to the spectra of hydrogen and ionised helium, are considered. Only a very few pages are devoted to this, for in the author's view the quantum theory of spectra belongs rather to mathematics and the theory of atomic structure than to light. It is perhaps debatable ground, like so much else in modern physics, but those who do not share his opinion will doubtless temper their criticism with appreciation of the many merits of the book in other respects.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Occurrence of Dwi-Manganese
(At. No. 75) in Manganese Salts.

IN investigations of the electrolytic deposition potentials of manganese solutions by the use of the dropping mercury cathode and the automatically registering "polarograph," comparatively large impurities (1:20,000) were detected even in the purest samples, e.g. Kahlbaum's or Merck's "pro analysi." (Cf. *Rec. Trav. Chim. Pays-Bas*, 44, 1925, 488-600.) From the position of the hump on the current-voltage curve (Fig. 1), the impurity was at first thought to be zinc (*l.c.* p. 520). However, on closer examination, the "saw-like" character of the undulations showed that this increase of current must be due to the deposition of a

metal or metals not alloying with mercury (*l.c.*). At the potential at which the manganese impurity is distinctly shown, i.e. at -1.0 volt (from the calomel zero), zinc, nickel, cobalt, and iron may be deposited from their 10^{-6} molar solutions (cathodic potentials 1.00, 1.06, 1.20, and 1.27 volts respectively). From the different heights of the humps on the polarographic curves, the impurity in the manganous solutions can be estimated as $0.5-4.0 \times 10^{-4}$ equiv. per litre, varying in different specimens within these limits. As analytical tests for zinc, nickel, cobalt, and iron in these solutions give negative results, these metals cannot be present in concentrations greater than 10^{-5} equiv. per litre. Hence the persistent impurity was suspected to be analogues of manganese—eka-manganese (43) and dwi-manganese (75).

The method of separation, first attempted in May 1925, consisted of dipping strips of zinc or platinum foils connected to zinc rods into concentrated manganous solutions; this would cause all metals having potentials less negative than zinc to be deposited. The deposit was scraped off, dissolved in a few drops of hydrochloric acid, evaporated to dryness or precipitated by sodium hydroxide and its X-ray spectrum examined.

Prof. M. Siegbahn's apparatus was used, as

described in his monograph. The $L\beta_1$ -line (Siegbahn's notation) of the element 75 was at once observed, the $L\alpha_1$ -line being masked by the $K\alpha_1$ -line of zinc. Owing to this superposition the wave-length of the zinc $K\alpha_1$ -line could not be accurately determined. Although this evidence did not seem sufficient to establish the new element, the authors have used it, in conjunction with the electrolytic method, to deduce some chemical properties of dwi-manganese. The impurity (1:100,000) causing the first hump was easily shown to contain no element 75, since it disappeared entirely from the graph when hydrogen sulphide was passed through the acidified manganous solution and the trace of precipitate thus formed gave on X-ray analysis no line of the element 75. The second "hump" was not affected by passing hydrogen sulphide through the acidic, or the sodium acetate solution, and when the solution was treated with sodium hydroxide, only the precipitated hydroxides showed the 75 line. Owing to the considerable amount of zinc which was introduced into the solution by the scraping, further polarographic investigation was inapplicable, and no progress was made until a few weeks ago, when the procedure was so modified that it yielded, in one operation, a pure X-ray spectrum of three lines of the 75 L series.

The method is as follows: Into a nearly saturated solution of pure manganous sulphate a small crucible containing manganese amalgam, prepared electrolytically, is introduced together with a large platinum foil which is connected to the manganese amalgam. After several days the platinum foil is removed, rinsed with water, and the deposit washed off with concentrated hydrochloric acid. The solution thus obtained is diluted with water, neutralised with sodium carbonate, and slightly acidified with acetic acid. Hydrogen sulphide is then passed to remove zinc, nickel, cobalt, and the metals of the first two analytical groups. The solution then remaining contains manganese with ca. 2 per cent. dwi-manganese, as shown from the spectrometric evidence

given by the hydroxides precipitated from this solution by sodium hydroxide.

The simultaneous polarographic examination of the manganous solutions always reveals two impurity humps which constitute 2-3 per cent of the manganous content (Fig. 2). One, as shown previously, is due to the element 75; whether the other hump is caused by the element 43 could not be determined, as the coil used would not withstand the powerful exposure for the K-series of element 43.

Concentrated acidic chloride solutions containing element 75 are greenish although nickel has been carefully removed; the dry green chloride darkens rapidly to black on standing. Neutral chloride solutions containing element 75 deposit a yellowish-brown precipitate on standing in air, probably due to oxidation; this precipitation is avoided in the electrolytic method where the solutions are kept in an atmosphere of hydrogen. This seems to indicate that higher valency compounds of element 75 are more stable than those of manganese. In agreement with this is the fact that the manganous chloride prepared from potassium permanganate (Merck's "pro analysi") gives a polarographic hump six times as high as an equi-concentrated solution of manganous sulphate. This chemical behaviour

coincides with that mentioned by Dr. G. Druce (*Chem News*, 131, p. 273, 1925), whose results indicate the presence of element 75 in crude manganese compounds.

The provisional spectroscopic results are: $L\alpha_1 = 1430$ X.U., $L\beta_1 = 1235.3$ X.U., $L\beta_2 = 1204.3$ X.U., $L\gamma_1 = 1059$ X.U. The copper $K\beta$ -line was used as reference (M. Siegbahn and V. Dolejšek, *Zeitschr. f. Phys.* 10, 1922, 159). No lines of other elements appeared in the spectra of the final specimens except the copper K -lines. The $L\alpha_1$ -line could not be measured with the same exactness as the others since only the most recent specimens were entirely free from zinc.

W. Noddack, I. Tacke, and O. Berg claim (*Naturwiss.*, 1925, 26, 567) to have discovered the element 75 in columbite. As there published, their spectroscopic evidence is not conclusive, since two of their β -lines of the L series of element 75, according to their own data, coincide with those of tungsten;

moreover, their observed $L\beta_2 = 1204.8$ X.U. and their $L\beta_3 = 1216$ X.U. for element 75 happen to coincide exactly with $L\alpha_1 = 1204.7$ X.U., $L\alpha_2 = 1216.0$ X.U. for thallium. In view of the accuracy of their measurements, their observed lines agree with those of thallium better than with those calculated for element 75, namely, 1204.1 and 1216.9. They do not state whether the specimen was freed from thallium, a common impurity in such minerals, which in the presence of arsenic would accumulate with the insoluble sulphides; their "eka-manganese" should not be precipitated by hydrogen sulphide (cf. Dr. Druce's results). The only free $L\alpha_1$ -line they recorded, which by the ordinary Siegbahn dispersion is indistinguishable from the $K\alpha_1$ -line for zinc (difference ca. 1 X.U.), might be, at the abnormal dispersion they used, a new, hitherto unobserved, line split off from the zinc doublet.

From the scientific point of view the chemical character of the element 75 seems to the present

authors more suitably expressed by the old Mendeléeff designation of "dwi-manganese" than by "rhenium," as proposed by the German authors.

The Law of Force and the Size of Diatomic Molecules, as determined by their Band Spectra.

It is well known that from an evaluation of the vibrational energy of a diatomic molecule, as a function of the vibrational quantum number n , it is possible to deduce quantitatively the law of force of the molecule, in the vicinity of the equilibrium position of the two nuclei. Now when the dipole rotates, the nuclear separation r increases, and the amount of this increase depends upon the forces called into play when the nuclei are displaced from the equilibrium distance r_0 . But these are the same forces which determine the frequency of vibration ν_0 and the vibrational energy. Hence, if neither the vibration nor the rotation is sufficiently violent to distort the electron orbits appreciably, there should be a direct connexion between the constants which enter into the vibrational energy function, and those which characterise the rotational energy.

Kratzer has obtained such a relation, in its first approximate form ($\nu_0^2 = -4B^2/D$), but in the few cases where this matter has been considered, the relation in question has been assumed rather than carefully tested. I have now, however, derived the following direct relations. If one assumes for the law of force the function $F = k_1(r - r_0) + k_2(r - r_0)^2 + k_3(r - r_0)^3$, etc., and for the rotational energy of a non-vibrating molecule the usual function $E_m = Bm^2 + Dm^4 + Fm^6$, etc. (where m is generally, but not always, an exact half-integer), then the k 's, I find, may be expressed as explicit functions of B , D , F , etc. Explicit expressions for the k 's in terms of the constants of the vibrational energy function may be obtained from the work of Born and Hückel (*Phys. Zeitschr.* 24, 1, 1923). From vibrational energy data it is possible to evaluate k_1 with great accuracy, k_2 and k_3 with fair accuracy, and in the case of HCl, even k_4 at least roughly (paper by Prof. E. C. Kemble, now in press). From rotational energy data it is possible to determine k_1 with fair accuracy, and in the case of CN, even k_2 at least roughly. The great difference in accuracy is due to the fact that the available data on rotation, in the case, for example, of CN, apply to a maximum value of $(r - r_0)/r_0$ of only three per cent., while the maximum observed amplitude of vibration is about fifteen per cent.

Using new measurements and calculations for the $\lambda 3883$ CN band, I have evaluated the rotational energy function, for the final (emission) state, up to $m = 91.5$, and from these data have obtained $k_1 = 16.12 \times 10^5$ dyne $\cdot$ cm $^{-1}$, $k_2 = -6.18 \times 10^{14}$ dyne $\cdot$ cm $^{-2}$. From the vibrational energy data, by the customary process I obtain $k_1 = 16.00 \times 10^5$ and $k_2 = -5.44 \times 10^{14}$. Considering the accuracy with which the rotational energy data must be known, to obtain a value even of k_1 , this agreement is quite remarkable, but can scarcely be accidental. It is to be emphasised in this connexion that the first set of values is obtained from an analysis of the energy of the molecule in a series of states in which it is rotating, but not vibrating, while the second set of values is deduced from the energy in a series of vibrating, but non-rotating, states.

Hence the two sets of data are entirely independent, and the agreement of the results is a real confirmation of the theory underlying this work.

In a similar manner I have obtained values of k_1 from the rotational and from the vibrational energy data, for the initial and for the final state of the CN, CuH, N_2 , and N_2^+ molecules, using for the rotational energy data the (O, O) bands $\lambda 3883$ CN, $\lambda 4280$ CuH, $\lambda 3914$ N_2^+ , and $\lambda 3371$ N_2 . The mean position of the doublets was used for the first three bands, and the middle component of the triplet for the last. The difference between the rotational and vibrational energy values of k_1 for the initial and final states respectively, for the four molecules in the order named, is -1.0 and $+0.75$, -1.7 and $+3.5$, $+0.4$ and $+2.2$, $+4.8$ and $+3.2$ per cent. In all cases the discrepancy is well within limits of error.

This quantitative agreement in the case of the two non-polar molecules N_2 and N_2^+ has an interesting consequence. As we now know, the successive lines forming the band series of such molecules usually alternate in intensity, and the explanation of this phenomenon has become a matter of considerable difficulty. The only promising explanation thus far is due to Dieke (*Zeit. f. Phys.* 31, 326, 1925), but it carries as a necessary consequence a reduction of the value of the moment of inertia to one quarter of the previously accepted value. A serious objection to such a reduction is the close correlation between the magnitude of the frequency of vibration and of the moment of inertia (using the older values), noted independently by several investigators (see, for example, Mecke, *Zeit. f. Phys.* 32, 823, 1925). This, however, is not necessarily a vital objection to Dieke's theory, since it may well be that there is such a correlation for both polar and non-polar molecules, but that the "correlation factor" is quite different in the two cases.

I now find that Dieke's interpretation of the band series of non-polar molecules, which involves halving the customary values of m in the expression for E_k , leads directly to a value of k_1 just four times as large as that obtained from the same rotational energy data, using the older theory. Hence the above quantitative agreements, which are based on the older interpretation, seem to offer conclusive evidence in favour of the usually accepted values of the moments of inertia of non-polar molecules, as against the new smaller values. This assumes of course that the value of k_1 as obtained from vibration is correct, and it may be noted that permitting the vibrational phase integral ($\int p dq$) to vary by only $h/2$ between adjacent possible values, would in turn lead to a value of k_1 four times as large. Since, however, Dieke's interpretation leads to no change in the assumed minimum possible variation (h) of the rotational phase integral, there seems to be no reason for modifying this fundamental postulate of the quantum theory, in the case of the vibrational phase integral.

RAYMOND T. BIRGE.

University of California, October 17.

The Variation with Depth of Certain Salts utilised in Plant Growth in the Sea.

DR. STANLEY KEMP and the scientific staff of the R.R.S. *Discovery* have been good enough to provide us with water samples which have rendered it possible to obtain information, long considered desirable, as to how far the depths of the oceans act as reservoirs of salts necessary for plant growth. The samples also enable a comparison to be made between the concen-

tration gradient found in these and in more southerly latitudes, between Lisbon and the Canary Isles.

The following determinations were made, and are shown in the table, along with the temperature records received from Dr. Kemp: alkalinity of the water, expressed as pH , namely, $\log 1/H$, where H is the hydrogen ion concentration in grams per litre; phosphate, expressed as phosphorus pentoxide, nitrate as nitrogen, and silicate as silicon dioxide, all three in milligrams per cubic metre, namely, parts per thousand million of sea water. The methods of analysis have already been described in the *Journal of the Marine Biological Association*, save that for nitrate, which forms the subject of a forthcoming paper by one of us.

Depth in Metres.	T. °C.	pH.	In mgm. per m ³ .		
			P ₂ O ₅ .	Nitrate-N ₂	SiO ₂
0	21.10	8.35	0	15; 11	220
10	21.10	...	...	7	
20	21.00	...	...	6	
30	21.00	...	...	...	
40	21.00	...	...	16	220
50	20.01	8.35	0	ca. 6	
75	17.31	8.31	5	6	
100	15.10	8.18	8	55	
150	15.06	8.16	10	65	250
200	13.86	8.11	22	100	
300	12.25	8.12	44	178, 158	
500	10.94	8.00	50	200	
1000	9.55	8.03	74	264; 262; 274	450
2000	4.81	7.94	78	ca. 265	480
3000	3.10	7.87	88	ca. 265	1200

These figures show a marked gradient in pH , due mainly to the activity of the phytoplankton in removing carbon dioxide, but in part also the high surface values are due to the high temperature altering the equilibrium between bicarbonate and atmospheric carbon dioxide. The persistence of high alkalinity down to 75 metres is doubtless associated with the more intense illumination of the southern regions. The samples were taken at $37^{\circ} 44' N$, $13^{\circ} 21' W$. on Oct. 12, save that at 3000 m., which was taken on Oct. 16 at $29^{\circ} 59' N$, $15^{\circ} 03' W$. They were analysed on Oct. 30-Nov. 2, in a comparatively fresh condition, though minor changes may have occurred.

Quite in keeping with the pH values are those for phosphate and nitrate. The complete removal of phosphate down to at least 50 m. shows that, as previously reported, lack of phosphate sets a limit to the multiplication of the phytoplankton. The corresponding low values for nitrate indicate that this constituent runs phosphate close as a limiting factor; indeed it is possible that it does limit growth under certain conditions, for in early August in the English Channel this year some regeneration of phosphate had occurred, but down to the bottom, 70 m., only traces of nitrate were found.

Once the illumination becomes inadequate, both phosphate and nitrate increase, so that in the deeper waters they accumulate; not until upwelling occurs, when the deep water is moved to good illumination, are these supplies again available for plant growth; from this it follows naturally, as suggested by Nathanson, that oceanic banks are noted fishing grounds, for the phytoplankton constitutes the ultimate food source of oceanic animals.

The silica analyses show that while much silica is removed—by the diatoms—from the upper water, lack of silica is not under these conditions a factor

limiting diatom growth. The values given may be somewhat high owing to the solution of silica from the glass during storage. Tests with similar bottles leave, however, little doubt as to the substantial accuracy of the conclusions reached from the figures given here.

The Stokes-Planck Theory and the Michelson-Morley Experiment.

It seems to have been implied, in recent discussions, that the Stokes-Planck ether theory, while correlating the facts of astronomical aberration and other first order phenomena having to do with the earth's motion, is also in harmony with Prof. Miller's recent experiments in which he concludes that there is an ether drift relative to the earth, amounting to zero at the earth's surface and to something of the order of 10 kilometres per second at the altitude of Mount Wilson. It would appear that this conclusion cannot be substantiated.

It will be recalled that the original Stokes' theory was unsatisfactory because, when the velocity normal and relative to the spherical boundary was assigned (its value being in fact zero), the problem for irrotational flow was uniquely determined, and the solution gave finite and indeed considerable tangential relative velocities at the surface. The Planck generalisation introduced the idea of a variable ether density, and, by making the ratio of the density at the surface to that at infinity sufficiently large, it was possible to make the tangential velocity as small as desired.

On looking more closely into the analysis, however, it appears that the Planck solution serves to determine the way in which the tangential velocity varies with altitude in the vicinity of the sphere, and denies the possibility of any such change as 10 kilometres per second for a change of altitude of 1.7 km.

Thus, referring to the solution as given in Note 67 of Lorentz's "Theory of Electrons," we have for the velocity potential

$$\phi = z \left[a \left(\frac{\mu\omega}{2r} - 1 \right) + b \left(\frac{\mu\omega}{2r} + 1 \right) e^{-\frac{\mu\omega}{r}} \right], \quad (1)$$

where

$$b - a = w_0$$

and

$$a = \left(\frac{\mu^2\omega^2}{2R^2} + \frac{\mu\omega}{R} + 1 \right) e^{-\frac{\mu\omega}{R}b},$$

and where μ and ω are constants, R is the radius of the earth, w_0 the relative velocity parallel to the axis of z at infinity. The origin is at the centre of the sphere, r is the radius vector, and z the distance from the origin parallel to w_0 .

From the above it is easy to show that, if V_R and V_{R+h} are the horizontal relative ether drifts for $z=0$ at $r=R$ and $r=R+h$ respectively, where h is a relatively small increment in r ,

$$\frac{V_{R+h} - V_R}{V_R} = \frac{h}{R}$$

Hence, if $h=1.7$ km, and R is the radius of the earth (6400 km.), it is obviously impossible to have the change of velocity $V_{R+h} - V_R$, which Miller concludes to be 10 kilometres per second, comparable even with the quantity V_R which the object of the large density ratio is to render negligible.

The Chromosome Complex of *Gammarus chevreuxi* Sexton.

THE spermatogenesis of *Gammarus chevreuxi* having been investigated by me at the Plymouth Laboratory of the Marine Biological Association, it was considered desirable, in view of the genetic interest of this form, and of the fact that detailed results will not be published for some months, to summarise briefly the essential conclusions. These are.

(1) The chromosomes of *Gammarus chevreuxi* are small, ovoid and minutely heteromorphic, and have a diploid number in the male of twenty-six, this number being arrived at by the study of a large number of spermatogonia, and also of spermatocytes and synapsis stages.

(2) This chromosome number includes in the male an X and a Y chromosome, the former being larger, and the latter smaller than any of the autosomes.

(3) The spermatogonial metaphase plates fall into two distinct classes as regards chromosome size. There is considerable evidence that the large plates are merely the later stages of the spermatogonial series.

(4) While *Gammarus* does not provide favourable material for the detailed study of synapsis, the chromosomes appear to spin out in the typical way in the early synaptic stages.

(5) Preliminary studies of the embryonic chromosomes indicate that the somatic chromosome number is about twenty-six, but sufficiently favourable material has not yet been obtained to warrant any more definite statement.

The Solar Constant and Terrestrial Magnetism.

DR. CHREE has obligingly sent me a copy of his paper entitled "The Relationship between the 'Solar Constant' and Terrestrial Magnetism" (*Proc. Roy. Soc. A* 109, 1925). He finds no indication in the solar constant data of 1918-1924 of a repetition of departures after a solar rotation period. This finding is quite in accord with ours. We have, indeed, noted the solar rotation period very plainly in some of the data, but only for a few months at a time, as in the year 1915. (See C. G. Abbot, "On Periodicity in Solar Variation," *Smithsonian Miscellaneous Collections*, vol. 69, No. 6, 1918).

In the second place, Dr. Chree does find indications of magnetic disturbance associated with low values of the solar constant. Inasmuch as higher solar constant values are generally associated with numerous sun-spots, and abundant magnetic disturbances, he thinks this paradoxical finding of low solar constants associated with magnetic disturbances is non-significant. On the contrary, it is exactly what we should expect.

Referring to a recent paper (C. G. Abbot, "Solar Variation and Forecasting," *Smithsonian Miscellaneous Collections*, vol. 77, No. 5, page 23, Figs. 15 and 16), the passage of an individual sun-spot group over the central meridian of the solar disc is almost always associated with decreased values of the solar constant, and doubtless frequently with terrestrial magnetic disturbances. Hence, it is prevaillingly with low rather than high solar constant values that individual magnetic disturbances will be found associated.

Examination of Bronze Implements.

By Prof. C. O. BANNISTER and J. A. NEWCOMBE.

THE results of modern methods of research on the constitution of metallic alloys and on the effects of varying mechanical and thermal treatment on their structure and mechanical properties have increased our knowledge of these subjects enormously. Of these methods, the use of the microscope for the examination of the micro-constitution and crystalline condition of suitably polished and etched specimens is one of the most important. This method of examination is capable of indicating not only how the component metals exist in the alloy, but also what mechanical or heat treatment the alloy has undergone. As regards constitution, the microscopical examination is used in order to ascertain whether the component metals are present in the free state, in chemical combination, or mutually dissolved and retained in solution in the solid state. As regards treatment, the structure observed is used to decide whether the metal object was obtained by a casting process or was shaped by mechanical work, and is also capable of indicating whether any work has been applied to the object and also whether this work has been followed by an annealing process. Below are given some results of an examination of a chisel and a palstave of the Bronze Age found about 1898 in a brick-field near the Hanwood-Shrewsbury road and supplied by Mr. F. Drinkwater of West Kirby through Miss L. F. Chitty of Yockleton, near Shrewsbury.

With regard to the constitution of bronzes, these consist of alloys of copper and tin in varying proportions, and if the molten metals be allowed to solidify and cool very slowly, or if cooled normally and then reheated for the necessary length of time, the tin is soluble in the copper in the solid state up to 13 per cent. of tin. After such treatment, the bronze would show one constituent only under the microscope.

On cooling a liquid alloy containing 8-13 per cent. tin, the first portions to solidify are richer in copper than the portions solidifying last. On polishing and etching such an alloy, these copper-rich portions are found to have a fern-like structure, and the presence of these dendrites, as they are called, is indicative of cast metal. The alloy not being homogeneous throughout its mass has areas with a greater tin percentage than 13, and in these areas a pale blue constituent, which is a very intimate mixture of two solid solutions, makes its appearance. The more of this second constituent that is present the harder and more brittle does the metal become, and with any definite percentage of tin the more quickly the metal is cooled, within limits, the more of this constituent is present in the casting. If the cast bronze be now heated for some hours at a temperature below its melting point, diffusion takes place, the metal becomes more or less homogeneous in composition, and the dendrites and the second constituent more or less disappear, the metal becoming more homogeneous the longer the annealing or the higher the temperature. With cast bronze of less than 8 per cent. tin, the dendrites would appear as above, but little or no blue constituent would be present because the tin rich areas would contain less than 13 per cent. of tin.

If the cast metal were cooled in the mould very slowly, this would have, as regards the homogeneity of the metal, a similar effect to annealing. The rate of cooling of a casting will depend on three factors: first, the temperature of the metal when it is cast, it being obvious that the higher this temperature the longer will the solidifying and cooling take. Secondly, the material of which the mould is made. If the material conducts heat rapidly from the metal, the rate of cooling will be greater than in the case of a mould from which the heat was less rapidly removed. The stone mould commonly used for casting antique bronzes would be a bad conductor of heat, and the cooling would take place very slowly. A bronze mould would chill the casting, and cooling would be very rapid. A sand mould would have an effect intermediate between these two. The third factor would be the size of the casting, one of large bulk cooling more slowly than a smaller casting, as there would be more heat to disperse.

Another important characteristic in the structure of bronze is the outline of the crystals revealed by the etching. In the cast metal the crystals are very irregular, some crystals being of large size compared with others, and having interlocked boundaries. If the metal be now worked in some way by hammering or rolling, an examination will show the results of this work in the distortion of the original crystals, which are often elongated to a considerable extent at right angles to the direction of the work when this has been excessive. The effects of less drastic amounts of work are seen in the appearance of parallel lines on the crystals, these lines being known as slip bands. If the metal be annealed after working, new crystals will make their appearance, appearing quite different from the casting crystals and characteristic of the annealed metal. These crystals are much more uniform in size, and have sharp lines as their boundaries. They invariably show a great deal of twinning, which is recognised by the crystals having two or more parallel lines traversing them. As a result of this working the dendritic structure will be somewhat destroyed. Instead of being fern-like, it generally appears as thick, dark, irregular parallel bands over the specimen in a direction at right angles to the force applied. A long annealing entirely eliminates this structure, but the new crystals grow before this is effected, so that in annealed metal, traces of the dendrites may still be seen.

It will be gathered from these notes that much can be deduced from the micro-examination of antique bronzes. From the fern-like, dendritic, or core structure, as it is variously called, and the type of crystal boundaries, the cast structure is at once recognised, and with an 8-13 per cent. bronze some sort of deduction can be made as to the mould used, because with very little of the blue constituent present the metal would have cooled slowly, and it is probable that a stone mould would have been used. The twinned equiaxed crystals and the partial or total absence of dendrites indicate that the metal had been hammered and annealed.

Examination of Chisel.

The chisel was 15.5 cm. in length and, as is shown in Fig. 1, was fractured when received. The fracture showed a considerable amount of porosity. An analysis shows copper 85.5 per cent., tin 14.2 per cent. A section taken of a part near the fracture was polished and etched in a solution of ammonia containing a few drops of hydrogen peroxide. Fig. 2 shows the dendritic structure at a magnification of 15 diameters. The section was again polished and photographed unetched. Fig. 3, at a magnification of 25 diameters, shows how very porous the metal is; the holes were formed at the

amount of blue constituent and the number of blow-holes would indicate the metal to be very brittle, and on examination the metal was found to be so brittle that it could be crushed by gentle tapping with a small agate pestle.

A very important matter brought out by the examination of this ancient chisel is the persistence of the dendritic or core structure, because it has been suggested that, during the course of a long time, even at ordinary atmospheric temperatures, diffusion would proceed in solid alloys, with the result that equilibrium would eventually be obtained exactly as it may be

FIG. 1.

FIG. 2. $\times 15$.FIG. 3. $\times 25$.FIG. 4. $\times 60$.FIG. 5. $\times 270$.

time of casting, and were due to the fact that the metal was cast at too high a temperature and insufficient provision was made for the escape of gases from the metal. Fig. 4 was taken to show the dendritic structure at the higher magnification of 60 diameters and is typical of cast bronze. Fig. 5, taken at a still higher magnification of 270 diameters, shows the blue constituent situated along the boundaries of the crystals. The percentage of tin present in the alloy would account for this apart from the heterogeneity of the metal.

From the well-defined dendritic structure and the large proportion of blue constituent, it may be assumed that the metal cooled quickly in the mould, the small bulk of metal being sufficient to account for this, apart from the nature of the material of the mould. The

obtained at higher temperatures in a few hours. The dendritic structure of this chisel, however, is so typical of a recently cast bronze that it appears safe to say that no diffusion has taken place during the ages.

Examination of Palstave.

The palstave examined is shown in Fig. 6, and is 15 cm. long. An analysis shows copper 86.9 per cent., tin 12.7 per cent. A portion of the socket was polished and a photomicrograph was made of a portion adjacent to the corrosion product at a magnification of 75 diameters; this is shown in Fig. 7. The corroding agent operates in the first place along the crystal boundaries, this being the portion of the metal in which any traces of impurities present become concentrated,

corrosion taking place more readily with impure than with pure material. The presence of corrosion of this type in bronze is a sure proof of its antiquity, and a check against the fraudulent "antiques" which are made with so much perfection at the present day. With recently cast bronze, although it is easy to imitate the effect of age on the outside by chemical means, age alone will allow the slow penetration of the corrosion around the crystal boundaries without too rapid attack on the crystals themselves.

Fig. 8 was very deeply etched by means of a solution of ammonia containing hydrogen peroxide to show the

A section of the cutting edge was polished and etched, and the photomicrograph is shown in Fig. 10, at a magnification of 75 diameters. The crystals shown here are much smaller in size and of a totally different shape from those of Fig. 9. They are more uniform in size, they are sharp, and a large number of them are twinned. It will be observed that indications of dendrites are almost entirely absent. This structure shows that this end of the palstave has been hammered and afterwards heated. There is little doubt that the hammering was performed with the object of sharpening or reshaping the palstave, and the reheating operation

FIG. 6.

FIG. 7. $\times 75$.FIG. 8. $\times 70$.FIG. 9. $\times 75$.FIG. 10. $\times 75$.

type of crystals present. The very irregular crystals can be seen, and it will be noticed that the corrosion follows the crystal boundaries. Some of the crystals show striations across their surfaces and these are slip bands. These slip bands are formed when a metal is subjected to an amount of work just sufficient to cause a permanent deformation in them. This would naturally be towards the end of the socket where the metal is thinnest, and would be caused by the force exerted on this part by the wooden handle fitted on to the socket when the palstave was in use. The smaller dark patches in Fig. 9 consist of the blue constituent, but the larger are the result of corrosion.

Fig. 9 shows more clearly the shape of the casting crystals and illustrates variation of size and interpenetration.

was used to remove the brittleness induced by the work, as it would soon become apparent to the ancient metallurgist that these operations would give a stronger and tougher metal. The metal could not have been hammered hot, because bronze of this composition is not malleable when hot. The palstave was finally annealed, as otherwise the effect of the work would have been apparent on the crystals in the photograph.

From Figs. 8 and 9 it is evident that the dendrites are not well defined, and very little blue constituent is present although the composition is near the maximum at which tin is soluble in copper. This is due to the comparatively long time the metal took to solidify and cool, thus allowing some diffusion to take place in the solid metal, and the composition to become approximately uniform.

It has been suggested that if an antique metal had been worked or strained, crystals may form at ordinary

FIG. 11. $\times 300$.

temperatures during the ages similar to those that would be formed in a short time if the metal were

heated. The evidence obtained from the examination of this palstave appears to prove that this is not so in the case of bronze. Fig. 11 is a photomicrograph of a portion near the cutting edge of the palstave and is similar in appearance to the structure shown in Fig. 10, but at a higher magnification of 300 diameters. This photograph was taken in order to illustrate the fact that corrosion on this part of the palstave follows the crystal boundaries, which are not of the casting crystal type but have been formed subsequent to mechanical work. The presence of the corrosion product in these boundaries indicates that these crystals must have been in existence before corrosion commenced and therefore had not been slowly formed during the ages. This photograph also shows that the crystals are still of the same size as they were when corrosion commenced and that no growth has taken place. This suggestion of the germination of crystals during the enormous time that has elapsed since the castings were made is further disproved by Fig. 8, as the slip bands shown in this photograph indicate strained metal and no new crystals are seen to have formed.

The Darling and Lothian Foundations for Research in Malaria.

SOME months ago we had to record (*NATURE*, May 30, p. 845), with much regret, the deaths in a motor-car accident, near Beirut in Syria, of Dr. S. T. Darling (United States of America), Dr. N. V. C. Lothian (England), and Mlle. Besson (France), members of the Malaria Commission of the League of Nations who, with Prof. Nocht (Hamburg), Swellengrebel (Amsterdam), Ottolenghi (Italy), Anigstein (Poland), and Colonel James (England), were undertaking a tour of investigation in Palestine, Syria, and part of Turkish Asia Minor. In the recently published report on the work of the fifth session of the League's Health Committee, held at Geneva on October 8-14, it is announced that the Committee, wishing to honour and perpetuate the memory of Dr. Darling and Dr. Lothian, has decided:

(1) To collect by private subscription a capital fund, the interest on which will be expended on a prize to be awarded periodically. This will be known as "The Darling Prize."

The prize (a medal or other reward) will be awarded by the Malaria Commission of the League of Nations to a scientific worker who, in its opinion, has carried out recent distinguished research on a subject connected with malaria which comes within the general scope of the Commission's investigations.

(2) To devote a portion of the credits provided for in the budget of the Health Organisation for the encouragement of malariological study to the establishment of a periodical scholarship to be known as "The Lothian Scholarship." This scholarship will be awarded by the Malaria Commission to a selected candidate whose course of study should be in conformity with the general programme of the Malaria Commission.

In our issue of August 8, p. 216, we printed the substance of an appreciation, from the pen of Prof. R. W. Hegner, of the life and work of Dr. Darling. In the Malaria Commission's report of the Palestine tour, which preceded the journey to Syria on which the tragic accident occurred, it is said that the Commission had frequent occasion for congratulation that Dr. Darling had found it possible to be one of the party. "His

previous experience of malarial epidemiology and anti-malarial operations in many countries was unrivalled. He appreciated very clearly the particular aspect of the subject with which the Commission's mandate is chiefly concerned, and his observations during the tour constantly proved that he was at the zenith of his powers as an expert adviser on antimalarial work."

Dr. Lothian joined the Secretariat of the Health Section of the League in May 1923, after a career of considerable achievement in the Royal Army Medical Corps. He had specialised in hygiene, and some of the scientific papers which he published during his army service were of outstanding merit and practical usefulness, notably his "historical inquiry into the load carried by the soldier of various periods," in which he showed that a soldier should not be required to carry more than 33 per cent. of his own weight; the load of a mule is 32 per cent. and of a horse 28 per cent., and to require a soldier to carry more than 33 per cent is to destroy his marching power and capacity for battle.

Dr. Lothian, during his two years' service with the League, travelled in many countries and came into close contact with administrators and public health officers of many nationalities. He accompanied and guided the "interchange courses" of foreign public health and medical officers which, in collaboration with the Rockefeller Foundation, now form a regular item in the programme of the Health Organisation at Geneva. He was secretary to the League's Malaria Commission, and in the report of the Commission's tour of investigation through eastern Europe and Russia, which was published last year, the chapter entitled "Summarised Impressions of the Tour" was wholly drafted by him. It is a sufficient illustration of his expert knowledge of the subject and of the industry which characterised all his work. His high sense of duty and his attractive personality gained him the highest regard and respect wherever he went, and the shock of his death was the greater because he was in the exuberant vigour of youthful manhood, looking forward with enthusiasm to the highest and best that life holds in store.

The Total Solar Eclipse of January 14, 1926.

NUMEROUS parties have been organised to observe the solar eclipse on January 14 next, which is total in central and eastern Africa, Amirante Islands, Sumatra, Borneo, etc. (Fig. 1). The duration of totality is $2^m 12^s$, and the sun's altitude about 26° on the African coast, which is to be occupied by Signor Horn d'Arturo. The Amirante Islands will not, apparently, be occupied, the meteorological conditions being unpromising.

Most of the parties will be stationed in Sumatra,

stood that this shift will be investigated by a party from Potsdam, stationed near Palembang, and by Prof. Miller of Swarthmore Observatory, who will use a coronagraph of 60-feet focus.

Several other parties from the United States will also go to Sumatra, representing the Observatories of Harvard, Mount Wilson, and Washington (Naval); the names of Messrs. Anderson, Littell, and Stetson have reached us as belonging to these parties.

Messrs. Vanderbilt and Voute are going from Java

FIG. 1.—Map showing the track of the solar eclipse of January 14, 1926.

Emery Walker Ltd. sc.

where the duration of totality will be about $3^m 13^s$, and the sun's altitude 54° . Benkulen, on the west coast, is near the central line; the British party, consisting of Col. Stratton, Mr. C.R. Davidson, and others, will be stationed here. They will reach Benkulen via Palembang on the river Musi, the landing of heavy packages at Benkulen being difficult. They are taking two coelostats and the Copeland coronagraph lens of 40-feet focus, which has seen service at several eclipses. Their work will be wholly on problems of solar physics, the "Einstein" shift being considered as sufficiently established in 1919 and 1922. It is, however, under-

to Palembang. There is no news to hand of any parties occupying the islands east of Sumatra. This is the second time that Sumatra has been visited by eclipse expeditions in the present century; there was a very long totality there in May 1901, when Sir Frank Dyson, among many others, made successful observations, though the weather conditions were not wholly propitious. There will be another totality in Sumatra (northern part) on May 9, 1929, with high sun and more than 5 minutes' totality. The island will then have a rest until March 18, 1988, which is a return of the Indian eclipse of 1898 after five saroses.

Obituary.

PROF. JEAN MASSART.

BRITISH botanists will have learnt with regret of the death of Prof. Jean Massart, of the University of Brussels, which occurred somewhat suddenly at Houx, a little village on the Meuse, in August last. Prof. Massart had retired thither to recuperate, his health being possibly impaired by a long journey in Brazil with some of his students, followed by a strenuous lecture tour in America.

Born in 1865 at Etterbeek, a suburb of Brussels, Prof. Massart obtained his doctorate in science at the University of Brussels and became professor there in 1895. His early researches turned upon general biological problems, such as chemotaxy, pathologic

infection by micro-organisms, immunity, etc. From a study of the lower organisms, especially flagellates and fungi, he passed gradually to still more botanical fields of work. After the death of his former teacher, Prof. Léo Errera, he was nominated director of the Institut Léo Errera, and a great deal of his botanical work is published in the memoirs of the Institute. His early work upon the lower forms of plant and animal life has imparted a distinctive character to his recent text-book, the "Éléments de biologie générale et de botanique." Prof. Massart, however, is probably most widely known outside Belgium for his beautifully illustrated vegetation studies, especially of the polder country. His account of the recovery

of the vegetation in the devastated region of the Belgian battle front was referred to in *NATURE* (vol. III, p. 97, Jan. 20, 1923).

During the War, Prof. Massart's outspoken comments upon the actions of his country's invaders led to his enforced departure, and he found refuge first in Holland and then in France. During this period he continued botanical work so far as possible, and also tried by various means to raise funds for the aid of necessitous fellow-countrymen, Red Cross work, etc. Prof. Massart was back in Brussels in January 1919, where the present writer found him busily engaged in re-establishing order in Institute and Botanic Garden. Students were gathering around him and further investigations were already projected or in progress.

A quiet, forceful personality, immersed in his scientific work and the interests of the students under his guidance, Prof. Massart's departure makes a gap in the ranks of Belgian botany that will not easily be filled.

J. H. P.

THE funeral took place in Paris on November 3 of M. Eugene Tisserand, for many years a most prominent figure in French agriculture. Born at Flavigny-sur-Moselle, he lived to the great age of ninety-five years. In 1850 he entered the recently founded Institut Agronomique at Versailles. After a distinguished student career he spent five years in visits to other countries, studying their methods of agriculture. On his return he set about the task of enriching large areas of poor agricultural land. After the war of 1870 he was appointed Inspector-General of Agriculture, and he commenced his great campaign in favour of the furtherance of scientific agriculture in France. In 1879 he was appointed director of the newly reconstructed Institut Agronomique. At the same time he

was Director-General of Agriculture. Under his directorship the study of agriculture spread rapidly, and he was instrumental in establishing new laboratories and institutes. In the little time he had to spare from administrative duties he was engaged in research, and among his chief publications are "Economic Studies of Denmark and Schleswig-Holstein," "Vegetation of High Altitudes," and "The Low Temperature Treatment of Milk." He was a member of the Paris Academy of Sciences and also of the Academy of Agriculture, of which he was president in 1911. For many years he was chairman of the editorial board of the *Journal of the Institut Agronomique*. For his services to agriculture he was awarded the Grand-Croix de la Légion d'Honneur. The passing of so notable a figure is a great loss to French agriculture.

WE regret to announce the following deaths:

Prof. J. Guiteras y Gener, professor of general pathology and tropical diseases in the University of Havana, president of the Cuban National Board of Health and a founder of the *Revista de Medicina Tropical*, whose name is associated chiefly with the campaign against yellow fever, aged seventy-three years.

Dr. George Reid, formerly medical officer of health to the Staffordshire County Council, who was known as an authority on sewage disposal with reference to bacterial filtration and as the author of "Practical Sanitation," on November 6, aged seventy-one years.

Canon C. H. Robinson, editorial secretary to the Society for the Propagation of the Gospel, formerly lecturer in Hausa in the University of Cambridge and the pioneer white man in Hausaland, on November 23, aged sixty-four years.

Prof. H. J. Waters, president of the Kansas State Agricultural College from 1909 until 1917, who was known for his work on the nutrition of farm animals, on October 26, aged fifty-nine years.

Current Topics and Events.

THE death of Queen Alexandra on November 20, when within a few days of the end of her eighty-first year of age, has aroused world-wide expressions of regret and brought Great Britain and Denmark close together in sorrow at the loss of one whose memory will long be cherished with affection in both countries. From the moment when, as Princess Alexandra, she arrived in England in 1863 for her wedding with the Prince of Wales, to the day of her death, the Queen-Mother occupied a place in the hearts of British people which can never be filled again. She was loved by all, and her sympathy and active interest were always forthcoming for any institutions or organisations which worked to promote human well-being. It was through her that the Finsen light treatment was first introduced into the London Hospital, of which she was president. While on a visit to her native city of Copenhagen, she was so much impressed with the good results obtained there by the treatment of lupus by light that she presented a set of the apparatus to the hospital and thus initiated here the treatment of disease by light, which has now a recognised place in the domain of therapeutics. While Princess of Wales, and as Queen

Consort when the Prince of Wales ascended the throne under the title of King Edward VII. in 1901, her royal and beautiful attributes did much to mould the character of our national life. She identified herself with many progressive movements, and with King Edward in 1909 opened the Victoria and Albert Museum and the new buildings of the University of Birmingham. Though Queen Alexandra has now passed into silence, her life and influence will be remembered with pride for many generations.

BIRTHDAY congratulations are due to Prof. J. Ambrose Fleming, who will be seventy-six years of age on November 29. Son of that well-known divine, the Rev. Dr. James Fleming, he was born at Lancaster, November 29, 1849. He was educated in the first instance at University College, London, and at St. John's College, Cambridge, and early enjoying the advantage of study under Sir Edward Frankland at the old Royal College of Chemistry, almost the whole of Prof. Fleming's long working life has been devoted to teaching, in University College, the theory of electricity and magnetism, together with its manifold developments and, in addition, the industrial

applications arising therefrom. In 1879 he was scientific adviser to the Edison Telephone Company; later, he was associated with the Edison-Swan Company, actively engaged on the arc lamp, its accessories, and incandescent lighting in general. In 1899, when wireless telegraphy was forsaking the abstract, Prof. Fleming was helping the Marconi Company. The electrical resistance of metals and alloys constituted the basis of researches with the late Sir James Dewar. Prof. Fleming received the Albert medal of the Royal Society of Arts at the hands of the Duke of Connaught, in 1921, in recognition of valuable contributions to electrical science and its applications and specially of his invention of the thermionic valve, so widely employed in wireless telegraphy and telephony and for other purposes.

THE year's work of the Imperial Cancer Research Fund was reviewed at the annual general meeting held on November 19. It is as usual a record of solid unhurried progress towards elucidating the nature and modes of origin of cancer. A few years ago it was discovered by Japanese workers that malignant tumours of the skin could be produced with ease and certainty by the application of tar or some of its components; this made available a weapon of further inquiry of the greatest value which has been vigorously exploited in many directions. Thus in the present report we find that Dr. Cramer has shown that denervated skin responds less readily than normal, and Dr. Findlay demonstrates that a single application of hot tar may be followed months later by the development of cancer, reproducing in this way experimentally what had been suspected from human experience and observed in the branding of sheep. Other researches on the influence of one tar cancer in inhibiting the development of another are in progress: they indicate clearly that changes in the skin in one part of the body may alter the skin everywhere. The other main line of investigation arises through Gye's recent clarification of Rous's old observation that certain fowl tumours could be transmitted by extracts which contained no cells. The fundamental experiments are being repeated by Dr. Begg with chicken sarcoma and the venereal sarcoma of dogs at the Fund's new laboratories at Mill Hill, where the work is carried on in close association with that of Gye at the establishment of the Medical Research Council next door. It is too early to discuss such results as have been obtained, but it is clear that the new methods provide possibilities of analytical experiment which enable many old problems to be attacked in a fresh way. The progress of cancer research at the moment is satisfactory. The new knowledge is nowhere discrepant with the old but is enabling us to add together a number of apparently disconnected facts into a coherent tale. Not the least of the services rendered by the Imperial Cancer Research Fund is its maintenance by continuous propagation through animals of a number of animal cancers which are always available for use in its own laboratories and in any other responsible hands when a new idea crops up which needs experimental testing.

IN the *Lancet* of November 14 there is a paper "On the Specific Character of Malignant Neoplasia," by Dr. W. Blair Bell, professor of obstetrics in the University of Liverpool. This paper was the subject of an address given at the Toronto Academy of Medicine, and press reports announced the view that the author had made an important addition to the knowledge and cure of malignant growths. Dr. Blair Bell holds that malignant tumour formation is a specific growth process and is a reversion, on the part of a cell that is starving, to the nutriment-seeking proclivities of its ancestral type, the chorionic epithelium. With the co-operation of other workers Dr. Blair Bell has confirmed the observation of Gye and Cramer (1913) that in certain rapidly growing malignant growths there is a high phosphatide content, approximating to that found in the chorionic villi. Experimentally it was found that certain compounds of lead have a specific action on the chorionic epithelium leading to its death. From the chemical analogy between chorionic epithelium and cancer tissue, it was argued that lead might be expected to have a destructive action on the latter and such indeed it is claimed to have. A considerable number of cases of malignant growths have been treated and two of the successful cases are published by Dr. Blair Bell in some slight detail. Dr. Blair Bell hopes, however, that less toxic and more potent chemicals than lead will be discovered in further study.

THE controversy on the alleged transmutation of mercury into gold by Prof. Miethe still continues. It will be remembered that Prof. H. Nagaoka communicated to our columns (*NATURE*, July 18, p. 95) his production of ruby glass by means of a discharge between tungsten and mercury electrodes in paraffin oil, and also that E. Tiede, A. Schleede, and F. Goldschmidt (*Die Naturwissenschaften*, August 28, p. 745) failed to detect any trace of gold in mercury that had been treated by Miethe's method after it had been twice distilled in a high vacuum. The *Scientific American* (November 1925) now reports a similar failure from the experiments performed by Prof. H. H. Sheldon and R. S. Estey, of Washington Square College, University of New York. Initially, these workers used a specially constructed quartz-lamp provided with electrodes made of pure tungsten, and redistilled gold-free mercury obtained from a natural source. They operated the lamp for three separate runs, ranging from 30 to 50 hours, with voltage 170 and current strength 13 amp., and if Prof. Miethe's contentions are correct, they should have obtained at least ten times the amount of gold that could be detected by the analytical tests employed. The experiments were repeated, using an exact replica of Prof. Miethe's lamp, and following his *modus operandi* in every detail, but purified natural gold-free mercury was again employed. As no trace of gold was found in any of the tests, the authors suggest that the mercury used by Prof. Miethe was not sufficiently purified. In Germany, Prof. E. H. Riesenfeld and W. Haase have recently found that

ordinary mercury can only be freed from gold by repeated slow distillation *in vacuo*; according to them, all mercury on the market contains gold, and all the metal that has hitherto been used in transmutation experiments contained that element

DR. F. GOLLA writes to say that he finds it difficult to understand how our correspondent, in remarking (*NATURE*, October 31, p. 660) upon the recent Harveian Oration by Sir Frederick Mott, has failed to appreciate the answer which "the lecturer himself gave and on which he laid great stress," to the question: What ontogenetic event coincides with the maturity at birth of the cells of Leydig? Dr. Golla then proceeds to quote at some length from the address. "Seeing that the male sexual hormones are active for probably more than six months in prenatal and post-natal periods, it follows that this influence has been operating on all the somatic cells, including the nervous system, during this time. And, if there be an elective storage of the sexual hormone in the nervous system, as Steinach's experiments indicate, then a masculine behaviouristic tendency may thus early be engraven upon the nervous system. Moreover, by the sensitising influence of the testicular hormone, the primary male characters are thus early made dominant in all the bi-sexual somatic cells." A reference to Lillie's experiments and the pathology of sexual hypoplasia follows. What our correspondent commented upon was the ambiguity of Sir Frederick Mott's terminology and the looseness of his argument. To the term "ontogeny," morphologists attach a precise meaning which can scarcely be identified with a "behaviouristic tendency," masculine or feminine. A few showy experiments do not set aside the fact which a rapidly increasing morphological literature is forcing upon our notice, that knowledge of the interstitial cells of the ovary and testis is fragmentary and conflicting. "Great stress" is a poor substitute for amply substantiated fact.

THE situation in China continues to attract a considerable amount of attention and a number of articles in the November reviews deal with various aspects of the subject. Among them Mr. George W. Keeton's study of the psychology of the Chinese student in the *Nineteenth Century and After* may serve to dispel a number of popular delusions on the characteristics of the race. At the same time, the author places his finger on perhaps the most important differences between the student of the west and of the east when he emphasises the Chinese student's lack of intellectual initiative and his proneness to memorise rather than reason—a characteristic in which the Chinese does not stand alone among eastern peoples. Another article in the same review, on the anti-Christian movement, by the Rev. A. Churwin, is also necessarily much concerned with the student as being practically the only articulate class in present-day China. Mr. Churwin shows that although much of the anti-Christian propagandist output is crude and, in so far as it is inspired by Soviet Russia, anti-religious, it is not so much the product of intolerance

as of an attitude based on a patriotic belief in Chinese culture with its long and creditable history of achievement. Against this is opposed a Christianity which, to the Chinese mind, represents in its past history and present performance an agency bringing interference with Chinese culture and ideals, western imperialism, and exploitation. This opinion is strengthened when the Chinese review the history of Christianity in the west, their judgment in this matter being strongly coloured by the critical point of view adopted by Mr. Bertrand Russell in his lectures delivered in 1922.

INTERESTING sidelights are thrown on the influences at work in present-day India by an article on "Orthodox Hindu Women," by Cornelia Sorabji, which appears in the *Empire Review* for November. The author gives a sympathetic account of the training of the Hindu girl with its insistence on the importance of caste and of marriage in the life of a woman. The resulting orientation of the female mind is entirely in the direction of the absolute acceptance of the complete subordination of the purpose of womanhood to the well-being of the soul of her husband after death and of the souls of his male forebears. This leads on one hand to the status of the wife being made dependent on the birth of sons who may inherit and thus carry on the cult, on the other hand, to the devotion of the widow, since the suppression of *suttee*, to ceremonial observances for the benefit of her late husband. The broader significance of this mental attitude is its indication of the almost complete preoccupation of the orthodox who form the majority of the Hindu population with religious rather than political matters. The position of "progressives" in these matters is delusive. The door has closed behind them; for the bulk of the population religion is still the dominant factor, and not negligible, as might be thought from a superficial view based upon the departure of the Progressives from certain observances, such as that by which the age of marriage has been raised. The successful suppression of a custom so fundamental psychologically as *suttee* is an indication of what has been possible in the past by the exercise of tact and informed judgment rather than force. Sympathetic knowledge of Hindu orthodox psychology is no less essential in dealing with the situation to-day, though this seems in danger of being overlooked.

THE November issue of *Scribner's Magazine* opens with a well-reasoned and temperate statement of the position of the American man of science in the evolutionist controversy by Prof. E. G. Conklin, who holds the chair of biology in Princeton University. His conclusions that the universality of natural law has not destroyed faith in God, that science leaves us faith in the worth and dignity of man, and that science gives us hope for the future, together with the arguments which lead up to these conclusions, are, in the main, such as will be familiar to those who have traced the development of thought on this subject in Great Britain. To English readers, however, the chief interest of Prof. Conklin's article lies in the exposition, thoroughly fair-minded, of the Fundamental point of view and the causes which have

strengthened this obscurantist movement in the United States. Among these causes, one of the most potent is undoubtedly the fact that the name of science has been taken in vain in recent years to justify license masquerading as freedom of development, moral laxity, and other social changes of an undesirable character, in a way that has brought the true spirit of scientific inquiry into disrepute with the uninstructed and narrower section of the population.

THE Cast Iron Research Association has now entered on the fifth year of its existence, and the report on its fourth year's working has just been published. The Association has a small central laboratory in Birmingham, but most of its investigators work in university or other public laboratories, or in the foundries of some of the component firms, often dividing their time between the foundry and the laboratory as the nature of the experiments demands. The programme of researches in hand is an interesting one, and although the record of definite scientific results is small in comparison with that of some other associations, this is largely to be accounted for by the fact that the industry formerly gave little attention to research, whilst problems of immediate practical importance were pressing for solution, and engaged the first efforts of the new body. Useful help has been given to the industry, and the investigators are now in a position to undertake more definitely scientific work. The determination of the ternary equilibrium diagrams which cover the range of composition of the cast irons has been begun at the National Physical Laboratory, and the results should assist materially in the control of the structure of cast iron. Reports on the progress of foundry methods in Germany have been issued to members, and the Association's Bulletins, containing full abstracts of technical literature and occasional longer articles on the theory and practice of foundry work, furnish another reason why it should receive the support of the industry.

AT the International Conference on Sleeping Sickness held in London during May last, it was unanimously resolved by the delegates to recommend to the Council of the League of Nations and to their respective governments to form a small international commission for the investigation of sleeping sickness in Africa (NATURE, June 27, p. 985). It was estimated that the expenses of such a commission would be about 10,000*l.*, and contributions were to be invited from the respective governments, the Health Organisation of the League of Nations, and scientific research institutions of certain countries. It was proposed to pursue investigations in Uganda and the regions adjacent to Lake Victoria, and the laboratories at Entebbe have been placed at the disposal of the commission. We now learn from the Geneva correspondent of the *Times* that the British Government has informed the Secretary-General of the League of Nations that it is ready to contribute a sum not exceeding 3050*l.* to the general expenses of the commission. The Belgian Government has already put at the disposal of the commission a sum of 100,000 francs, the Spanish Government 5000 pesetas,

and France the sum of 50,000 francs in the name of the administration of French Equatorial Africa and the French Cameroons.

CONSIDERABLE interest has been aroused by the announcement in the *Observer* of Sunday, November 22, of the discovery by Dr. Robert A. Millikan, director of the Norman Bridge Laboratory of Physics of the California Institute of Technology, Pasadena, of "ultra" X-rays of great penetrating power. It will be remembered that Dr. Millikan gave a series of three lectures at University College, London, in June 1924, and an abstract of the lectures, prepared by Dr. Millikan himself, was printed in our issue of July 26, 1924, p. 141, under the title of "Atoms and Ethereal Radiations." The last of the lectures dealt with "The Penetrating Radiations of the Upper Air" and it would seem that the recent announcement refers to a continuation of the work described in this lecture. In conjunction with Mr. I. S. Bowen and Dr. Russel Otis, measurements were made of the ionisation of the upper air by means of sounding balloons, during aeroplane flights and finally on top of Pike's Peak (14,100 ft) in Colorado. The conclusion reached from the latter experiments was that the whole of the radiation measured in the closed vessel used was of local origin and that "there can exist no such penetrating radiation" of cosmic origin as had been suggested by Kolhörster's work on the ionisation of the atmosphere. Dr. Millikan's new results are referred to as showing the existence of radiation of wave-lengths shorter than the γ -rays and capable of penetrating 6 ft. of lead. The publication of his results will be awaited with great interest.

IN consequence of the death of H. M. Queen Alexandra, the anniversary dinner of the Royal Society on November 30 has been cancelled.

THE eighth annual Streatfeild memorial lecture will be delivered at the Finsbury Technical College, Leonard Street, E.C.2, at 4 o'clock on Thursday, December 3, by Mr. F. H. Carr. The subject will be "The Scientific Basis of Industry."

THE second Röntgen Award of the Röntgen Society has been made to Dr. Robert Knox for his paper entitled "The investigation of the movements of the heart by the use of the slit diaphragm and the moving film," which he read before the Society during the course of the past session.

THE Council of the Royal Meteorological Society has awarded the Symons Gold Medal for 1926 to Lieut.-Col. Ernest Gold, assistant director of the Meteorological Office. The medal is awarded for distinguished work in connexion with meteorological science, and will be presented at the annual general meeting on January 20.

MR. L. C. M. S. AMERY, Secretary for Dominion Affairs and the Colonies, stated in the House of Commons on November 23 that the Governments of the East African Territories are prepared to grant sufficient funds to enable the Amani Research Institute in Tanganyika Territory to be reopened. The

necessary capital expenditure in this connexion can be found from the proposed guaranteed loan, for which a Bill will in due course be laid before Parliament. His Majesty's Government is, he said, fully alive to the importance of Amani for the future development of East Africa.

THE July number of the *Australian Museum Magazine* urges the need for additional building. The exhibition galleries are congested, the lecture-room should be doubled in size to accommodate all who desire to attend, and there is an entire lack of space for research students. It is sixteen years since additions were made to the building, and during that time the population of Sydney has increased from 600,000 to more than a million. To judge from this most attractive magazine, the Australian Museum is appealing on the best lines to the intelligent lay public of the Commonwealth, and it thoroughly deserves public support.

Messrs. W. Heffer and Sons, Ltd. (Cambridge), have in the press "The Nature of Tumour Formation," by Dr. G. W. Nicholson. The work embodies the Erasmus Wilson lectures of 1925, and seeks to

correlate the knowledge of the cellular changes which result in tumour formation with the established facts of biology and physiology, and to show that, although the etiology of tumours is still obscure, there is evidence that it is to be sought for in extrinsic causes.

Messrs. George Allen and Unwin, Ltd., have in the press "University Reform in London," by T. Lloyd Humberstone, giving an account of the establishment of the university and of the controversies which preceded its reconstruction as a teaching university in 1900. It will deal with current questions of university politics, including the reconstitution of the Senate, the policy of incorporating colleges in the University, and the site question. The work has an introduction by Mr. H. G. Wells.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned—A principal for Rutherford Technical College—Director of Education, Education Office, Newcastle-upon-Tyne (December 12). Junior scientific assistants in the Engine Research Section, Royal Aircraft Establishment—Superintendent, Royal Aircraft Establishment, South Farnborough (December 19).

Our Astronomical Column.

THE DETONATING FIREBALL OF SUNDAY, NOVEMBER 15.—A splendid fireball which gave a vivid illumination and, a few minutes later, a thunder-like detonation, was seen on the early morning of November 15 at 2^h 40^m. It was observed from many places in the eastern counties, and several descriptions came from London and its suburbs. At Caterham, Surrey, it left a brilliant train of sparks, and a loud report as of an explosion was heard shortly afterwards. At Bletchingley the object threw a strong light through a green curtain, and the moving shadows of the window frame showed the direction of the flight to be from S.W. to N.E. At London, E.C., the duration of the object was estimated as 3 seconds, and the interval between the outburst of light and the thunder-like sounds was the same (3 minutes) as at several other places. A resident near Uxbridge, Bucks., noticed the brilliant light through his window-blind and the noise, as of a distant explosion, 2½ minutes later. At some places houses were shaken and birds and animals much startled by the vibration and suddenness of the visitation, which might have been mistaken for an earthquake had not the light of the blazing meteorite proved its real character.

It was thought that the object was one of the Leonids, as the date conforms with that of this shower's return, but the direction of its motion from the S.W. proves that it belonged to some other stream than that of Leo, the latter constellation being in the east by south at the time of the meteor's appearance. It was a fine Taurid and a member of a system which annually supplies us with some brilliant detonating meteors between about November 15 and 25. The observations already to hand are not sufficiently precise to enable the real path of the fireball to be accurately determined, but its height was approximately from 62 to 30 miles over Hampshire and across the northern limits of Surrey and southern boundaries of Middlesex. The velocity was about 17 miles per second, and the detonations seem to have occurred over the neighbourhood of Houndslow.

TWO NEW COMETS.—Comet 1925 *j* was discovered by Prof. Van Biesbroeck at the Yerkes Observatory on November 17, at 11^h 31.9^m Univ. T., in R.A.

11^h 56^m 32.6^s, N. Decl. 34° 55' 8"; magnitude 8. The news was circulated in London by the British Broadcasting Company the following evening, and Dr. W. H. Steavenson found the comet the same night as a result of sweeping in Canes Venatici, which was the only clue to the position given by the B.B.C. His position was Nov. 18^d 2^h 46.6^m Univ. T., R.A. 11^h 57^m 2.70^s, N. Decl. 34° 41' 51.2". Both positions are for the equinox of 1925 0. The deduced daily motion is +47.4^s in R.A., -20.91' in Decl.

Dr. Steavenson stated that there was a nucleus of magnitude 11, and that the coma had a parabolic outline, being extended in position angle 310°. Clouds have prevented further observations in England, and none has been received from abroad, so material for the orbit is still lacking. Assuming uniform motion, the position on the morning of November 28 will be R.A. 12^h 5^m, N. Decl. 31° 13'.

Comet 1925 *k* is of magnitude 7 or 8, and was first found by Mr. Peltier, of Delphos, Ohio; Nov. 14^d 0^h 12^m Univ. T., in R.A. 15^h 25^m 0^s, N. Decl. 44° 0'.

Mr. Wilk found it independently in Poland; Nov. 19^d 17^h 10.0^m U.T., in R.A. 17^h 18^m 28^s, N. Decl. 33° 4'. It was apparently observed the following night at Cracow, as Prof. Banachiewicz telegraphed that the daily motion was +14^m 24^s, South 2° 27'. A further observation by Herren-Guthnick and Prager has since been received: Nov. 18^d 17^h 42.6^m Univ. T., R.A. 17^h 1^m 37^s, N. Decl. 35° 28' 20"; daily motion +17^m 20^s, South 2° 30'. From these data the following very rough orbit has been deduced, the elements being referred to the equator, not the ecliptic.

T 1925 Dec. 4.29 U.T.			
ω'	124°	49'	} 1925.0
Ω'	132	25	
i'	128	56	
log q	9 8960.		

There are now ten comets observed, the perihelion passage of which lies in 1925, thus equalling the record of 1898. If the perihelion passage of 1925 *j* lies in 1925, the present year beats all previous records.

Research Items.

THE ANCIENT INHABITANTS OF CALIFORNIA.—Mr. A. L. Kroeber's long-expected study of the Indians of California is now published as Bull. 78 of the Bureau of American Ethnology. It contains a detailed study of some fifty tribes. In the concluding chapters Mr. Kroeber gives some attention to ethnological questions of a broader character. Of these the one of most general interest deals with the archæology of California. The most important sources of information bearing upon the early inhabitants are the shell mounds found in several parts of the State, but investigated with most profit in the Santa Barbara area and San Francisco Bay. The antiquity of the mounds has been calculated in various ways, such as the extent to which they have been submerged by subsidence of the shore, the rate of deposit on the basis of an assumed population, the cubic contents of the mound, and the quantity of shell or wood ash mixed with the other material. These concur in pointing to an antiquity of about 3000 years for the first settlers. In cultural areas the subdivisions are constant. It is evident that the culture of the general Californian area was formed a long time ago and has remained constant ever since. During the whole shell mound period the culture remained identical in implements and utensils, in food, and in religion, the last being indicated by the charms found throughout the strata of the mounds. This permanence of Californian culture is of more than local interest. It contrasts with almost every other area in the world, while even in North America, in the Atlantic, and Mississippi regions, decisive evidence has been found of two, or several, distinct cultures in each area.

IMPLEMENTS OF THE EXTINCT ADELAIDE TRIBE.—In *Man* for November, Dr. H. Basedow discusses the purpose of certain unrecorded stone implements from South Australia to which both he and Dr. T. D. Campbell, independently, have directed attention recently. Specimens have been found at Port Noarlunga, Normanville, and Woodville, west of Adelaide. They are of blue, brown, or banded clay-slate, in general form a flat segment approximately equal to or greater than a half circle. The edge representing the chord is either straight or notched, and sharpened. Dr. Campbell suggests that they may be sacred objects akin to the stone "churinga" of Central Australia, partly on the ground of form, partly because they show certain incised markings and traces of red ochre. Dr. Basedow, however, considers that the markings are due to scratching in the making, and thinks the implements are scrapers. He relies upon information obtained from an old native of the Murray River. The tribes in the area in which these implements are principally found, the southern coast and Rapid Bay, served as a connecting link between the natives of Adelaide and the Murray River. The implement must therefore have been known to all the tribes between those two areas. According to his informant, the implements were used exclusively for scraping fat and fleshy tissue from the opossum skin used for rugs. The skin was laid over a cylindrical rod held vertically and drawn tight, the convex edge of the scraper being laid on the skin and used in a downward-direction. The advantage of the concave notch for this purpose is obvious.

ETHNOLOGY OF NORTHERN AFRICA.—Some interesting and suggestive conclusions relating to the ethnology of North Africa were put forward by Mr. Francis Rodd in a paper on "The Origin of the Tuareg" read at the Royal Geographical Society on November 16. There are among the indigenous peoples of North

Africa—for whom the name Libyan, first used by Herodotus, is preferable to that of Berber—certain nomads inhabiting the Sahara, some of whom are known by the Arab name of Tuareg. Of this race there is little known that is authoritative. They live principally by means of and on camels. Of their numerous peculiarities the best known are their intractable character, the veiled faces of the men, and the freedom of their women. Although Moslems, they retain matriarchal customs from which good Moslems would be averse. The usual statement that racially they are Berbers or Libyans conveys little. Three physical types can be distinguished among the Libyans: (i.) a tall dolichocephalic type with narrow face; (ii.) a short dolichocephalic type with broad face, obviously related to Cro-Magnon man; and (iii.) a short brachycephalic type with short, broad face. The Tuareg belong to the first of these. No nomads occur in the second and third groups, this mode of life apparently being a racial characteristic. The second type is probably that which is the prototype of the race responsible for the agricultural people who predominantly populate North Africa. Egyptian records of the invasion of the Nile Valley by the Libyans in the eighteenth and nineteenth Dynasties suggest that the Tuareg are to be identified with the Temahu and Tehenu of those invasions. The Tuareg type displays certain Nordic characters which may therefore be tentatively explained by attributing to them a northern origin due to the racial movements which took place at the beginning either of the Bronze Age or of the Iron Age, and of which the invasions of the Nile Valley from the west at various periods were a result.

THE STRUCTURE OF PROTOPLASM.—Prof. Josef Spek of Heidelberg summarises briefly in *Die Naturwissenschaften* for October 30 the change in the attitude of the investigator towards this problem. No longer is there an attempt to find, with improved microscopic methods, an ultimate unit of living matter, or to resolve all protoplasmic structure upon a "foam" structure, such as advocated by Bütschli. Microdissection experiments, experiments with centrifugal force, etc., have led to the recognition that the plasma may vary in consistency from fluid to solid gel, and that both types may coexist in different parts of the same cell. Spek reviews the results obtained by studies of transparent infusoria in the dark field illumination, when these organisms are subjected to various external solutions, and shows that for many protoplasmic masses, but not all examined, the evidence supports the presence of an emulsion of very fine dispersed watery droplets in another continuous phase. He illustrates the manner in which these droplets can be brought readily within the limits of vision by treatment with salts near that end of the "lyophile" series which indicates great activity in producing precipitation. Spek shows that in emulsions of various immiscible liquids a similar microscopic dispersion of one phase within the other takes place, e.g. of glycerin in olive oil, water in aniline, etc. The physical chemistry of such a distribution is not clear; either one substance disperses through the other by methods that are non-molecular but in the form of particles that are colloidal and even of microscopic visibility, or it dissolves in the dispersing medium and afterwards comes again out of solution.

THE SARGASSO SEA.—In the *Geographical Journal* for November, Capt. C. C. Dixon gives the results of many observations on the amount, extent, and condition of weed in the Sargasso Sea at various seasons.

He shows on a map that the extent of the Sea is approximately between lat. 15° and 40° N., and between the West Indies and long. 35° W. Within this area weed occurs. By adopting a scale from 1 to 10 he has been able to map the distribution of weed, while on several occasions he conducted experiments to determine the amount of weed per square nautical mile. From this he estimates that in the whole area of the Sargasso Sea there are about twenty million tons of weed. If the supply comes from the Caribbean Sea, as seems probable, it must come mainly through the Straits of Florida, where estimates show that about five million tons pass in a year. These estimates would suggest that the weed in the Sargasso Sea cannot all die and be replaced in less than four years. The state of the weed appears to be a question of locality rather than season or sea temperature, for most of the dead weed is found in the warmer waters, while the freshest weed is on the north-western side of the Sea nearest to the source of supply. Capt. Dixon contends that from past records there is evidence that the weed-strewn area is decreasing in extent or changing its position, but the evidence for this conclusion is somewhat slender.

ARGON IN LIVING CELLS—The presence of argon in living cells has been shown by the experiments of Amé Pictet, W. Scherrer, and L. Helfer, described in the *Compte rendu des Séances de la Société de Physique et d'Histoire Naturelle de Genève*, vol. 42, No. 2, 1925. The authors proved that the small quantity of argon they found in the fermentation of glucose came from the yeast. It was roughly estimated by distillation in a vacuum and by passing the gases over heated copper oxide. The nitrogen evolved contained about 3 c.c. of argon for 10 grams of yeast. Bullock's blood and sheep's brains on similar treatment yielded slightly higher proportions of argon. The exact origin of this argon has yet to be found.

VEGETATIVE PROPAGATION OF RUBBER.—The *Malayan Agricultural Journal*, September 1925, reproduces fully Dr. Heusser's important report upon the experimental tapping of Hevea budded trees. Dr. Heusser's work has now progressed so far as to lead him to recommend firmly the budding from selected stock instead of the planting of seedlings. If budding methods prove successful, this advice almost inevitably follows, as it permits of a plantation in which a few "clones," that is, trees all propagated vegetatively from one common stock, give a uniform grade of produce, instead of the variable yield and quality obtained from a plantation consisting of seedlings. Thus gradually tropical agriculture may be expected to follow along the lines which cultivation has followed in the Old World and in North America.

ENTOMOLOGICAL ANALYSES OF TREES—In the *Bulletin of Entomological Research* for October 1925, Dr. Ivar Tragårdh, of the Swedish Forest Experiment Station, has an interesting paper on this subject. The forest entomologist, examining dead or dying trees, is confronted with the problem of the species responsible for the attack, and why particular trees should suffer while their neighbours of the same species are left untouched. These points are vital in that if we know exactly what type of tree is liable to be attacked by a certain insect, it opens up the possibility of prevention by the aid of improved forest management. In order to obtain the requisite information, Dr. Tragårdh is of opinion that two things at least are necessary: first, an extensive series of analyses of felled dead or dying trees, recording the ways in which different species of insects succeed one another, the nature and extent of the injuries they occasion,

and the position of such species in the tree; secondly, experimental plots for the purpose of watching the attacks from their initiation. By combining the results obtained by these two methods, with a thorough analyses of ecological factors, it is hoped that we shall eventually be in a position to formulate better-founded opinions respecting the activities of injurious forest insects.

FIBRE FROM PINEAPPLE LEAVES—Messrs. R. O. Bishop and E. A. Curtler have some interesting notes upon the experience of the Department of Agriculture, Malay States, in preparing fibre from the leaves of *Ananas sativus*, of which some 20 tons were shipped from an $8\frac{1}{2}$ -acre plantation in which pineapples were grown for the canneries (*Malayan Journal of Agriculture*, September 1925). So far as could be judged, this amount of leaf stripping had no appreciable effect upon the plantation. The 20 tons of fresh leaves only gave some 4 cwt. of fibre, but the fibre appears to be of high grade, fine in staple and lustrous, and with a fine silky texture. The leaf was stripped in a raspador machine designed to treat sisal, and the fibre required further washing and scraping with a blunt knife. Its commercial utilisation would depend upon a more suitably designed machine, but in view of the comparatively small leaves with low yield of fibre, the authors conclude that whilst fibre can be obtained from the leaves as a by-product in canning the fruits, it is extremely doubtful whether the process would be profitable commercially.

PERMIAN INSECTS—Dr. R. J. Tillyard continues his work on the Permian insects of Kansas (*Amer. Journ. Sci.*, 9, 1925, p. 328, and 10, 1925, p. 41) and Australia (*Proc. Linn. Soc. N.S. Wales*, 49, 1924, p. 429). The earliest remains of beetles hitherto known are of Triassic age. In the Upper Permian of Belmont, New South Wales, numerous elytra of beetles have now been discovered, and include a form (*Protocoleus*) which differs in important respects from all known Coleoptera, for this genus a new order (*Protocoleoptera*) is proposed and is regarded as the forerunner of the Coleoptera, and as intermediate between the Carboniferous *Protoblattoidea* and the true Coleoptera.

SWEDISH TRILOBITES.—A monographic account of the trilobites of the Leptæna limestone of Dalarne is given by Miss Elsa Warburg (*Bull. Geol. Inst. Upsala*, 17, 1925). The fauna is a rich one, and includes about 120 species or varieties of trilobites. It is of interest to British geologists from its resemblance to the Upper Ordovician faunas of Keisley and Kildare. The Leptæna Limestone is a reef rock found in the neighbourhood of Lake Siljan. The author concludes that it was formed during two periods separated by a time during which no reef building took place; so that there is a Lower and an Upper Leptæna Limestone, and it is the latter which seems to represent the limestones of Keisley and Kildare. The systematic part of this memoir is preceded by a discussion of the morphology, classification, and affinities of trilobites.

TILTING OF THE GROUND AT THE HAWAIIAN VOLCANO OBSERVATORY (KILAUEA).—Mr. R. H. Finch has contributed a preliminary note on this subject to the *Volcano Letter* (October 8, No. 41) of the Hawaiian Volcano Research Association. In addition to the diurnal and seasonal tilts which follow closely the diurnal and seasonal temperature changes, there is a much more distinctly marked tilt in connexion with volcanic activity. From 1913 to 1919-20, there was a gradual rise of 600 feet in the mean lava level. This was accompanied by a gradual swelling of the mountain-top as shown by the north-east tilt of

the observatory seismographs. The re-levelling of the ground from the sea-level showed that the height of the observatory had increased by more than a foot between 1912 and 1921. From 1919-20 to 1924, the lava column gradually sank, and, with this sinking, there was a rapid south-west tilt of as much as $1' 32''$ during the three years 1922-24. Re-levelling from the observatory to two points near Halemaumau showed that one point had sunk five feet and the other nine with respect to the observatory, which itself had undoubtedly sunk several inches.

ECHO SOUNDING IN THE PACIFIC OCEAN.—The method of echo sounding has been illustrated by the voyage of the U.S. destroyer *Stewart* across the Atlantic, through the Mediterranean, across the Indian Ocean and into the Pacific. Profiles of depths have been published by the Hydrographic Office of the Navy Department at Washington. When steaming on a north-westerly course between Manila and Hongkong, a rapid decrease of depth from 2140 to 300 fathoms was recorded at five-minute intervals over a distance of nine miles. After passing the bank into deeper water again, the course was turned sharply to south, then east, then north-west again so as to obtain further soundings. It is evident that the method of echo sounding is of very great value for detecting and surveying hitherto unsuspected shallows. In the Pacific and Indian Oceans it is of further interest in connexion with Darwin's theory of upgrowing coral reefs on subsiding foundations. Fuller details and a map of the Stewart Bank in lat. $17^{\circ} 16' N.$, long. $118^{\circ} 34' E.$, are given in an article by Prof. W. M. Davis, of Harvard, in *Science* for October 30.

WEATHER IN THE WEST INDIES.—The annual summary of the weather for 1924 by Mr. Oliver L. Fassig, meteorologist in charge of the West Indies and Caribbean Service, in co-operation with the Weather Bureau of the U.S. Department of Agriculture, has recently been issued. For the first time during the last four years, since the establishment of the West Indies Climatological Service, the total annual rainfall for the section as a whole was above the normal; the average rainfall was 66.67 in., or 7.39 in. above the normal. The result is based upon reports from more than 500 stations. The rainfall on the whole was well distributed through the year. The areas of lightest rains, about 30 in., are the Bahamas and Turks Islands in the north, and the Islands of Curaçao, Aruba, and Bonaire off the coast of Venezuela. The areas of heaviest precipitation are the Central American States from Costa Rica to Guatemala, with annual amounts varying from 118 in. to 147 in. The number of days with appreciable rainfall varied from 64 in the Bahamas to 212 in Nicaragua. The average temperature in 1924 for the entire section was $78^{\circ} 7' F.$ or $0^{\circ} 9'$ above the normal; temperatures are said to have been above the normal for every month of the year. Two hurricanes passed over the Lesser Antilles during August; the storm of August 27-31 was one of the most destructive in recent years, doing much damage along its path, while in the Virgin Islands the estimated wind velocity was more than 100 miles per hour during the night of August 28-29.

ATOMIC STRUCTURE.—The November issue of the *Philosophical Magazine* contains a paper by Sir E. Rutherford and Dr. J. Chadwick describing their experiments on the scattering of α -particles by light elements like aluminium and magnesium and by heavy elements like gold and uranium. The velocities of the α -particles were varied by interposing sheets of

mica in the paths of the rays, and the number of particles scattered at an average angle of 135° was counted. No divergence from the scattering deduced on the assumption that the inverse square law of repulsion holds within the atom could be detected in the cases of gold, platinum, silver, copper, and uranium, but in aluminium and magnesium the number scattered in the observed direction for speeds of the α -particles, giving them ranges of about 5 cm. in air, was considerably less. This decrease was confirmed by measurements of the scattering at 90° . The authors consider that these facts point to the central nuclei in the aluminium and magnesium atoms being surrounded by a shell of negative charges beyond which is a further shell of positive charges. α -particles which penetrate the outer shell are repelled by a field due to the difference of the nuclear positive and the negative shell charges, and are therefore less scattered than those which do not approach the centre of the atom so closely.

A NEW WESTON CELL.—The preparation of a reproducible Weston cell with a low temperature coefficient is described by W. C. Vosburgh in the *Journal of the American Chemical Society* for October 1925. The reduction in the temperature coefficient is effected by introducing tin, lead, or bismuth into the cadmium amalgam electrode. The presence of tin caused an increase from 1.01805 volt to 1.01901 volt at 25° , while the temperature coefficient was reduced to about two-fifths that of the Weston cell. Lead gave a cell of electromotive force 1.01918 volt at 25° , but the temperature coefficient was greater than that of the cell containing tin. The introduction of bismuth changed the electromotive force of the Weston cell to 1.01976 volt at 25° , the temperature coefficient being positive and equal to the negative coefficient of the cadmium-tin amalgam electrode. The values of the electromotive force were constant over the periods of time during which they were examined.

THE SEPARATION OF SILVER FROM HALOGEN COMPOUNDS BY STRONG ILLUMINATION.—Experiments to show that silver is separated from its halogen compounds by light, without the use of a photographic developer, are described by P. P. Koch and H. Vogler in the *Annalen der Physik* for September. Most of the work was done with silver bromide, which was used either in a fine powder or in a gelatin film shaved off from a soaked photographic plate, a number of these films were piled on one another to make a small slab to be placed in the Debye-Scherrer camera. When the preparation was made in red light the ring system, obtained by passing X-rays through it on to a photographic film, showed in both cases the simple cubic lattice of silver bromide as described by Wilsey, with lattice constant $a = 2.89 \times 10^{-8}$ cm. When the silver bromide was exposed to strong light before being placed in the camera, the ring system of silver was superposed on that of silver bromide, and when the silver bromide was removed from these preparations by an acid fixing bath, the ring system of silver alone was produced. The dimensions of the minute silver crystals, as determined by the breadth of the rings, were more than $24 \text{ \AA.U.}$, so that it appears that the silver crystallises round a comparatively small number of "buds," formed at the commencement of the illumination. It is shown that 31 per cent. of the silver in the plate was separated out by strong illumination. The X-rays used did not separate an appreciable quantity of silver from silver bromide, but this was not true of silver chloride. No silver was separated from silver iodide by the action of light.

The Chemistry of Painting.¹

IT is noteworthy that the modern oil picture is apt to darken, or lower in tone, while, on the other hand, not only the oil pictures of the fifteenth century, but also in many cases the oil pictures of later schools, such as the Dutch school, have altered little from the day they left the studio. It must not be supposed that all modern pictures suffer equally from this defect; some artists have successfully avoided it, but in other cases the lowering of tone has been very serious.

An examination of the information to be obtained from old manuscripts describing painting methods from the twelfth century up to the time of Vasari is in favour of the view not only that oil was used as a medium throughout this period,—at any rate in the north,—but also that there is no suggestion of any special mystery in the nature of the medium itself. The oils used were linseed and walnut, and, later on, poppy; and the methods of preparation and purification did not differ widely from those used to-day, but when exactly repeated, they do not yield an oil which enables the difficulties of the modern painter to be overcome.

When we turn from the oil to the pigments, we find that many of the pigments used to-day are those which have been used throughout the history of painting, and many modern pigments are undoubtedly preferable to those used in earlier times, and are more permanent. We are driven to the conclusion that the troubles of the modern artist are due not to his materials, but his methods, and are, moreover, due not to his pigments, but to the medium in which the pigments are ground, namely, oil. It therefore becomes necessary to study carefully, not so much the chemical as the optical properties of oil, and the optical principles underlying oil-painting.

Pigments can be regarded as if they are little particles of coloured glass, and their apparent opacity is due to their high refractive index. It therefore follows that when ground and mixed with a medium like oil, which has a fairly high refractive index, their so-called opacity will depend upon their having a much higher refractive index than oil.

The oil painter then must know the comparative opacity of his pigments, and such a table has been prepared by Prof. Laurie, by grinding the pigments in liquids of higher and higher refractive index until they proved transparent by transmitted light under a $\frac{1}{4}$ -in. objective. White lead, for example, ground in bromonaphthalin is found to consist of transparent doubly refractive crystals, thus confirming the researches of Green under high pressure. In this table the pigments are arranged not only in order of opacity, but also according to their position in the spectrum, from red

to blue. In order to understand the reason for that double grouping it is necessary to consider the properties of the linseed oil film. The dry film in oil in course of time becomes yellow, and also gradually increases in refractive index. The yellowing of the oil will obviously affect pigments at the blue and green end of the spectrum more than those at the red and yellow end; and the slow rise in refractive index will make the more transparent pigments deeper and more translucent in tone than the more opaque.

The pigments of the artist's palette can be divided roughly into two groups—those to be used for solid painting and those to be used for glazing. For example, cobalt blue is in itself a permanent pigment, but it consists of transparent blue particles; consequently the light penetrates deeply into a mixture of cobalt blue and oil, and if such a mixture be painted on thickly, the yellowing of the oil will finally result in cutting out the whole of the reflected spectrum, the mixture of oil and cobalt blue therefore becoming black.

Early methods of oil-painting as revealed by certain unfinished pictures—such as the two unfinished Michael Angelos in the National Gallery—illustrate these principles. Starting with a white gesso, the light and shade were put in in tempera, the white gesso being kept for the whites, and in some cases even colour was laid on in tempera—the modelling, for example, of a robe being done in bright red on the white gesso. The egg or size medium, being of low refractive index, gave the full value to the brilliancy of the pigments, and also has proved, under the test of time, not to change. A thin glazing of transparent oil colour on this foundation, while suffering degradation from the yellowing of the oil, would increase in brilliancy from the rise in refractive index of the oil making the pigment more transparent, and allowing more light to be reflected from the tempera pigment below.

At a later stage in the history of oil-painting, while the preliminary painting in tempera was abandoned, the white gesso surface was still used, and the high lights of white lead and oil painted as thinly as possible, so as to ensure reflection from below. With Rubens the custom of transparent shadows and solid lights came in, but, here again, as the pictures of the Dutch school show, the practice was still continued of painting thinly on a white gesso, and where white lead was used for a solid light, it was ground very stiffly with a minimum of oil.

These pictures are of great interest, as showing how far the ancient methods can be adapted to the requirements of the modern artist, as has been shown by Mr. Sims, R.A., whose portraits of the King and Prof. Hay are interesting examples of painting in egg alone, and doing the first painting in egg and finishing in oil.

¹ From lectures delivered by Prof. A. P. Laurie to the students of the Royal Academy of Arts, London, on Wednesday, November 11, and subsequent dates.

Geological Survey in Great Britain.

THE "Summary of Progress of the Geological Survey of Great Britain and the Museum of Practical Geology for the year 1924" (H.M.S.O., price 2s. 6d.) gives proof of energy and increasing usefulness in all branches of the institution. As a result of the strengthening of the staff of late years it has become possible to carry on field-work in so many as nine districts. Branch offices have been established at Newcastle-on-Tyne, Whitehaven, Manchester, and York, and thus the work of systematic surveying has been facilitated, and a closer touch has been maintained with all parts of the kingdom than was

formerly possible. This leads to the securing of many records of temporary excavations and other works that might otherwise have been lost. The results of the year's work are presented in a volume of undoubted value, but we find in it a report by the Geological Survey Board, a report by the director, an introduction on coal-field revision by the director, and detailed reports on the Districts by the district geologists, all touching upon more or less the same subjects. Repetition under such conditions is inevitable.

In the field-work the first importance has been

attached to the 6-inch surveying of coal-fields and their surroundings, and to the revision of those which have been surveyed on that scale but have not been re-examined within the last thirty years. At the same time the information collected concerning the mineral resources of Great Britain, the value of which has been abundantly recognised, is being kept up-to-date by periodic visits of members of the staff to working mines and by maintaining contact with new developments. The information is published in the Special Reports on the Mineral Resources of Great Britain, of which it is stated that twenty-eight volumes have been issued and two more are in the press.

The Districts in which systematic surveying is in progress include the south-eastern counties. The Aldershot sheet of the 1-inch map, which has special claims as illustrating a military and residential centre, is being surveyed for the first time on the 6-inch scale. Maps and memoirs on the Hertford, Dartford, Brighton and Worthing sheets were published during the year. Inquiries relating to underground sources of water are especially numerous in this part of the country, and a close watch is kept on deep borings. The records of some recently examined appear in an appendix, with a map showing the underground limits of the Lower Greensand, one of the most important sources. The absence of this formation at Fobbing, in Essex, has been proved by a boring which entered Cambrian rocks underlying Gault at a depth of 1127 feet. In the Midland District the Flint map and memoir have been published and those relating to Wrexham are well advanced. The Birmingham and Wem sheets have been published and the memoirs written. The surveying of the Wolverhampton, Shrewsbury and Stafford sheets is in progress. In the Lancashire District revision is proceeding in the Rochdale and Manchester area. A special feature in this revision is the attempt to decipher the succession of the Millstone Grit and Lower Coal Measures by means of *Goniatites* as zone-fossils. In the Yorkshire District work in progress in the Huddersfield sheets carries on eastwards the work done in Lancashire. The explorations in the concealed Yorkshire and Nottinghamshire

coal-fields, one of the most important reserves of coal in Britain, are receiving careful attention. In the Cumberland District progress has been made in the Whitehaven and Brampton sheets. The Carlisle, Silloth and Longtown sheets with the corresponding memoir are on the point of publication. In the Northumberland and Durham District revision has been carried on in the Ford, Alnwick and Rothbury sheets and some work has been done in the Morpeth and Newcastle sheets. The Norham, Berwick and Holy Island sheets are being engraved.

In Scotland attention was centred chiefly on the lowlands and coal-fields, but, as the director points out, Highland geology has not been neglected. Six Highland memoirs were written or corrected for press, including that on the Tertiary and Post-Tertiary geology of Mull, etc., in which is described one of the most intricate regions that it has fallen to the Scottish Survey to interpret. In the Lowlands the Kilmarnock sheet is completed and the Ayr sheet well advanced. In Lanarkshire the older rocks underlying the production strata to the south of the central coal-field are being re-examined. The economic memoir on Area VI. (Bathgate, Wilsontown and Shotts) has been published, and second editions of other memoirs are in hand.

Special mention must be made of the bequest to the Geological Survey by the late Dr. Kidston of his collection of fossil plants, photographic negatives and manuscripts. The acquisition of these beautiful specimens will make the Museum one of the principal centres of systematic Carboniferous palaeobotany in the world, when it becomes possible to exhibit them. The preliminary plans for the new Museum and Survey Offices at South Kensington are now under consideration—the building will adjoin the Natural History Museum on one side and the Science Museum on the other. The two national geological collections will then be in close communication, the one biologically arranged and illustrating the evolution of forms of life on the globe, the other stratigraphically arranged and illustrating the stage in evolution attained at each successive period of the globe's history.

The Principal Botanical Garden, Leningrad.

By Prof. BORIS FEDTSCHENKO (Leningrad).

THE Botanical Garden was founded at St. Petersburg in 1713 by Peter the Great as a Druggist's Garden. In 1824 it was reconstructed into a scientific institution under the name of the "Imperial Botanical Garden," and in 1917, at the beginning of the Revolution, it was renamed "The Principal Botanical Garden of the Russian Republics."

The former activity of the Garden is well known, but it is of interest to make a brief survey of the present activity of this institution. It can be said that, on the whole, the Botanical Garden has successfully survived the difficult times of the War and of the revolution. The buildings are now nearly in the same condition as formerly, or better, since in 1924 the Garden was allowed a sum of money for the reconstruction of all the houses which had fallen partially into disrepair at the time when the coal supply was insufficient. The staff, both scientific and technical, is now no smaller than before the War; the number of principal departments of the institution is now twelve—before the War there were eight. The director of the Garden is Prof. B. Issatchenko, the well-known botanist who recently visited the great European botanical gardens.

One of the principal departments of the Garden is that for the cultivation of living plants. The large number (about twenty-four) of hot-houses and temperate houses are well stocked with many interesting tropical and subtropical plants from all parts of the world; in the rockeries and beds and in the grounds there are many cultures of herbaceous and woody plants chiefly from Northern and Central Asia, from Siberia, North America, and so on. Every year the Garden receives from correspondents a large stock of bulbs, seeds, etc., of new and interesting plants for cultivation; tropical and subtropical plants are received from other Gardens in exchange. The department of living plants is under the direction of Prof. Komarov, a well-known botanist and traveller.

The Herbarium of the Garden is the centre for the systematic and geographical exploration of the flora of Russia. The immense collections (about three million specimens) are stored in what is probably the largest Herbarium house in Europe. The building is of four stories and was built in 1913, the ground-floor being the library of the Garden. The principal work of the Herbarium at present is the

compilation of a flora of Asiatic Russia under the direction of Prof. Boris Fedtschenko, chief of the Herbarium, and some other specialists and volunteers. Local floras of Turkmenistan and south-east Russia, among others, are also being worked up. Recently much work has been done on South American plants. Herbarium specialists are preparing monographs on Tulipes, Artemisia, Tamarix, Gramineæ, Leguminosæ and many other groups of plants. Every year most of the botanists of the Herbarium staff go to the different countries of Russia and adjacent Asia for botanical and geographical studies; this year some are in Turkmenistan, Persia, and in Mongolia.

The cryptogamic department, formerly a part of the Herbarium, is now separated under the direction of A. A. Elenkin and is carrying on intensive studies upon Russian mosses, lichens, algæ, and fungi.

The geo-botanical department, under the direction of Prof. N. Kuznezov, has in hand the making of a geo-botanical map of the European part of Russia. This map is now ready on the scale of 1:2,500,000, and the staff of the geo-botanical department is working on the more detailed maps.

One of the most recent departments of the Botanical Garden is that of acclimatisation, under the direction of W. Sukatshef. The purpose of this department is to introduce into cultivation new and interesting plants from different parts of Russia and from adjoining countries. This department has special grounds for the cultures of perennial, herbaceous, and woody plants, as well as for the experimental nurseries of different varieties of fruiting trees and shrubs.

The museum of the Garden since 1891 has been under the direction of N. Monteverde; it has received very large and interesting collections in the last few years. A special section of the museum is working on the study of medicinal plants, which is of great importance for human welfare and health.

There are two departments of the Garden which deal chiefly with practical problems: one is that of seed studies, where numerous analyses of seeds and germination tests are made. Scientific studies on seeds are also carried on. Two important and interesting problems have recently been worked out: the first upon the difference between winter and summer wheat and barley, the other in distinguishing correctly between living and dead seeds.

The other department with many practical problems is that of phytopathology, in which specimens of plant diseases sent from different parts of Russia are studied, and new plant parasites are described.

The department of plant physiology is working on several physiological problems, chiefly dealing with assimilation. The department of hydrobiology is carrying on studies upon the cryptogamic plants of

the plankton of Russian rivers and lakes, particularly in the Leningrad region.

The Library of the Garden is the richest botanical one in the country, and it has a large stock of recent and back publications of the Garden for exchange.

The Garden has now three affiliated gardens: one of these is in a suburb of Leningrad, another in Omsk (Western Siberia), and the third in Vladivostok (Eastern Siberia).

The results of the scientific studies of the staff are published by the Garden in numerous botanical articles and larger works, although handicapped by the very small sums granted for publications. The principal and the oldest publication of the Garden is *Acta Horti Petropolitani*, started in 1872, now under the direction of B. Fedtschenko. This journal contains chiefly voluminous works such as those of Komarov, Fedtschenko, Roshewitz, and other botanists of the Garden. The *Bulletin* of the Garden is chiefly for the publication of short articles on all branches of botany. The *Morb: Planiarum* and the *Annals of the Department for Seed Study* are the special organs of the departments of plant pathology and of seed study.

Recently the Garden has commenced the publication of three new periodicals: *Conspectus litteraturæ botanicæ*—an abstract journal chiefly for Russian botanical literature. Without this it would be very difficult to know of all the botanical publications which are now appearing in large numbers every year in different parts of Russia. Another new publication of the Garden is *Notulæ systematicæ ex Herbario*, this contains chiefly descriptions of new species and genera from all parts of the world from the specimens in the Herbarium of the Garden. In this publication, as well as in the others, contributions are received both from the staff of the Garden and from botanists in other parts of Russia (including Ukraina, Caucasus, Turkestan, Siberia). A similar publication, *Notulæ systematicæ ex Instituto Cryptogamico*, deals with the cryptogams.

Every year the Garden sends botanical expeditions to study plants in different parts of Russia and Asia. The most important journeys have been into Central Asia, Transbaicalia, Mongolia, Persia, etc.

The facts given above show that the Botanical Garden in Leningrad is at the height of its activities in botanical study, and that excellent opportunities are afforded for solving important problems. Now, as formerly, the Garden is in correspondence with the chief botanical institutions of the world. Any question upon the flora of Russia or Russian botanical literature, or regarding botanical research in Russia, will be gladly answered from the Garden or by the present writer.

Stone-dusting Tests in England and America.

THE Safety in Mines Research Board has just issued a pamphlet¹ which will be of great interest to mining engineers both in the United States and in Great Britain. It contains the first fruits of that arrangement for co-operative research which was made last year between the U.S. Bureau of Mines and the British Safety in Mines Research Board, and is published under the joint names of the two directors of research, Mr. G. S. Rice and Prof. R. V. Wheeler.

The investigations begun in the large steel gallery at Eskmeals by the Home Office Committee on the efficacy of "stone-dusting" in preventing coal-dust

¹ Mines Department. Safety in Mines Research Board. Paper No. 13. Stone Dust as a Preventive of Coal Dust Explosions. Comparative Tests By G. S. Rice and R. V. Wheeler. Pp. 15 (London: H.M.S.O., 1925.) 3d net.

explosions were soon supplemented by the researches made in the experimental mine at Bruceton, near Pittsburgh, by the Bureau of Mines. But the results obtained at the two stations showed differences which led to the assumption that the Pittsburgh coal was much more sensitive to ignition than the Altofts Silkstone used as the standard at Eskmeals. Such an assumption rendered futile any comparison between the two sets of experiments, and the conclusions drawn in one country could not be applied; it was thought, to the conditions of the other. The first step in co-operation was taken when a consignment of Altofts Silkstone was sent to Bruceton, and a similar supply of Pittsburgh coal was received at Eskmeals. The experiments carried out at the two

stations now described show that the behaviour of the two coal-dusts is very much the same when the experimental conditions are similar; and the conclusion is drawn that the differences between the results at the two stations are due to the greater severity of the American tests. At Bruceton the experimental mine is driven into an actual coal-seam and has a cross-section of 58 square feet; the powder-charge used as the source of ignition is 4 lb.; the dust is spread on cross-beams near the roof as well as on side shelves and on the floor. At Eskmeals the original experiments were carried out in a circular steel gallery of 7½ feet diameter; the later comparison-experiments were made in a smaller steel tube 38 inches in diameter with a charge of 28 oz. of blasting-powder.

Again, in a number of experiments where small percentages of gas were present with the dust, the Americans used their natural gas containing, besides methane, some 15 per cent. of higher paraffins—ethane, propane, etc.—which ignite more readily than the pure methane derived from coal. The conditions both of ignition and of propagation were therefore more favourable at Bruceton than at Eskmeals. It is a clear gain to have established that the standard coals used at the two stations are so nearly similar that the varied experience obtained in one country can be applied, under the same working conditions, to the other.

The Data for Weather Forecasting.

METEOROLOGISTS are being urged to extend the periods covered by their forecasts,* and in a recent paper¹ Exner has worked out the correlation coefficients between contemporary monthly pressure departures at Stykkisholm (Iceland) and those of seventy other places distributed over the earth. The data handled are from 1887 to 1916, and the monthly departures of pressure and temperature for all the stations are most generously printed at length for the benefit of other workers. Their mean square values also are tabulated and briefly discussed.

Relationships in the North Atlantic had previously received considerable attention, from Exner and others, so the results in the present paper, though of the greatest value, are not in general surprising. There is a region of close positive relationship extending from Baffin's Bay to Norway, and one of negative relationship near the Azores, in winter extending from the Bermudas to Italy, with an outlying region in Japan: with places in the southern hemisphere there is little connexion.

An important feature of the paper is its hope of inauguration of a programme of calculation of which the present 840 coefficients form but a small fraction. If all were worked out, there would be more than 120,000 contemporary monthly relationships between 143 variables, 71 of pressure and 72 of temperature. But, though Exner does not suggest any extension, this would not be enough; for with many places, especially in the southern hemisphere, there are essential effects produced after six months. These non-contemporary effects are vital for forecasting, and if we were to correlate a monthly value at one place with values from seven months before to seven months after at other places, we should multiply our coefficients by 15.

There is much to be said for the plan adopted in Walker's two papers on world-weather of using quarterly values. With twenty "centres of action," the total number of coefficients, including time intervals of ± 2 , ± 1 , 0 quarters, is then 7600, and a number

¹ "Monatliche Luftdruck- und Temperaturanomalien auf der Erde: Korrelationen des Luftdrucks auf Island mit dem anderer Orte." *Sitzber. d. Akad. d. Wiss. in Wien*, Abt. IIa, 133 Bd., 7 u. 8 Hefte, 1924.

of stations may be added without a prohibitive amount of labour.

Exner's argument for dividing the year into twelve rather than four periods is that he proposes in this way to distinguish real from accidental relationships, the former being distinguished by a smooth, regular series of values during the year.² But it has not been shown that statistical criteria applied to quarterly values have failed; and as the largest of twelve errors in Exner's coefficients has a probable value of 0.35, a smooth series is as accidental as a fairly irregular one.

It is a matter of sincere congratulation that Exner's great ability is being directed to the elucidation of these questions of commercial as well as scientific importance.

* "Regelmässige Verlauf durch die zwölf Monate," *loc. cit.* p. 329

University and Educational Intelligence.

CAMBRIDGE.—Mr. J. A. Chadwick has been awarded the Arnold Gerstenberg Studentship (for moral philosophy and metaphysics). Mr. Chadwick took the Natural Sciences Tripos Pt. I. in 1923 and the Moral Sciences Tripos in 1925; he was recently elected to a fellowship at Trinity College.

A grant of 50*l.* has been made to Miss Marion F. Bridie of Birmingham to facilitate her research as to the ultimate effect of education among the mentally deficient.

LEEDS.—The West Yorkshire Coal Owners' Association has given 25,000*l.* to the appeal fund. In accepting the gift, the council of the University passed a resolution stating that the success of the University's Department of Mining is due in large measure to the co-operation of the industry, not only in the form of subscriptions, but also through assistance given on the Mining Advisory Committee, by facilities offered to students for gaining practical experience, and in other ways. The annual grants made through the Association amount to nearly 10,000*l.*, and these are to be continued at the rate of 1000*l.* a year.

The following appointments have been made:—Mr. W. Murphy to be demonstrator in experimental physiology, and Dr. Arthur Raistrick to be research assistant in geology.

LONDON.—Mr. Hilary Jenkinson has been appointed as from August 1 last to the University readership in diplomatic and English archives tenable at King's College. Mr. Jenkinson is the editor of volumes of the Surrey Archaeological Society and Surrey Record Society, and is the author of numerous works on palæography.

It has been resolved to institute an M.A. degree in geography for external students.

The following doctorates have been conferred:—*D.Sc. (Chemistry)*, Mr. J. M. Johlin (University College), for a thesis entitled "The Surface Concentration of Colloids at a Liquid-Gas Interface"; *D.Sc. (Entomology)*, Mr. H. P. Hacker, for a thesis entitled "How Oil Kills Anopheline Larvæ," and other papers.

THE effect on school-holidays and on the various branches of education in every country of a fixed date for Easter is being investigated by the League of Nations' Special Committee of Enquiry into the Reform of the Calendar. This Committee, on which the Rev. T. E. R. Phillips, Secretary of the Royal Astronomical Society, represents Great Britain, has been devoting particular attention to the question of the fixing of Easter and now wishes to conclude its general inquiry. While the need of fixing this festival

has been felt more especially in economic circles, certain replies received by the Committee seem to show that a similar desire exists in educational circles, since, if Easter be fixed, the date selected would be of great importance from the point of view of holidays, holiday courses, etc. A circular-letter has accordingly been sent to all the Governments asking them, before December 15 next, for the views of their Education Departments and other educational authorities.

THE 'Secretary' for Scotland, in consultation with the Minister of Labour, has appointed a Committee "to inquire into and advise upon the public system of education in Scotland in relation to the requirements of trade and industry, with particular reference to the adequacy of the arrangements for enabling young persons to enter into and retain suitable employment." The Committee will be composed of the Right Hon. Lord Salvesen (chairman), Dr. R. S. Allan, Prof. T. Hudson Beare, Mrs. Charles Douglas, Mr. James Elder, Mr. William Lorimer, and Mr. D. J. Macdonald. Mr. James Clark, H.M. Inspector of Schools, and Mr. W. H. Lowe-Watson, Ministry of Labour, will be joint secretaries. All communications should be addressed to the joint secretaries at the Divisional Office, Ministry of Labour, 44 Drumsheugh Gardens, Edinburgh.

A THIRD series of "Methods and Problems of Medical Education" has been issued by the Division of Medical Education of the Rockefeller Foundation. These publications contain brief descriptions of clinics, laboratories, and methods of teaching in different parts of the world. The articles are not copyright, and permission to reprint or otherwise to utilise them is not necessary. It is hoped that the material may be of assistance to those planning improvements in buildings and methods. The present volume deals with nineteen departments of physiology, anatomy, pathology, biochemistry, pharmacology, surgery, and obstetrics. The articles are written by the heads of the departments and are illustrated with plans and views. They include descriptions of the department of physiology and the Moltano Institute, Cambridge, the department of anatomy, University of Leyden, the pathological laboratory of the Johns Hopkins University and Hospital; the department of surgery, Peking Union Medical College; and the obstetrical unit, Royal Free Hospital. Brief details are appended of the staffing, finance, and lines of research and instruction given in the various institutions.

FROM the Northern Polytechnic, Holloway, London, we have received a prospectus for 1925-26 containing particulars of the three-years' course in architecture which has lately been recognised by the Royal Institute of British Architects as qualifying those who obtain a first- or second-class pass in the school examination for exemption from the R.I.B.A. intermediate examination. The Polytechnic is the only institution in Great Britain which offers courses of university grade in rubber technology. The senior day course is described as suitable for university graduates working for higher degrees who select as their subject for research problems connected with rubber. The advanced day and evening courses offer suitable preparation for the examinations for the associate diplomas awarded by the Institution of the Rubber Industry (A.I.R.I.). A Rubber Trades School has also lately been established to provide boys of fourteen to fifteen with the necessary basic training in rubber workshop practice and allied subjects previous to entering the rubber industry. The full term of apprenticeship is five years, of which the first year is spent as a full-time day course at the school, while in subsequent years the boys attend the school two evenings a week.

Early Science at Oxford.

November 30, 1683. Some Iron ore, which was dug at Wassall in Staffordshire, and had been lately calcined, was observed to draw ye needle: it being true, that scarce any Iron ore will apply to ye magnet, unless it has first undergone ye fire; This gave matter to a quære, whether fire may not be supposed to make these ores attract the needle? A little peice of a sewing needle, about $\frac{1}{4}$ of an inch long, being placed on a peice of paper, and a loadstone applied under ye paper, was seen to raise its self on its greater end; upon applying ye other pole of ye loadstone ye peice of needle affected to raise its self on its point. There followed some discourse concerning ye sawing of Diamonds, with ye hair of a man's head, as fetters are commonly saw'd off, by Prisoners, with a steel virginal string. A letter from Dr. John Bagly gave an account of some observations, he had lately made on ye *Lumbricus Latus*; particularly that in every joint of ye worm, there appears an insect, not unlike an ant, which may be seen with ye bare eye; He says a patient of his voided 100 yardes of this sort of worm in 24 hours.

1686. Dr. Plot communicated ye following curiosities: A large shell which had its turnings from ye left to ye right contrary to almost all shells hitherto described. In the Catalogue of Shells preserv'd in ye Ashmolean Repository 'tis called *Buccino-cochlea atrovirens*, a Sinistra in dextram obvoluta, mucrone obtuso, lutescenti. A sort of amphibious Crabfish from ye Island of Barbados, which when they return to sea, keep their course soe directly forward, that they usually climb over rocks, houses, and what other obstacles soever; rather than take any compasse.

The Society desired an account of ye number of Christenings and burials in Paris and London in ye years 1670 and 1671.

December 1, 1685. Dr. Bernard gave an account, that the Eclipse of the Moon the night before, could not be observed here by reason of a thick fogge at that time.

He also gave an account of a fat man that lived a fortnight together upon Tea alone, and by these means cured himself of a fitt of the Gout. Other Instances of fasting were mention'd. One John Scot in ye time of K. Hen: 8th fasted 30 or 40 dayes together in an Abbey at Edenburgh, and 32 daies in ye Castle there: He also did the like at Rome; and fasted 50 daies in prison at London. This is affirmed by Bp. Spotswood in his history of Scotland A.D. 1539. One Cisely de Ridgeway being condemned fasted 40 daies in prison, and was therefore pardoned: Dr. Plot produced a copy of her pardon, wherein her fasting 40 daies was mention'd; It was dated Anno 3^{mo} Edv. 3^{ij}. Dr. Plot said, he was credibly informed, that a Dog being casually locked up in a study at Canterbury, fasted 24 daies together, and afterwards recovered. Mr. President said, his sister told him, she had a hen, that lived without meat and drunk 9 weekes together, being by chance shut up among some faggots, and afterwards recovered. She was observed to drink much, as soon as she was released.

There was read a paper proposing a way to remember numbers by words, ye vowels whereof may represent figures; with a large scheme of instances in Chronology to that purpose.

Dr. Plot shew'd us ye skins of ye Otter fish and of ye *Canis marinus* or dog-Fish, which is not ye same with ye Sharke or *Canis Charcharias*.

December 2, 1684. The President, Director, and Secretary being all out of town, we had no meeting for a fortnight.

Societies and Academies.

LONDON.

Royal Society, November 19.—J. W. Pickering and R. J. Gladstone: The development of blood plasma. Pt. I.: The genesis of coagulable material in embryo chicks. An excess of material which is protective against the inception of clotting exists in the plasma of early embryos. This material does not possess antithrombic properties. Antithrombic material can be prepared by heating embryonic blood to 60° at the stage of development prior to the appearance of prothrombin. The inception of the coagulation of embryonic blood may occur, at room temperatures, prior to the agglutination and lysis of thrombocytes.—D. J. Scourfield: On a new type of crustacean from the Old Red Sandstone (Rhynie Chert Bed, Aberdeenshire), *Lepidocaris rhyniensis*. This form only reaches about 3 mm. in length in the fully grown adult. Both sexes in various stages of development are found. Owing to the semi-transparent nature of the Chert and the excellent preservation of minute structures therein, it has been possible to reconstruct the animal in practically all its external details. A new order of Branchiopoda, the Lipostraca, has been formed to receive it. Considered as a whole, *L. rhyniensis* does not seem to have led to any subsequent development. It was in many ways more specialised than any living anostracan, and probably fitted into a very peculiar environment. The absence of all certain traces of "pond life" organisms other than *L. rhyniensis* seems to confirm the theory that the water in which the Rhynie Chert bed was deposited may have been hot and highly charged with silica.—J. R. Norman: The development of the chondrocranium of the eel (*Anguilla vulgaris*), with observations on the comparative morphology and development of the chondrocranium in bony fishes: For purposes of comparison, the development of the chondrocranium in the herring (*Clupea*) and the salmon (*Salmo*) has been studied. A general comparative account of the morphology and development of the chondrocranium of bony fishes has been included. It is concluded that the hyomandibular of bony fishes represents the epal element of the hyoid arch, and is homologous with the hyomandibular of selachians, the interhyal of bony fishes is a new structure. The condition of hyostyly has been independently acquired in the two groups.—J. Needham and Dorothy Needham: The hydrogen-ion concentration and oxidation-reduction potential of the cell-interior before and after fertilisation: a micro-injection study of marine eggs. A study of eggs of four echinoderms, of one tunicate, and of one polychaete worm has been made by the method of micro-injection. The conclusions rest on appearances seen in 3300 injected eggs. The internal pH of all eggs studied is in the close neighbourhood of 6.6. It does not change on fertilisation, nor are any subsequent rhythmical changes to be seen. On cytolysis it is lowered to a point below 5.0 and above 4.0. The pH varies more than the pH, but it is within the limits 19 to 22; it does not change on fertilisation or cytolysis. Vital staining and micro-injection give diametrically opposite results.—R. R. Armstrong: Studies on the nature of the immunity reaction. (i.) The protective power of sera, prepared by immunising rabbits with pneumococcal vaccine, can be measured accurately against measured doses of living pneumococcal cultures, using mice as test objects. Immunity is developed in a very characteristic manner, whether it be following experimental inoculation in the rabbit

or the natural stimulus of a lobar pneumonia in man. An inductive phase, lasting from three to five days, is followed by an outpouring of protective antibodies into the serum, at a rapidly increasing rate; a maximum concentration of protective substance being reached on the eighth day after inoculation. Strict correlation is found to exist, within certain limits, between the size of the dose of vaccine administered and the degree of immunity developed. (ii.) The pneumococcus combines proportionally with its homologous protective anti-bodies to form a "sensitised" vaccine. On inoculation, a sensitised vaccine liberates the greater part of its charge of anti-bodies, rapidly conferring a slight degree of immunity; and afterwards excites an active immunity in a manner comparable with that of raw vaccine. Sensitisation, however, leads to a reduction in the intensity and to delay in the immunity response, compared with that following an equal dose of raw vaccine.—R. J. Ludford: The cytology of tar tumours. Tumours were produced by painting regularly the skin of mice with tar. Epidermal cells show changes associated with the process of keratinisation, pathological conditions, hypertrophy, and degeneration, being of common occurrence. Sebaceous glands in the thickened epidermis surrounding tar tumours show marked hypertrophy. The secretion process is essentially the same as in the normal gland. Penetration of the *panniculus carnosus* by tumour cells induces reaction on the part of the muscle fibres, seen in an increase in sarcoplasm and in number of nuclei, and also in the behaviour of cytoplasmic organs.—Eric Ponder: The inhibitory effect of blood serum on hæmolysis. The reaction is described by equations similar to absorption equations; the inhibition is probably due to the formation of a loose physical compound between the lysis and the serum proteins. The reaction is little influenced by temperature within the experimental range.—L. Brüll and F. Eichholtz: (1) The effects of calcium and potassium ions on urine secretion as studied in the whole animal. In the intact anaesthetised dog, potassium chloride injected intravenously increases the urine flow to a much higher extent than injection of corresponding amounts of sodium chloride. Potassium or calcium chloride, either isolated or combined, have no constant nor specific effect on chlorides output; the intact animal behaves as it does towards sodium chloride, using its general power of concentrating chlorides. When the pituitary body is removed, and the kidney has consequently lost its power of concentrating chlorides, the animal reacts to calcium and potassium ions as in the lung-heart-kidney preparation. Hence in the lung-heart-kidney preparation reactions of the kidney can be studied and elucidated under simplified conditions. (2) The secretion of inorganic phosphate by the kidney. Infusions of sodium or potassium solutions increase the output of inorganic phosphate and also the urine flow, but in a smaller proportion. Small amounts of calcium chloride may increase the phosphorus output; large amounts diminish or even abolish inorganic phosphate secretion. This decrease of phosphate in the urine is generally accompanied by an increase of the phosphate level of the serum.—F. Eichholtz, R. Robison, and L. Brüll: Hydrolysis of phosphoric esters by the kidney *in vivo*. The isolated kidney, perfused by means of the heart-lung preparation, which is unable to concentrate the normal inorganic phosphates of the blood serum, is able to concentrate and to hydrolyse added organic phosphates, and to excrete their phosphorus as inorganic phosphates in the urine in a much higher concentration than that of the inorganic phosphates in the serum. In the whole animal in which the

urinary inorganic phosphates have sunk to a minimum, injected organic phosphates are excreted, after an initial stage, entirely in inorganic form. It is considered that normally a considerable part, if not all, of the urinary phosphates are derived from the organic phosphates of the serum, by hydrolysis in the cells of the kidney under the action of the kidney enzyme.

Mineralogical Society, November 3—C S Garnett. The dissociation of dolomite. Further evidence in support of the conclusion that true dolomite dissociates under the influence of heat in a single step and not in two stages as formerly supposed. The setting of semi-burnt dolomite with water is due to free lime and not to a mixture of magnesium oxide and calcium carbonate.—B J Tully. A new refractometer. The special features of this new refractometer are thorough rigidity and an exceptionally large and flat field of vision due to the long optical system employed, the shadow edges being straight instead of curved as in older types. All adjustments for focusing, lighting, etc., being independent of the main body which contains the optical system and graticule scale in a dust-proof enclosure, little damage is possible by inexperienced usage.—A Russell. Notes on some new British localities for barytocalcite and alstonite. Barytocalcite is found at Ayleburn Mine, Northumberland, 2 miles north of Alston, where it occurs, abundantly and well crystallised, with blende in brown limestone. Heartycleugh Mine, West Allendale, Northumberland, in small quantity with barytes, and Lolly Scar Mine, Nidderdale, Yorkshire, massive and in small crystals with fluor, chalcopyrite, witherite, etc. Alstonite, massive and in crystals of the usual habit, was found as a single specimen in the witherite vein worked in Ushaw Moor Colliery, near Durham.—G T. Prior. The meteoric iron of Vaalburg and meteoric stones of Witklip and Queens Mercy, South Africa. A mass of meteoric iron weighing 26 lb was found on Vaalburg farm, Prieska Division, Cape Province. It is a coarse octahedrite having about 7 per cent of nickel, with a ratio of iron to nickel of about 13. The Witklip stone fell on May 26, 1918, on the farm Witklip in Carolina District, Transvaal, after a loud explosion and a flash of light. It is a grey chondrite resembling Cronstad. Only a few grams appear to have been preserved. The Queens Mercy stone is also a grey chondrite which fell on April 30, 1925, about 20 miles from Matatiele, Cape Province, after the appearance of a bright light and a loud detonation. The stone, which measured about 1½ ft in length, was broken up by the natives and only a few fragments have been recovered.

Society of Public Analysts, November 4—G D Elsdon and Percy Smith. The determination of palm kernel oil and butter in margarine. The Reichert, Polenske and Kirschner values of a series of mixtures of palm kernel oil and butter fat in mixtures of other oils and fats have been determined. The differences between the calculated and observed values are very much less in the case of palm kernel oil than in the case of coconut oil, the relationship between the Reichert and Polenske value of a given mixture may assist in deciding on the relative proportions of palm kernel oil and coconut oil present.—Clive Newcomb. The determination of alcohol and ethyl chloride in chloroform. Alcohol is removed by washing with water in a special apparatus, and by determining the density of the chloroform before and after the washing a measure of the amount of alcohol is obtained, whilst the difference between the density of the washed chloroform and that of pure chloroform affords a

measure of the amount of ethyl chloride.—H Atkinson. The volumetric determination of soluble sulphates by means of barium chloride and potassium stearate. Sulphates in fairly dilute solution can be determined by precipitating them with excess of standard barium chloride solution, and titrating this excess with standard potassium stearate solution, the end point being shown by B D H universal indicator. Metals forming insoluble stearates (e.g. aluminium, zinc, calcium, magnesium) are removed by precipitation with the potassium stearate solution prior to the titration of the sulphate. The limit of error in the method is of the order of 0.05 c.c. of a 0.1 N solution.

Linnean Society, November 5—Marius Maxwell. The home of the eastern gorilla.—Miss E Bolton. Validity of certain species in Neuropteris, Brongni.

November 19—H S Holden and S H Clarke. On the seedling structure of *Tilia europaea*.—L R Crawshaw. Sponge fishery investigations in the British West Indies. The investigations were instituted by the Colonial Office in 1920. Among the problems requiring attention are that of depletion of the sponge beds through unrestricted removal of the sponges over many years past, and the cultivation of sponges from planted cuttings. The latter offers undoubtedly valuable possibilities of development of a sponge fishery along the best lines for the improvement and extension of its resources. The general subject of sponge-fishery control can only properly be dealt with in the light of knowledge gradually to be obtained by study of the living sponges, and especially in regard to the relationships of the chief market types, and their form-variations, age, growth and growth-rate, and reproduction.—G Claridge Druce. Recent additions to the British flora.

Mathematical Society, November 12—H B C Darling. Expansion of the elliptic integrals u and $E(u)$ in series of sines of multiples of the amplitude.—H Hilton and Sybil D Jervis. On plane quartic curves with a triple point.—C G F James. (1) On cycles of corresponding points in Cremona transformations. (2) Generation of quadratic plane transformations by means of double projection.—P A MacMahon. Euler's ϕ -function and its connection with multipartite numbers.—W P Milne. The harmonic and equianharmonic envelope of a cubic surface.—C A. Stewart. The integration of linear partial differential equations with constant coefficients and distinct characteristics.—E C Titchmarsh. A series inversion formula.—C E Weatherburn. On congruences of curves.—E M Wellish. Electric and magnetic displacement currents.—F J W Whipple. (1) On well-poised series, generalised hypergeometric series having parameters in pairs, each pair with the same sum. (2) Well-poised series and other generalised hypergeometric series.

Royal Anthropological Institute (Indian Section), November 17.—E H Hunt. Hyderabad cairn burials. At "Mauli Ah, South," last May, five burials were opened. Finds included the bones of a hare in a pot, bovine teeth, much iron, pottery showing new features, and a fine gold spiral, with a large number of minute gold rings, other rings were of silver, plated with gold. These burials differed in type from those of Raigar and elsewhere in that the cist slabs were vertical, and overlapped at the ends. In the north slab, a large round hole had been cut, bringing these underground burials into line with the surface "holed dolmens" of Rajunkalur. In May 1923, further investigations

were made, with Mr. L. Munn, into the ancient iron industry of the Hyderabad State. No limiting date can be placed on the smelting of iron in South India. Continued study of the literature of the subject yields little, though excellent descriptions of surface conditions are given by the older writers. Destruction of these remains is rapid, their chief enemy being the cultivation of castor seed. At least six distinct types of burials can be distinguished, and the total period covered must extend to thousands rather than hundreds of years. Some types must be far older than others, but before any attempt at "sequence dating" can be begun, there must be much organised and careful excavation. There is urgent need for the provision of some central collecting station where type-specimens of pottery, beads, rings, human and animal remains, articles of gold, silver, copper, and iron, etc., can be collected for comparative study. England appears to be the natural place for this, but, so far, no museum affords the requisite housing space.

Royal Statistical Society, November 17.—G. Udny Yule. Why do we sometimes get nonsense-correlations between time-series?—a study in sampling and the nature of time-series. (Presidential address.) When graphs are plotted of (1) the standardised mortality in England and Wales, 1866–1911, (2) the proportion of Church of England marriages to all marriages during the same years, they shew a very close relationship, measured by a coefficient of correlation of more than +0.9. Such a correlation is completely nonsensical; but the fact that we can get such correlations leads us to mistrust the serious arguments that have sometimes been based on time correlations. Even though two simple functions of time are completely independent when the correlation is considered over a long period, short "time-samples" tend to give correlations departing as far as possible from the truth and approaching ± 1 . Turning to empirical series, a method of classification is suggested based on the "serial correlations" for the series, that is, the correlations between terms distant from each other by 1, 2, 3, . . . units of time. The dangerous class of series is that for which not only the serial correlations for the series itself but also those for its first differences are all positive. Applying the method of serial correlations to the analysis of Sir William Beveridge's index-numbers for wheat prices in Western Europe, 1545–1844, and also to rainfall at Greenwich, 1815–1924, the differences of the former series are found to be oscillatory, as in Sir William Beveridge's periodogram analysis, while the latter appears to be mainly random.

PARIS.

*Academy of Sciences, October 12.—J. Costantin: Two new experimental stations of *Pleurotus Eryngii*. An account of two attempts to grow this edible fungus at Guignecourt-sur-Vence (Ardennes) and the forest of Fontainebleau.—André Blondel: Measurement of the photometric yields of optical apparatus.—A. Vayssière: The nymphosis and metamorphosis of a *Prosopistoma foliaceum*.—E. Bataillon: New technical methods for the study of gastrulation and germinal localisations in the batrachians.—Georges J. Rémondos: The extension of Picard's theorem to multiform functions.—E. Baticle: The correction of the effects due to permanent expansions or contractions in concrete arches.—Thadée Peczkalski: The cementation of metals by volatile salts. Study of the effects of prolonged heating of iron and copper in contact with fused chromium chloride and fused

nickel chloride. The penetration of copper by nickel under these conditions is shown by microphotographs.—L. Meunier and A. Bonnet: The fluorescence of the colouring matters of plants. The fluorescence under Wood's light is of value in the characterisation of commercial tinctorial extracts.—Volmar: The photolysis of the ethylenic dibasic acids. Fumaric, maleic, mesaconic, itaconic and citraconic acids have been exposed to ultra-violet light under comparable conditions, and the volumes of gas produced measured. The unsaturated acids are more easily decomposed by ultra-violet light than the corresponding saturated acids. The *cis* isomers are more readily decomposed than the *trans* isomers.—A. Gruvel: A fishing map of a part of the western coast of Morocco.—C. T. Popesco: Movements of sleep and awakening compared in *Desmodium canadense* ungrafted and grafted.—Risbec: The production of light by a nudibranch mollusc from New Caledonia. This mollusc, named provisionally *Triopa fulgurans*, emits a series of short bright flashes when disturbed.—J. Athanasio: The nervous mechanism of the rhythmicity of the myocardium.—P. Lasareff: The change in the electrical conductivity of the visual purple during illumination. The retinal purple of the frog was dissolved in solution of bile salts, and submitted to prolonged dialysis. The increase in the electrical conductivity produced by illumination was determined and could be expressed by the formula $\sigma = a - be^{-at}$, where σ is the electrical conductivity, a and b constants, t the time, and a a constant depending on the light intensity. These experiments are regarded by the author as giving an experimental basis to his ionic theory of luminous sensations.—Samec: The chemico-colloidal properties of the components of starch.—P. Cappe de Baillon: The embryogenesis of double monsters in phasmids (*Carausius morosus*).—Pierre P. Grassé: The vacuome and Golgi apparatus in Euglena.

MELBOURNE.

Royal Society of Victoria, September 24.—G. A. Ampt and E. J. Hartung: Occurrence of helium in a spa gas, Victoria. A distinctly radioactive spa gas from Hepburn, Victoria, was analysed for helium by standard methods. The volume composition proved to be: carbon dioxide 97.0, nitrogen 2.55, oxygen 0.46, inert gas 0.045 per cent. The last was shown to be a mixture of argon and helium, with traces of neon. Its average molecular weight was 35.1, as determined by an Aston density balance, and corresponded with 13.4 per cent. of helium. The volume concentration of helium in the spa gas was therefore 6 parts in 100,000. This is the first recorded occurrence of helium in any Australian natural gas.—E. F. J. Love: A low-lag thermocouple with a novel type of insulation. A method of insulating wires and thermojunctions by means of a thin film of rubber, deposited from solution in benzine—petroleum motor spirit—and afterwards vulcanised with sulphur chloride. Couples so insulated are found to have a very small lag and have proved of service in some recent experiments on meat refrigeration. As the materials required are regular articles of commerce and the operations simple, the method may find other applications.—D. K. Picken: Geometry, the basic physical science; a modern equivalent to Euclid. This is the final paper of a series published in the *London Math. Soc. Proc.* (ser. 2, vol. 23, pt. i.) and in the *Math. Gaz.* (Dec. 1922, Oct. 1924). An attempt is made to recover the point of view of the Greek philosopher-geometers, while embodying all the essential relevant ideas

that have accrued in modern times. This paper discusses the fundamental definitions and axioms of geometry—especially the necessary axioms of order—and a natural logical sequence of propositions. The "complete angle" method is used to resolve outstanding difficulties in the proof of Euc. i 8—A. W. Turner. Sensitising powers of parasite proteins. By using Dale and Laidlaw's isolated sensitised guinea-pig uterus technique, the biological relationship of some metazoan parasites (Nematoda, Trematoda, and Arthropoda) were investigated: Uteri sensitised by proteins from one species of a genus may exhibit non-specific sensitiveness towards another species, but after being desensitised to the non-specific factor, delicate specific sensitiveness towards the sensitising proteins remained. If first desensitised against the sensitising proteins, uteri exhibit no non-specific sensitiveness. There is an analogy between this phenomenon and group agglutination and precipitation. The method may be useful for specifically diagnosing mutilated parasites—A. J. Ewart, Lesley R. Kerr, and E. M. Derrick. Contributions to the flora of Australia (30). An account is given of the first results of the examination of a collection of plants made by Prof. Ewart during a visit to Central Australia in 1924. It consists mainly of new or additional records, the new species being kept for a later paper. Attention is directed to the existence of a large belt of timber of *Casuarina*, *Decasmanian* south of the McDonnell Ranges, the existence of which may prove of considerable importance in connexion with the approaching extension of the railway from Oodnadatta to Stuart in the McDonnell Ranges. The character of the vegetation in many areas north of the McDonnell Ranges indicates the existence of land valuable not merely for grazing but also in the future for quickly ripening summer grain crops. Far from being a desert, much of this land is highly fertile and has a rainfall of 12 to 20 inches. Interspersed with these areas are, however, large tracts of sandy porcupine grass country representing a difficult problem of economic handling and treatment.

VIENNA

Academy of Sciences, October 15—G. Weissenberger, R. Henke and L. Bregmann. Divalent phenols and their ethers.—G. Weissenberger, R. Henke and E. Sperling. The behaviour of deka-hydro-naphthalin.—M. Kohn and S. Sussmann. Some tri- and tetra-halogen-phenols.—R. Weiss and K. Woidich: On 1-phenyl-naphthalin and its derivatives.—J. Pollak and E. G. Fulnegg. On derivatives of resorcin.—H. Michel. The fall and finding of a meteoric stone at Lanzenkirchen, Lower Austria. Eye-witnesses in Wiener Neustadt report that on August 25, 7.30 p.m., a fireball emerged from between the clouds, burst asunder and fell to earth in rapidly fading pieces. After 20 to 30 seconds, according to the distance of the observer, several shot-like detonations followed by irregular thunder roll for a minute were heard. The meteor left a vivid shining track. Next day Herr Flickentanz found a peculiar hole in his meadow. Half a metre deep was a meteoritic stone weighing more than 5 kgm., the size of a child's head.—O. Furth and J. Marian: On the decomposition of hexosediphosphoric acid in the mammalian organism.—E. Cartellieri: Contributions to our knowledge of the absorption system of Rafflesiaceae Brugmansia.—O. Koller: A new species of *Barbus* from Albania, from the stream Fandi Vogelj.—J. Schädler. Scharizerit, a new mineral from the dragon cave at Mixnitz in Styria, has a high nitrogen content.

Diary of Societies.

SATURDAY, NOVEMBER 28.

JUNIOR INSTITUTION OF ENGINEERS (at Shipping Engineering and Machinery Exhibition at Olympia), at 3.—T. E. Dumbleby. Introduction as an Aid to an Industrial Revival (Lecture).

MONDAY, NOVEMBER 30.

ROYAL SOCIETY, at 4.—Anniversary Meeting.

ROYAL IRISH ACADEMY, at 4.15.

INSTITUTE OF ACTUARIES, at 5.—D. Houseman: Some Notes on the Changes made by the New Law of Property Acts, with special reference to Life Assurance Practice.

INSTITUTION OF ELECTRICAL ENGINEERS (Western Centre) (at South Wales Institute of Engineers, Cardiff), at 6.—J. H. Thomas. Switch-gear Developments during the Past Twenty Years (Lecture).

ROYAL SOCIETY OF ARTS, at 8.—Dr R. Lessing. Coal Ash and Clean Coal (Cantor Lecture II).

TUESDAY, DECEMBER 1.

INSTITUTION OF CIVIL ENGINEERS, at 6.—H. A. Reed: Trafford Wharf Reconstruction at the Manchester Docks.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Society of Arts), at 7.—Capt R. K. Hubbard. The Requirements of the Military Motor Vehicle.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at 17 Albert Square, Manchester), at 7.—T. Carter. The Engineer, his Due and his Duty in Life (Lecture).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—T. H. B. Scott. Lourdes Revisited.

INSTITUTE OF METALS (Birmingham Local Section) (in the Chamber of Commerce, New Street), at 7.—Discussion on The Production of Sound Ingots.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Broadgate Cafe, Coventry) (Coventry Graduates' Meeting), at 7.15.—G. H. Day. Some Notes on Service.

SOCIETY OF CHEMICAL INDUSTRY (South Wales Section) (at Technical College, Cardiff), at 7.30.—O. Bateman. Manufacture and Neutralisation of Ammonium Sulphate.

INSTITUTE OF METALS (North-East Coast Local Section) (in the Electrical Engineering Lecture Theatre, Armstrong College, Newcastle-on-Tyne), at 7.30.—Dr. M. Cook. The Solidification of Metals.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—G. Butler. The Products and By-Products of a Modern Iron and Steel Works.

INSTITUTE OF MARINE ENGINEERS (at Shipping Engineering and Machinery Exhibition at Olympia), at 8.—A. C. Hardy. Motor Ship Progress in 1925.

ROENTGEN SOCIETY (at British Institute of Radiology), at 8.15.—R. J. Stephenson: A Study of Interrupters for Induction Coils.—Dr. E. A. Owen. Oscillographic Observations on Induction Coils and Transformers.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Z. le Rouzic. Les Monuments mégalithiques du Morbihan; leur définition, leur destination et leur âge d'après les dernières découvertes aux environs de Carnac.

WEDNESDAY, DECEMBER 2.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—R. D. Oldham. The Depth of Origin of Earthquakes.

INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—H. F. Molony. Escalators on the Central London Railway.

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6.—H. A. Thomas. The Performance of Amplifiers.

INSTITUTION OF ELECTRICAL ENGINEERS (South Midland Centre) (at Birmingham University), at 7.—Prof. S. P. Smith. An All-Electric House.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at Shipping Engineering and Machinery Exhibition at Olympia), at 7.30.—J. E. Boaz. The Requirements of Ablutionary and Recreative Bathing Establishments as affecting the Heating and Ventilating Engineer.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—Dr. J. S. Owens: Measuring the Smoke Pollution of City Air.—Dr. O. L. Brady. 2. 4-Dinitrophenylhydrazine as a Reagent for Aldehydes and Ketones.—G. Jorgensen: The Determination of Phosphoric Acid as Magnesium Ammonium Phosphate.—O. H. Thomson: On the Effect of "Blowing" on the Composition of Certain Fatty Oils.

ROYAL SOCIETY OF ARTS, at 8.—Lt.-Col. Sir Alan H. Burgoyne. The Future of the Motor Car.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

THURSDAY, DECEMBER 3.

ROYAL SOCIETY, at 4.30.—W. A. Bone and G. W. Andrew. Studies in Catalytic Combustion. Part II. The Union of Carbon Monoxide and Oxygen in contact with Nickel Copper and other Oxides.—F. H. Constable: Immovable Groups of Atoms with Strong Specific External Fields as the Cause of Catalytic Activity.—S. C. Roy. On the Law and Mechanism of Monomolecular Reaction.—F. A. Williams: The Effect of Temperature on the Viscosity of Air.—R. W. Fenning: Gaseous Combustion at Medium Pressures. Parts I. and II.—R. K. Schofield and E. K. Rideal. The Kinetic Theory of Surface Films. Part II.—To be read in title only.—H. B. Dixon and G. Greenwood. On the Velocity of Sound in Mixtures of Gases.—A. Fage and L. F. G. Simmonds. An Investigation of the Air-Flow Pattern in the Wake of an Aerofoil of Finite Span.—W. L. Webster. Magneto-Striction in Iron Crystals.—R. W. James and W. A. Wood. The Crystal Structure

of Barytes, Celestine, and Anglesite.—O. Maass and J. H. Meunier: Aberrations from the Ideal Gas Laws in Systems of One and Two Components.—R. G. Lunn: Fluid Resistance to Moving Spheres.—W. G. Palmer. The Adsorptive Equilibria of Binary Gaseous Mixtures.—I. Sandeman: The Secondary Spectrum of Hydrogen at Higher Pressures II.—P. A. M. Dirac. The Fundamental Equations of Quantum Mechanics.

LINNEAN SOCIETY OF LONDON, at 5.

ROYAL AERONAUTICAL SOCIETY, at 5.30.—Prof. B. Melville Jones: The Control of Stalled Aeroplanes.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Prof. S. P. Smith: An All-Electric House.

GLASGOW UNIVERSITY ALCHEMISTS' CLUB, at 7.30.—A. Stevens. Arctic Exploration.

INSTITUTION OF STRUCTURAL ENGINEERS, at 7.30.—H. G. Lloyd. A Method of Testing Concrete Blocks.

CHEMICAL SOCIETY, at 8.—B. Lewis and E. K. Rideal. On the Budded Effect in Bromine. Part I. The Photoactive Constituent in Wet Bromine. Part II. The Kinetics of the Reaction and the Light Absorption of Wet and Dry Bromine.—R. Gane and C. K. Ingold. The Influence of Carbon Rings in the Velocity of Reactions involving their Side-chains. Part I. The Hydrolysis of Cyclic and Open-chain Malonic Esters.—H. V. A. Briscoe, P. L. Robinson, and G. E. Stephenson: The Density of Boric Oxide Glass and the Suspected Variation in the Atomic Weight of Boron.

INSTITUTION OF MECHANICAL ENGINEERS (Glasgow Local Meeting)—Sir John A. F. Aspinall. Some Railway Notes Old and New (Thomas Hawksley Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Manchester Local Meeting).—H. F. L. Orcutt: Characteristics and Uses of Ground Gears.

FRIDAY, DECEMBER 4.

INSTITUTION OF WATER ENGINEERS (at Geological Society), at 10.30 A.M.—Dr J. C. Thresh and J. F. Beale: Recent Studies relating to the Purification of Water, and the Action of Various Waters on Lead and Copper Pipes.—Dr. W. Rushton and P. A. Aubin. Further Observations on the Biology of Jersey Waterworks.—W. N. McClean: An Analysis of Scottish Rainfall Records.—Lt.-Col. J. R. Davidson: The Afforestation of Watersheds.—H. E. Stiggoe: The London Water Supply (Lecture).

ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.—Sir Gilbert Walker. Vortical Theories in Meteorology, followed by E. V. Newham. Chairman, Sir Napier Shaw.

SOCIETY OF CHEMICAL INDUSTRY (Manchester Section) (at 16 St. Mary's Parsonage, Manchester), at 7.—M. Barash: A Standard Method for the Determination of the Agglutinating Value of Coal.—C. M. Keyworth and Dr. R. B. Forster. The Separation of R, G, Schaffer and Crocin Acids and their Arylamine Salt.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Pictorial Group Meeting.

PHOTOMICROGRAPHIC SOCIETY (at 4 Fetter Lane), at 7.—T. Thorne Baker. The Role of Photomicrography in the History of Plate Making.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. E. Bowyer-Lowe: Super Heterodyne Reception.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Literary and Philosophical Society, Newcastle-upon-Tyne), at 7.30.—G. Constantinesco: Transmission of Power—the Present and the Future.

GEOLOGISTS' ASSOCIATION (at University College), at 7.30.—Dr. W. D. Fung. The Submerged Forest at the Mouth of the River Char, and the History of that River.—S. W. Wooldridge: Some Phases in the Structural Evolution of the London Basin.

SATURDAY, DECEMBER 5.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—Miss G. Lister. Swiss Memories (Lecture).

PUBLIC LECTURES.

SATURDAY, NOVEMBER 28.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—E. Lovett: The Luck of an Old Shoe.

MONDAY, NOVEMBER 30.

UNIVERSITY COLLEGE, at 4.30.—Prof. Y. Henderson: The Efficiency of the Heart and its Measurement. (Succeeding Lecture on December 1.)

UNIVERSITY OF LEEDS, at 5.15.—Dr. G. W. C. Kaye. X-Rays in Industry.—At 8.—Sir Henry Hadow. Chamber Music, illustrated from the Elizabethans and J. S. Bach.

TUESDAY, DECEMBER 1.

KING'S COLLEGE, at 5.30.—Miss Hilda D. Oakeley. The Philosophy of Aristotle; Theory of Art. Characteristics of Aristotle's Genius.

THURSDAY, DECEMBER 3.

FINSBURY TECHNICAL COLLEGE, at 4.—F. H. Carr: The Scientific Basis of Industry (Streetfield Memorial Lecture).

FRIDAY, DECEMBER 4.

ST. THOMAS'S HOSPITAL, at 5.—Prof. F. G. Parsons. The Earlier Inhabitants of London.

SATURDAY, DECEMBER 5.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Travel and Transport in Ancient Egypt.

SATURDAY, DECEMBER 5, 1925.

Atomic Structure and the Quantum Theory.

WE publish this week, as a special supplement, the substance of an address by Prof. N. Bohr on the development of the theory of atomic structure, and in particular of the latest form and tendencies of the quantum theory in their relation to mechanics. New points are raised which seem likely to be of such importance that some attempt at a general description may be of interest. The prevailing theory of atomic structure, which we owe so largely to Prof. Bohr himself, might be characterised as "the central orbit theory." In this theory we visualise the atom as a nucleus surrounded by electrons. Each of these moves in a mechanical (but non-radiating) nearly central orbit, characterised by special fixed values of energy and angular momentum which are functions of two quantum numbers. The immense success of this theory in co-ordinating the facts of optical and X-ray spectroscopy and the general physical and chemical periodic properties of the elements is well known, and its correctness in broad outline is scarcely open to question. But it is equally certain that in its finer details the theory has proved inadequate. As soon, for example, as we begin to ask why the D-lines of sodium are a doublet instead of a single line, we leave the certain field of the theory for far less certain extensions. We can introduce formally the third quantum number necessary to "explain" the doubling (trebling, etc.) of spectral lines, and similarly the fourth quantum number necessary to "explain" their splitting in a magnetic field. Such "explanations" are elegant in form and convincing so far as they go, but when we try to interpret them on the basis of natural extensions of the mechanical model of the central orbit theory, we meet at every turn with perplexing contradictions which suggest that the proposed revision of the theory has up till now scarcely been sufficiently fundamental.

On another point the prevailing theory has proved somewhat inadequate. It has put forward a semi-mechanical model of the atom, which possesses mechanical frequencies. It is well known, however, that these differ from the observable frequencies of the atom, as shown, in the only way they can be shown, by their action on and-reaction to radiation. There is only an asymptotic equality between the two sets of frequencies for large quantum numbers. The theory has, however, been able to derive the exact observable frequencies from the mechanical frequencies by a *transformation* (Bohr's frequency condition) which forms an essential part of the postulates of the theory. The asymptotic equality, however, between the properties of the mechanical model and of the atom of any quantum

theory seems certain to subsist, not merely for frequencies but, generally, for all properties, including amplitudes or intensities of the various component oscillations. Underlying this there is doubtless an exact intensity relationship to be brought to light by a suitable transformation of the mechanical one, as Bohr's transformation brought to light the exact relationship for frequencies. Special cases of this relationship have already been recognised and embodied in what have been called "refined" applications of the correspondence principle. Some are old, such as the selection and polarisation rules: others more recent and perhaps more artificial, such as the summation rule, and the general intensity rules for multiplets and for the components of a line split by a magnetic field. But these are only special cases, and one can scarcely rest content with any transformation which utilises less than all the information about intensities as well as frequencies which the model can provide.

These and other similar ideas underlie the new attempt to formulate a more satisfactory theory, recently made by Heisenberg. Heisenberg's "transformation" of the equations of mechanics is much more general than Bohr's. Every mechanical quantity appearing is transformed at once in the new theory into an observable quantum quantity, so that the new theory does employ *all* the available information and provides complete intensity rules as well as frequencies for any soluble model. The mathematics required will be severe—in particular, the necessary algebra must obey a non-commutative law of multiplication and progress may be slow. In fact, once again physical theory seems likely to be a source of inspiration to mathematical thought. But enough appears to have been done to make it most probable that the new quantum theory will be still more fertile than the old, and to justify a hope that it may resolve some at least of the difficulties which now confront extensions of the older theory. Students of the quantum theory will wait with impatience for the publication of the results hinted at in Prof. Bohr's concluding paragraphs.

Weeds and their Control.

Ugress i nutidens jordbruk (Weeds in present-day agriculture). By Emil Korsmo. Pp. 694. (Oslo, Norway: J. W. Cappelens, 1925.)

THE eradication of weeds is regarded by many people as merely a matter of practical farming to which scientific methods have no application. This, however, is far from being the case, and it would be equally logical to deny the importance of science in other branches of agriculture. The possibility of effective control will increase in proportion to the increase in our knowledge of the plants usually regarded as weeds, especially with regard to their habits and

conditions of growth, revealing vulnerable points at which they may effectively be attacked.

The close study of weeds, with the direct objective of methods of control, brings to light valuable and interesting biological characters and relations of many widespread and common plants. Biological investigation from this point of view is a comparatively recent development, and no comprehensive work on the subject has hitherto been published, rendering this volume by E. Korsmo (professor in weed science at the Norwegian Agricultural College at Aas) a most welcome addition to botanical and agricultural literature. The book comprises the results of laborious and careful researches, representing much pioneer work, and extending over a period of thirty years. The author, however, is fully justified for the labour expended, as it must be admitted that the volume is probably the most valuable, from the biological point of view, of those hitherto published on the subject. The extensive collection of facts and their careful treatment are quite convincing, and reveal a power of observation combined with a patience in research which must awaken admiration. To sum up, the work is as conclusive as it is comprehensive and interesting.

At the outset, weeds are classified into biological groups determined by the author from the practical point of view, as follows:

- (1) Weeds multiplied by seeds only, including annual, "winter annual," and biennial plants.
- (2) Perennial weeds which multiply by seeds but may form clusters of shoots if the root is injured.
- (3) Perennial weeds which multiply mainly by creeping shoots.

Under each of these headings are various subdivisions which differentiate Korsmo's classification from those usually employed, and are based essentially upon differences of habit. Every species dealt with is minutely described throughout its life-history from seed to seed, and the numerous careful and detailed drawings make the book of great value to botanists as well as to agriculturists. Indeed two-thirds of the book is devoted to the botanical aspect of the subject. The scope of the work may be indicated by a reference to *Chenopodium album*. Its appearance, distribution, times of flowering and ripening of seed are given, together with large-scale drawings. The power of germination of the seed after burial at different depths has been determined by direct experiment, and the occurrence of the seeds in such substances as chaff, hay refuse, seed mixtures, dung, etc., is outlined. The description concludes by analyses of the mineral constituents of the plant, showing to some extent it demands upon the soil, and analyses of the organic constituents, which may indicate its feeding value for animals. Most of the work is original throughout, but

various figures and statements are quoted from other authors to strengthen the arguments or to point out the different results sometimes obtained under other conditions.

On the practical side is set forth the damage wrought by weeds, their differing capacities for spreading themselves and the best means of eradication and control. The value of systematic weed eradication is emphasised by numerous figures from experimental trials showing considerable increases of crop where good methods have been adopted. These chapters are of special interest to the practical farmer, and if the advice given were carefully followed out it should result in considerable decrease in the weed population, and a corresponding increase in the space available in the fields for actual crop growth. For many years Korsmo has been adopted by the government as weed adviser to the farmers, and has in that capacity gained a wide practical experience. His fundamental idea is to show the possibility of an economic fight against weeds, provided it be acknowledged that the old time-honoured methods are not sufficient, and that newer and more scientific methods must be brought into play, and he has endeavoured to point out that under these conditions excellent results have been obtained.

The book is written in Norwegian, making it comparatively inaccessible to the ordinary student, and an English translation is much to be desired to bring it within reach of the many whom it will deeply interest.

W. E. B.

Medieval Anatomy.

Monumenta Medica. Under the General Editorship of Henry E. Sigerist. Vol. 2: *The Fasciculus di Medicina, Venice, 1493.* With an Introduction, etc., by Charles Singer. Part 1: *Description of the Fasciculus; Discussion of its Editions, Art, Language, Sources, and Influence; Translation of the "Anathomia" of Mondino da Luzzi; An Account of Medieval Anatomy and Physiology; and an Atlas of Illustrative Figures from Manuscript and Printed Sources.* Pp. 112 + 73 (Atlas). Part 2: *Facsimile.* Pp. 108. (Florence: R. Lier and Co.; London: D. Stanton, 90 North Road, Highgate, 1925.) Half-linen, 66s.; half-leather, 80s.

THESE two stately volumes, which form an abiding memorial of Dr. Singer's scholarship and research, will appeal alike to the medical historian, the antiquarian, and the artist.

The "Fasciculus di Medicina" is a collection of medical treatises which was first printed in Latin at Venice in 1491, when it had attached to it the name of Johannes de Keetham, which according to Prof.

Sudhoff is a corruption of Kircheim. It is remarkable as being not only the first illustrated medical book, but also as being the best-illustrated work that had hitherto appeared.

The second edition, which was published in 1493 and is here reproduced in facsimile, differs from the first by containing among other additions the "Anathomia" of Mundinus or Mondino da Luzzi.

The "Fasciculus" passed through many editions, of which thirteen are known to Dr. Singer. The last appeared at Venice in 1522. A belated edition is said to have been published in the seventeenth century, but Dr. Singer has been unable to verify its existence.

Of the two volumes before us, the first contains a commentary on the "Fasciculus," including a discussion of its editions, art, language, sources, and influence, as well as a complete translation of Mondino's work. An atlas of illustrative figures from manuscripts and printed sources with explanatory legends is appended.

The second volume consists of a facsimile of the second edition of the "Fasciculus," and contains, in addition to the text, ten full-page illustrations including one in colour.

The illustrations comprise, among others, figures of the vein man, the wound man, and the zodiacal man, but those most worthy of attention are the frontispiece representing Petrus de Montagnana, the professor of Padua, seated at his desk surrounded by his books, with his waiting-room containing three patients in the foreground; a figure of a puerperal woman remarkable for being the earliest instance in a printed book in which an organ of the body, in this case the uterus, is drawn from the object; and a dissection scene which forms one of the earliest examples of printing in colours.

The "Anathomia" of Mundinus, who has been called the "Father of Modern Anatomy," represents the principal item in the "Fasciculus." In spite of its elementary character and numerous inaccuracies, such as the descriptions of a spherical stomach, a five-lobed liver, and a spleen with imaginary channels evacuating the black bile into the stomach, the work forms a landmark in the history of anatomy, though, as Dr. Singer points out, it is less a text-book of anatomy than a post-mortem manual. Its errors were doubtless partly due to the fact that, owing to the absence of preservatives, anatomical examination had to be performed very hurriedly. The whole procedure did not occupy more than four sessions, the first being devoted to the abdominal viscera, the second to the thoracic organs, the third to the head, and the fourth to the extremities. Subsequent reforms in anatomy were due to artists such as Mantegna, Pollajuolo, Michelangelo, and especially Leonardo da Vinci, rather than to professional anatomists.

Dr. Singer is entitled to special commendation for his translation of the "Anatomia," which, in view of the nomenclature, corruptness of the text, complexity of style, and confusion of thought and expression, was an unusually difficult task. An archaic style has been adopted in the translation, and most of the anatomical and technical nomenclature of the original has been preserved, the terms being explained in a glossary.

The Methods of Systematic Zoology.

Reform der paläozoologischen Nomenklatur. By Rud. Richter. Koehler's *Nachrichtenbl. f. Geol.* 2, Nr. 1-2. (Leipzig, 1925.)

Handbuch der biologischen Arbeitsmethoden. Herausgegeben von Prof. Dr. Emil Abderhalden. Lieferung 144. Abt. 11: *Methoden zur Erforschung der Leistung des tierischen Organismus.* Teil 1, Hälfte 1, Heft 4 (Schlussheft): *Allgemeine Methoden. Allgemeine Methoden des zoologisch-systematischen Arbeitens: die Nomenklatur.* Von W. A. Collier. Pp. 585-676+xii. (Berlin und Wien: Urban und Schwarzenberg, 1924.) 4.20 gold marks.

THESE two publications are welcome as a sign that some attention is being paid to the rules and methods of systematic zoology in quarters where there was much need of more observance. Most of those who are professional systematists have learned from sad experience the harm that has been wrought by want of thought in these technical details; none the less, many zoologists, often eminent in their own lines, continue to commit the same faults as their predecessors and to sow fresh seeds of future confusion. If authors cannot be made to realise their responsibility, there should at least, as Dr. Richter urges, be some hope of impressing editors and publishing bodies with a sense of their still greater responsibility. A committee of the British Association has for many years tried to do this, with some success no doubt, but evidently not with enough. The fact is that in Great Britain at least, and apparently in most other countries, systematic biology is no longer a "discipline." Our universities provide no training in either its principles or its methods; with rare exceptions the professors are as ignorant as the students. The botanists still retain a tradition of Linnæus, ornithologists and entomologists are forced in self-defence to have some method, but the young man who wishes to describe new species in any other groups is fortunate indeed if he has a competent elder colleague to guide him.

If these wanderers recognised their need they would welcome a brief work covering the field implied in Dr. Collier's title. In his text as it stands they will find some good counsel and some sound directions, but he is

not in all respects a safe guide. He is to be commended when he advises a knowledge of the living animal, when he protests against the dispersal of related material through a multitude of minor museums, or when he condemns those who base new species on the descriptions or figures of other authors without themselves seeing actual specimens. Excellent too is his advocacy of precise measurement and numbers, of a recognised colour-scale, of reasonable citation of references as opposed to a peppering of *loc. cit.* and *ibid.*

Sometimes, however, Dr. Collier is not so satisfactory, and occasionally he is actually misleading. The rules of the International Zoological Congress for the placing of figures are good, but need supplementing for the Invertebrata. There is, for example, a recognised way of orienting figures of various echinoderms. A warning is needed against filling a plate with figures lit from different points of the compass—a piece of carelessness that is as irritating as it is inartistic. Reference-letters affixed to drawings are better than nothing; but there is usually plenty of room for the whole word, and its use saves much time. Though many zoologists lessen the value of their work by giving some vague or inaccurate name to their material (*e.g.* "the common sea-urchin"), it scarcely seems necessary to rule that a complete and personally verified synonymy should be prefixed to every systematic note. It is frequently enough to refer to some clear and accessible description and figure. Still, even pedantry is preferable to a lack of precision, for experience shows that a name unsupported by evidence is of little value. Dr. Collier is entitled to use the expression "Trivialnamen" for vernacular names, but it seems a pity to do so, seeing that in the Linnæan system of nomenclature the *nomen triviale* is the second component of the *nomen specificum*, the first being the *nomen genericum*. The few remarks on type-specimens are not free from error. The erroneous definition of "paratype" is particularly unfortunate; that of metatype is incomplete; "homotype," which was preoccupied, has long been replaced by "homoeotypé," but it is little needed. Nothing is said about the subsequent selection of holotypes and genotypes, although this is one of the most important and most difficult questions for a systematist.

Apart from these details, important as they are in a handbook of practice, the whole of Dr. Collier's work seems to be weakened by what may be called a topsyturvy philosophy. Quite correctly he divides systematic work into analysis and synthesis, the analysis consisting in the discrimination of units and their precise description in every aspect, the synthesis which follows being the building up of these units into the hierarchy of systematic categories. As a method of research this

has very much to commend it, and the author could have made a still better case for it had he paid any attention to phylogenetic inquiry, especially that undertaken by palæontologists. But this synthetic method cannot be applied to the practical work of description and exposition; here a fresh analysis is needed. Nevertheless, directions are given for the construction of a system from below upwards, and there are many expressions which seem to imply that the definition of each category should summarise the characters of all its constituent inferior categories.

This method consistently carried out would break down of its own weight. Surely the method most natural to the human intellect is the old logical series of definitions *per genus et differentiam*. Here one begins at the top and gradually works downwards by repeated subdivision. There is no good reason as yet for discarding so clear and concise a method. Nowadays we find some authors establishing new genera or species without any diagnosis at all, and other authors introducing into a wordy description abundance of matter as unnecessary as the statement that a new species of *Equus* has four legs and a head. Had Dr. Collier explained the construction of an old-fashioned diagnosis he would have done a useful service and might have spared a good deal of less practical discussion. His work as it stands is disappointing. F. A. BATHER.

A Register of Harrow School.

The Harrow School Register, 1845-1925. Second Series. In 2 vols. Edited by J. H. Stogdon. Vol. 1: 1845-1885. Pp. xi+472+113. Vol. 2: 1885-1925. Pp. xi+442+113. (London: Longmans, Green and Co., 1925.) 15s net each vol.

TWO big volumes full of names, a fireside, and an editor who requests a notice of the book: where shall we begin? A list of distinguished Harrovians might be attempted, but NATURE would never print it and we should annoy some we forgot to mention. The worst of books like these is that it is impossible to do anything straightforward with them. One is always being side-tracked by something which catches the eye as one turns the pages. What about the editor of the book himself, what sort of fellow is he? Doubtless a clerkly man, but he must have a great love for his school to undertake the colossal task of this compilation. There is his name on the title page, "*J. H. Stogdon*, Member of the Stock Exchange." Now for the index: there he is again, 1889/3. Back to that term in the book: there is his name under that of his headmaster, *Bishop Welldon*—just a seven-line entry, which reveals that at school he was captain of cricket and winner of public schools rackets; that he got his "blue" at Cambridge for both

these games; and that he served with the R.N.V.R. in the War—a man we should like to know.

This is the way one reads a register, but it is scarcely a "review." Let us try what Church and State can offer. Five Harrovians, including the Prime Minister, are in the present Cabinet. There were two in the last one, which says something for the breadth of view taken from the Hill. The *Archbishop of Canterbury* is an Harrovian and a governor of the school. The latest and youngest addition to the Episcopal bench, *Dr. E. A. Burroughs*, is another Harrovian. Generals *Smith-Dorrien*, *Lawrence*, and *Lord Horne of Stirkoke*, also a governor of the school, represent Harrow in the army, as does *Sir Gerald du Maurier* on the stage. *Dr. Walter Leaf*, combining classical scholarship with finance, is equally renowned in each. *Col. the Hon. F. S. Jackson, M.P.*, is even better known for his cricket than for the minor interests indicated in his style, though he raised and commanded a battalion in the War and is chairman of the Conservative and Unionist Central Association. "A Gentleman's A-bowling" is a song which every Harrow boy knows and sings.

Of the nine fellows of the Royal Society whose names appear in the Register, *Lord Rayleigh* is the most famous Old Harrovian. *Sir H. K. Anderson, F.R.S.*, who now represents science on the governing body, is master of Caius College, Cambridge. At Oxford, *Dr. F. W. Pember*, Warden of All Souls, stands for Harrow and classical learning. This reminds one that *Dr. Godley*, the recently lamented Public Orator at Oxford, came from Harrow. So too did *Calverley*, but Godley had all his wit and more stability: at least he did not "migrate," as the Register so kindly puts it, from Balliol to Christ's.

Let us look up Godley. There is his name: came in 1869/1, while *Henry Monagu Buller*, the late Master of Trinity, was headmaster. What schoolfellows Godley had! The following names occur in the year of his entry: *William Henry Grenfell (Lord Desborough)*, chancellor of the Primrose League, president of the London Chamber of Commerce, chairman of the Thames Conservancy Board, who in his youth was president of the O.U.B.C. and O.U.A.C., swam Niagara and stroked an eight-oared racing boat across the Channel; *Walter Hume Long (Baron Long of Wraxall)*, who was in succession Secretary and afterwards President of the Local Government Board, President of the Board of Agriculture, Chief Secretary for Ireland, First Lord of the Admiralty and Secretary of State for the Colonies; *Walter Sydney Sichel*, barrister and author; *A. J. Webbe*, for many years captain of Middlesex Cricket Club; *A. S. Hewlett*, who left missionary work at home to minister to the lepers in Japan; *G. F. Chance*, at one time chairman of Chance Bros. and Co. and high

sheriff of Worcestershire; *P. N. Evans*, whose brilliant career as a consulting chemist was cut short by death in 1893; *H.R.H. The Duke of Genoa*, admiral in the Italian Navy, who was offered the crown of Spain while still at school; and *William Dodge James*, one of the first explorers of Somaliland. A notable year, one may say; but, in fact, it is an average one: at least, it was taken at random.

The Register reveals that, in 1845, the number of boys in the school was about half of the present one, which is about 650. Although *John Lion*, the pious founder, received his Charter from Queen Elizabeth, it was not until the early years of last century that the school outgrew the original buildings. In 1880 the boarders could all be accommodated in the houses of four "dames," whose names are recorded in the Register. *Dame Armstrong's* house has recently been pulled down to clear a site for the war memorial buildings which now approach completion. Nearly all the fame of Harrow has been won since the days of *Sheridan* and *Byron*.

It is worth while to consider the reasons for the success which seems to fall to the lot of Harrow's sons. "Influence," the sceptic may say: well, that counts for much, where the parent knows his world and exercises good judgment. Wealth? No, it is nearly true that the less money a man has, when his education is done, the better off he is. Scholarship? No again, so far as schooling goes. We are nearer the mark when we hazard freedom of thought and the absence of early pressure on immature minds. But the real secret lies in the spirit of service, for the leaders of men will always be chosen from those who have proved themselves willing to give of their best without thought of reward. This is what British public schools stand for, and it is the happiest augury for Britain in these distressful times, that there is growing up a whole host of secondary schools with the same ideals.

Unknown Egypt.

Ministry of Finance, Egypt: Survey of Egypt. Geology of Egypt. Vol. 1: The Surface Features of Egypt, their Determining Causes and Relation to Geological Structure. By Dr. W. F. Hume. Large 8vo. Pp. xliv+408+122 plates. (Cairo: Government Publications Office, 1925.) P.T. 50 (10s. 3d.).

THIS is a study of the conditions of a region which, though easily accessible, is not known to more than a dozen visitors beyond its mere fringe. Of the thousands who go up and down the Nile, not one in a year goes a march into the high desert. The two hundred views here are a joy to any who know the glorious spaciousness and scenery of the wild, and the

many questions that arise in trying to visualise its history. Eocene hills capped with crystallised calcite, or mountains with Tertiary basalt tops; the torrential gravels high up, with boulders which pounded the *ostræa* until it grew shells an inch thick; the collapsed strata dropped four hundred feet into caverns which fed the deep Nile gorge; all these are alluring prospects. The subjects discussed in this volume are naturally more physical than stratigraphic, as dealing with the surface conditions, and in several directions further experiment is needed to solve questions. After an outline of the past work by various nationalities, the variations of temperature are stated as leading to scaling of the rock, often under a difference of 50° C. The effect of this in flaking away architraves when ancient roofing is lost, might well be added.

An important chapter is that on the formation of sand dunes, and on sand erosion. The various types of dune are described, the size up to 30 metres high, the advance of 10 to 20 metres yearly, and the means of arrest. There does not seem to be a known cause for the difference between the ridge dunes, up to 50 or 100 miles long, and the rounded crescent dunes. No doubt one is favoured by a uniform direction of wind, the other by shifting winds which scour round the convexity, but it is not clear how such types begin. A beautiful example of seven parallel ridges, about a quarter of a mile apart, with grassy plains between, might be quoted from the south of Behnesa. The formation of oases is attributed to wind scour, but it is hard to imagine wind scooping out more than 500 feet depth of rock with steep sides, as in the Fayum; it looks more as if seepage had dissolved away lower strata of Eocene limestone into the adjacent Nile gorge, when that was empty to many hundred feet below the present level.

The action of rain is considerable, for though it is rare, the sudden amounts are violent, in the absence of vegetation. The formation of limestone caves is noted; the cisterns natural and artificial are described, some holding up to 500 tons. Forms of denudation on different kinds of rock are finely illustrated. The underground water is largely in the porous Nubian sandstone, which supplies the oases, and can be tapped by wells 250 feet deep in the intervening desert. Deep water supplies, independent of the Nile, are found at 150 to 300 feet, and now supply the larger cities. Frequent discussion has arisen about the black films formed on rocks and stones. These are stated at some length, referring to the sandstone rocks, loose flints, large siliceous nodules, and the granite rocks washed by the Nile. The colour is due to iron and manganese; these are supposed to be dissolved by the dew and brought to the surface by evaporation; but a difficulty is that such colouring is seen on flints which have no

depth to supply the colour. A ground-water source is also stated, and thought probable. The strong tendency of manganese elsewhere to form dendritic crusts, should be considered in this connexion. Another mode of surface action, which is not noticed, is the hardening of limestone superficially, while it crumbles away inside, thus forming a hollow box. Similar internal crumbling—or possibly sea action—is seen in the sentry-box caves formed in the red granite of Sinai. The natron lakes, soda supplies, and soil analyses are also fully dealt with.

There are several other subjects noticed in the 219 pages, and it is clear that there are many matters which need more study, as on scarcely any point is there finally conclusive information. In spite of a bibliography of 912 works, Egypt is still an open field for investigation in many lines, and Dr. Hume obviously would welcome scientific work auxiliary to his department. The facilities of this volume are admirable; the bibliography of 68 pages has a subject index of 10 pages; and the whole 314 pages have a remarkably full index of 94 pages. A geological map on 1:2,000,000 is supplied at the end, and there are half-a-dozen detail maps beside the wealth of photographs. The work bears imprints of 1922, but was delayed in issue until 1925. We hope that we may soon see the next volume, and that the Nile borders may be described as well as the desert.

FLINDERS PETRIE.

Our Bookshelf.

- (1) *The Fundamentals of Statistics*. By Prof. L. L. Thurstone. (Experimental Education Series.) Pp. xvi+237. (New York: The Macmillan Company, 1925.) 8s. 6d. net.
- (2) *Statistical Methods for Research Workers*. By R. A. Fisher. (Biological Monographs and Manuals.) Pp. x+239. (Edinburgh and London: Oliver and Boyd, 1925.) 15s. net.

MODERN statistical methods are now used in such widely different spheres of activity that it is natural that several books on the subject should be produced to meet the needs of the various persons concerned. It is of interest to notice that these books, being of the textbook variety, usually assume an air of certainty with regard to some things which are still almost within the region of controversy. This becomes the more obvious as the subject-matter becomes more advanced.

(1) Turning to the two books before us, we find that Prof. Thurstone has set himself the task of providing an elementary book on statistics for students of psychology who have little mathematical knowledge. The book is about as elementary as it can be, and it assumes that the reader is so poorly equipped as to need to have the graphical expression of a straight line and the most elementary aspect of the binomial series explained. It will, however, enable these non-mathematical students to follow, in a reasonable way, results obtained by others and expressed in terms that would

be meaningless without some help such as this book gives. A good many elementary books of this kind have been published in recent years in the United States, and this is one of the best of them.

(2) Mr. Fisher's book is written for a more advanced type of reader, and it has much to commend it. It treats of the interesting and important subject of small samples in statistical work; it has originality; its author is full of ideas, and its appearance is all that can be desired. But, unfortunately, the book suffers from an introductory chapter which seems unnecessarily hard to follow, and from the difficulty of the subject, which has, we fear, often prevented Mr. Fisher from writing down to his reader. The book is intended for biological research workers, and it is apparently assumed either that they already know sufficient of the theory to accept, without proof, the methods given, or that they will adopt these methods on Mr. Fisher's authority. A statistical "research worker" may be willing to dispense with rigid mathematical proofs when it can be seen from several arithmetical examples that a method carries its own justification, but in the present work the absence of proof goes rather far, and we fear that readers with little knowledge of the most recent statistical work will find the book as a whole difficult to follow, while those unfamiliar with the terms used in biological research work will have trouble with some of the examples.

In many places throughout the book a reader may hesitate, wish perhaps that he could share Mr. Fisher's confident assurance, and then find himself wondering whether deep down under much of the theory about which Mr. Fisher is so sure, there may not lurk the assumption that we can approximate to the whole population from a sample in a way that resembles the theory of "inverse probability" which he "wholly rejects."

It seems to us probable that the book will be read as much by statisticians who wish to study Mr. Fisher's methods and views as by those research workers who merely went to apply the methods he describes. Such readers will find so much that is interesting, suggestive, and useful that they will forgive the weaknesses we have tried to indicate.

The Theory of Electric Cables and Networks. By Dr Alexander Russell. Third edition. Pp. xii+356. (London: Constable and Co., Ltd., 1925.) 24s. net.

WITH the rapid growth of electrical distribution, and the increasing size of networks, the most economical design of the distributing system is becoming more important every year. The third edition of Dr. Russell's well-known book will therefore be welcomed by all engineers who are concerned with cable manufacture or with the business of electric distribution. This edition does not differ very much from the second edition, which was published in 1919, nor is it necessary that it should, for the book deals mainly with fundamental principles.

The tables of standard sizes of wires and cables and of the electrical and thermal constants of materials are of great value, and the discussion in the second chapter of the mechanical and electrical properties of copper is one of the most complete that is to be found in any standard text-book. Equally thorough is the study of insulativity and insulating materials. The treatment

of distributing networks and the determination of the fault resistance of such networks is especially good. The author has himself contributed largely to the technical literature of this subject, and his method of finding fault resistance is well known to all distribution engineers.

Dr. Russell is also a well-known authority on dielectric strength. This subject is of growing interest on account of the higher pressures at which cables are being operated. The heating of cables is discussed, but in any future editions of the book it is hoped that reference will be made to the heating of buried cables and to the extensive researches that have been carried out in recent years under the auspices of the Electrical Research Committee. The chapter on electrical safety valves, also, should include some reference to the lead peroxide arrester, which is now being used so largely in the United States.

The chapter on lightning conductors contains material which is not available except in the *Proceedings* of learned societies, and the new appendix on the interesting problem of the most economical site for a power station is of special value in view of the growing importance, economically, of the electrical aspect of this problem. This book is well known as a standard textbook on the theory of electrical cables and networks, and should be on the shelves of all cable manufacturers and distribution engineers.

The Journal of the Institute of Metals. Vol. 33. Edited by G. Shaw Scott. Pp. xii + 710 + 15 plates. (London: Institute of Metals, 1925.) 31s. 6d. net.

SCIENTIFIC readers of the new volume of this Journal will probably turn first to the May Lecture, in which Prof. H. A. Lorentz deals in a most fascinating manner with the most recent knowledge of the motion of electricity in metals, including the determinations of the velocity of moving electrons in a conductor, and with the phenomena of super-conductivity. The whole lecture is a model of reasoning and exposition. The papers contributed to the Institute cover a wide range, the properties of the various alloys of copper occupying as usual a considerable proportion of the space. Problems of corrosion are dealt with in several papers, and it is satisfactory to notice that the apparently irreconcilable positions taken up by different investigators have now been examined in an impartial spirit, and an agreed statement has been issued, so that further experimental work can proceed without the atmosphere of controversy which has so long enveloped the subject. An important practical paper describes experiments on the production of castings of aluminium alloys with greatly diminished porosity, the method used being to free the alloy from dissolved gases by bubbling nitrogen through the liquid just before solidification, afterwards remelting. The inert nitrogen washes out the gases which give rise to blowholes, and sound castings result. This method has also been applied with success to other alloys. More than half of the volume is occupied by abstracts of work published elsewhere, and this section is invaluable to the metallurgist, the abstracting being done with remarkable thoroughness, so as to include research in pure physics and chemistry wherever it touches metals. The arrangement is clear, and the method of presentation is attractive.

Abbeys. By Dr. M. R. James. With an additional Chapter on Monastic Life and Buildings, by Dr. A. Hamilton Thompson. Pp. x + 154 + 107 plates + 13 plans. (London: Great Western Railway, Paddington, 1925.) 5s. net.

It is only fair to warn the unwary that this book is not a treatise on abbeys in general, or a comprehensive survey of the abbeys of Britain. It deals only with those abbeys which are on or accessible from the Great Western Railway system. There is no hint of this on the title-page, except in the publisher's imprint, which many will not notice. It is, in fact, a glorified guide-book; but a guide-book of a type which we wish were more frequent. Nearly every building is illustrated in one or more photographs, excellently reproduced. In addition, several examples of the priceless manuscripts which were produced by the monks of the abbeys are given in colour. The letterpress of the Provost of Eton is to a great extent, though not entirely, a compilation. As he explains in his preface, he has visited most of the buildings, and to his authorities he has added something of his own. Not only are the buildings adequately explained for the needs of the visitors, but the author has also brought out in each case the relative importance of each and of the community to which it belonged. The list of abbeys classified according to religious orders will be found a great convenience. Prof. A. Hamilton Thompson has contributed an admirable chapter on monastic life. The book is a remarkable production at so low a price.

Summation of Series. Collected by L. B. W. Jolley. Pp. xi + 232. (London: Chapman and Hall, Ltd., 1925.) 13s. 6d. net.

A COMPREHENSIVE collection of series and their sums would be invaluable to the university teacher, the research worker, or the technician, according to the principle guiding the selection, but an attempt to cater for all parties must necessarily spell failure. The present volume, containing about seven hundred series, is well arranged and includes individual types easy of reference. The series are set out clearly on one page, and the sum on the page facing. In spite of the compiler's intentions, we believe the collection will be of value mainly to the not too advanced student. Fourier series, Bessel functions, and elliptic functions are treated in cursory fashion, although quite a number of Fourier series are classified under the heading of trigonometric series. The general expression for Fourier coefficients does not appear to be given. It is eminently desirable that the limits of the variable within which the series is a valid representation of its "sum" should be systematically stated—a dangerous omission if the collection is intended for the use of the technician.

Life: a Book for Elementary Students. By Sir Arthur E. Shipley. Second edition. Pp. xvi + 204. (Cambridge: At the University Press, 1925.) 6s. net.

It is a pleasure to find that Sir Arthur Shipley's little book, which was reviewed in *NATURE* of July 5, 1924, p. 6, has been so much in demand that a second edition has already been called for. A few minor changes have been made.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Selective Action of Polarised Light upon Starch Grains.

IN a recent note (*Annals of Botany*, 39, 651, 1925) Prof. Neilson Jones has criticised our statement (*Proc. Roy. Soc.* 97 B, 250, 1924) that starch grains are selectively hydrolysed by polarised light in the presence of small quantities of diastase. Prof. Jones is under a misapprehension when he says that we accepted the frilling or serration of the grains as evidence of hydrolysis. We did not do so, for what we observed was the complete disappearance of the starch grains when illuminated with polarised light, slight serration only occurring in heterogeneous light. Further, after complete hydrolysis of the starch grains by polarised light, the solution deposited crystals which reduced Fehling's solution.

If Prof. Jones is correct in saying that the serration of the starch grains may be caused by other influences, he removes the last difficulty from our minds, namely, the slight change we observed with heterogeneous light. This may now be attributed to those secondary effects and not to incipient hydrolysis.

As the principal cause of these secondary effects Prof. Jones cites the pressure of the cover slide, but this naturally cannot account for the disappearance of the starch grains and their conversion into crystalline compounds which reduce Fehling's solution.

If any doubt remains on this point, we are now able to say that when starch grains in pure water are placed in a Petrie dish or in a flask and illuminated with a strong beam of polarised light, they are hydrolysed. The breaking down of the grains is obvious when they are examined microscopically, and the aqueous film on evaporation deposits crystals which have been found to reduce Fehling's solution.

Although in our paper we refrained from entering into the theoretical explanation of the phenomenon, it is obvious that it must be connected with a selective absorption of polarised radiant energy by the optically active starch grains. In this connexion, the observations made by Liebisch and Rubens of the different absorptive power for polarised and ordinary infra-red radiation of optically active crystals are of great significance (*Berl. Ber.*, 1919, 198 and 876).

Prof. Jones makes no mention of other observations which confirm our results. These observations may be divided into two classes, namely, those which had been made previously to the publication of our paper and may be explained by our results; and those observations which have been definitely undertaken as the result of our work. Amongst the first group we may quote the work which was carried out by Knauth on the influence of moonlight on the photosynthetic processes of certain plankton. His results are quoted at length by Kofoid (*Bull. Illinois State Labs. Nat. History*, 8, 305, 1908). Knauth found that the relative efficiency of moonlight and sunlight was about 2:9, and Kofoid considers this ratio to be smaller than the maximum and above the average. The relative intensities of sunlight and moonlight were given by Zollner as 618,000:1, and it would seem, therefore, that for equal intensities moonlight is more than

100,000 times as efficient as sunlight. Kofoid followed up this work and established an undoubted correlation between the maxima in the seasonal variation of these micro-organisms and the period of the full moon. This phenomenon may well find an explanation in the fact that moonlight is on the average polarised to the extent of 10 per cent.

As a second example of the well-known influence of polarised light we may mention the peculiarly bad effect on the eyes of the light scattered from a snow field, a phenomenon which is painfully familiar to mountaineers. The high polarisation of such light is well known.

We may also refer to Padoa's observation that crystals of *o*-nitrobenzaldehyde are selectively decomposed by polarised light, provided that the crystals are correctly oriented to the plane of polarisation (*Atti R. Accad. Lincei*, 28, 372, 1919). Other similar phenomena are probably too well known to need mention, such for example as Weigert's observations of the effect of polarised light on the photographic plate.

Of the second group we may quote Morrison's proof of the selective action of polarised light on the growth of luminous bacteria, *e.g.* *Photobacterium phosphorescens* (*Science*, 61, 392, 1925), an observation which has been confirmed by Macht and Hill of the Johns Hopkins University with *B. coli* and *B. typhosus* (*Proc. Soc. Exp. Biol. and Medicine*, 22, 474, 1925). Mention may also be made of Bryant's observation that the polarised light from the moon has a selective action in causing the putrefaction of pieces of fish (*J. Chem. Ind.*, 42, 681, 1924).

Then, again, we may mention the observation by Macht and Hill that the hydrolysis and fermentation of cane sugar by *Saccharomyces cerevisiae* is selectively promoted by polarised light (*Proc. Soc. Exp. Biol. and Medicine*, 22, 474, 1925), and lastly, we have Macht's direct confirmation of our own work (*ibid.* p. 473). In the latter experiments, starch solutions containing definite quantities of taka-diastase were exposed to polarised and non-polarised light. The conversion of the starch into sugar took place more rapidly in polarised light than in non-polarised light of the same intensity, and, as Dr. Macht says, the results he obtained fully corroborate our observations.

Prof. Jones says that he has been unable to repeat our observations, and describes his method of observation with a pointolite lamp. We would suggest that the presence of gelatine in his experiments is very undesirable. If we are correct in our assumption that the phenomenon is due to the selective absorption of polarised radiation, then no other inert colloid must be present, as such may completely interfere with the progress of the particular phenomenon to be observed. If an inert colloid be added, then care must be taken that it does not protect the starch by having the same absorptive power towards radiant energy, and further, that it scatters and polarises radiant energy of the correct wave-length. In short, the extraneous colloid, if it is not in correct tune with the starch and its own particular enzyme, will act as a negative catalyst of the reaction. These correct conditions are undoubtedly secured in the natural enzyme, and it is very questionable whether an entirely foreign colloid such as gelatine conforms to these conditions. This most probably accounts for Prof. Jones's negative results, especially in view of the confirmatory evidence we have previously mentioned.

ELIZABETH SIDNEY SEMMENS.

The University, Liverpool, and
Bedford College, London,
November 6.

The Blindness of Cave-Animals.

It is with much diffidence that I take up my pen to reply to the letter of Sir Ray Lankester, which appears in *NATURE* of November 21. I have been brought up to venerate Sir Ray as the leader of British zoology, and if I cannot claim him as my zoological parent, I can at least regard him as my zoological uncle, for between him and my teacher and friend Adam Sedgwick there always reigned complete sympathy and co-operation.

Sir Ray blames me for having, in a chapter entitled "Zoology" in a book on "Evolution in the Light of Modern Knowledge," come to the conclusion that the inheritance of the results of use and disuse has been the main factor in evolution. He says that this idea is not modern but was put forward by Lamarck a hundred years ago. He also says that he thinks that judgment on the value of Kammerer's experiments should be suspended until they have been repeated, for, as he goes on to say, J. B. S. Haldane points out, that in the past critical repetition of similar experiments has been fatal to the conclusions drawn from them.

Sir Ray then goes on to criticise the theory of inherited disuse as applied to the explanation of the blindness of cave-animals, and to put forward a theory of his own in place of it.

Now I should like to say at once, with reference to Mr. Haldane, that when he thinks fit to publish his criticisms in a recognised scientific journal, instead of in the "Annual of the Rationalist Press Association," which no scientific man is bound to consult and which I, for one, never see, it will give me the greatest pleasure to criticise his criticisms.

As I have pointed out in a review which appears in *NATURE* of November 28, it is not the lack of evidence which has prevented Lamarckian experiments from bringing conviction, but it is the obsession of minds with the Weismannian complex which has stood in the way and which has caused any attempt, however flimsy, to explain Lamarckian results away, to be accepted as disproving them. For a recent example of this spirit I may refer readers of *NATURE* to the issue of June 2, 1923, in which a leading English Mendelian, in endeavouring to discredit the evidential value of Kammerer's celebrated specimen of *Alytes* with the horny pad, says: "but on the palm of *Alytes* they [the horny callosities] would be as unexpected as a growth of hair on the palm of a man." My comment on this statement is that I have preserved in my laboratory the fore-arms of four male frogs—the first four that I looked at—all of which show the extension of the pad to the palmar surface of the hand.

As Sir Ray Lankester, perhaps, has scarcely been able to keep up with the recent literature bearing on this controversy, he is probably unaware that Kammerer's critical experiments, namely, the hanging on to posterity of the effects of the reaction of the skin to coloured surroundings, have been repeated by Durkhen on totally different animals, with the most meticulous care, and that Durkhen's results entirely confirm Kammerer's conclusions. Durkhen's work again has been repeated by Fr. Brecher of Vienna and confirmed.

I am sure that Sir Ray would agree with me that the evidence for evolution is mainly derived from three sources, namely, systematic zoology, palaeontology, and embryology. I find that the most distinguished systematists and palaeontologists are openly accepting the Lamarckian view; as an embryologist, I myself have been driven to it; and when the experiments just alluded to are taken into account, would Sir Ray not admit that the most

modern knowledge on the subject of evolution favoured Lamarck's hypothesis even though that theory was put forward a hundred years ago?

I now come to the special case of the blindness of cave-animals. I am well acquainted with the hypothesis which Sir Ray advances to explain this blindness, namely, that animals with congenital eye-defects stayed in the dark whilst their more gifted brethren escaped into the light. Did I not derive a large part of my early attraction to zoology from Sir Ray's inspiring writings? Nevertheless, I consider Sir Ray's hypothesis unsatisfactory for the following reasons:

(1) The only case in which the cause of blindness in a cave-animal has been analysed is that of the cave-newt, *Proteus*. Here, as Kammerer has shown, the cause of blindness is not congenital defect, but lack of stimulus to growth, for *Proteus* can, under proper conditions, produce a perfectly normal eye. Whatever hesitation may remain about accepting Kammerer's results in other matters, there can be no dubiety about his results on *Proteus*. In common with other zoologists who attended the special meeting of the Linnean Society in May 1923, I saw these large-eyed specimens of *Proteus*, the most wonderful specimens in my judgment which have ever been exhibited to a zoological meeting.

(2) Congenital eye defects, of course, occur, and I believe that before long we shall discover the causes of them. But they are correlated with general weakness and sickness of constitution. Microphthalmic rodents, for example, rarely survive. It is most unlikely that such weakly specimens would give rise to a new species.

Sir Ray says that there is no evidence that the eyes of animals bred in the dark diminish in size, and he cites experiments by Payne quoted by Haldane. Payne bred *Drosophila* for 75 generations in the dark and observed no effect: 75 generations of *Drosophila* would occupy a little over two years. In an article on "The Inheritance of Acquired Characters," contributed to *Science Progress* in 1921, I showed that there was evidence that the eyes of gammarids, which had lived in pools in deserted salt mines in Austria for two hundred years, had undergone definite reduction, and that this reduction was totally unlike what was met with in congenital eye defect.

Carnot's Cycle and Efficiency of Heat-Engines.

THE cycle proposed by Dr. J. S. Haldane (*NATURE*, August 29, p. 326) as a standard of comparison for steam engine performance can be shown quite readily on a temperature-entropy chart, and thus be directly compared with the Carnot cycle and also with the Rankine-Clausius saturated steam cycle, and the relative efficiencies of the three cycles can be viewed at a glance.

Starting first with water at the lower temperature T_2 , heat is added until all the water has been evaporated into steam at a temperature T_1 , and in a closed space. This process is shown on the chart (Fig. 1) as the constant volume line abc , and the heat added is shown by the area $fabce$. Then follows adiabatic expansion represented by cd down to the lower temperature T_2 , and finally isothermal condensation along da , with rejection of heat measured by the area $edaf$.

The efficiency of the cycle is therefore

$$\frac{\text{area } abcd}{\text{area } fabce} = \frac{A}{A+B}.$$

On the ordinary steam temperature-entropy chart, *ag* being the water line, the line *abc* divides the whole area *fagce* into external energy *E* and internal energy *A + B*. The Rankine-Clausius cycle being *ag, gc, cd, da*, its efficiency is $\frac{A+E}{A+B+E}$, and this is obviously greater than the Haldane cycle efficiency, since the area *E* bears a greater proportion to the area *A* than to the area *A + B*.

The Carnot cycle is simply *ah, hc, cd, da*, and its efficiency is $\frac{A+E+D}{A+B+E+D}$, which, for a similar reason, is greater than $\frac{A+E}{A+B+E}$ for the Rankine-Clausius cycle.

As a numerical example, take 1 lb. of water at a temperature of 140° F. corresponding to 3 lb. per sq. in. absolute back pressure, and let this be evaporated into steam at 341° F. corresponding to an absolute pressure of 120 lb. per sq. in.

From steam tables, the total heat in 1 lb. of water at

FIG. 1.

341° F. above 32° F. is 1186 B.T.U., the external energy *E* is 82.1 B.T.U., and latent heat is 874 B.T.U. Hence

$$A + B = 1186 - (140 - 32) - 82.1 = 995.9 \text{ B.T.U.}$$

To find area *B*, first calculate *ad* or ϕ_2 .

$$\phi_2 = \log_e \left(\frac{341 + 460}{140 + 460} \right) + \frac{874}{341 + 460} = 1.3803.$$

Thus

$$\text{area } B = 600 \times 1.3803 = 828.18 \text{ B.T.U.}$$

and

$$\text{area } A = 995.9 - 828.18 = 167.7 \text{ B.T.U.}$$

The efficiency is therefore $\frac{167.7}{995.9} = 16.7$ per cent.

For the same data, the Rankine-Clausius efficiency is

$$\frac{A+E}{A+B+E} = \frac{167.7 + 82.1}{995.9 + 82.1} = 23.1 \text{ per cent.},$$

and the Carnot efficiency

$$= \frac{A+E+D}{A+B+E+D} = \frac{ah}{fh} = \frac{801 - 600}{801} = 25 \text{ per cent.}$$

The chart is drawn approximately to scale for the above data. The higher efficiencies of the two last-named cycles are simply due to the addition of a large proportion of heat at the higher temperature. The Haldane cycle omits this and is therefore of lower efficiency.

The London Skull.

IN his most interesting article on the London Skull, in NATURE of November 7, Prof. G. Elliot Smith states that "The deposit in which the human remains were found forms part of the third (or lowest) terrace of the Thames containing the characteristic late Pleistocene fauna . . . presumptive age [of the skull] must be assumed to be later than the Mousterian phase of culture."

On the Geological Survey Maps (one-inch sheet 256 North London; six-inch London 7 SE) the site is shown as Middle Terrace. In the memoirs dealing with the area it is stated that this terrace has yielded late Acheulian types of implements, and that from its surface, overwhelmed by Coombe Rock or Trail, numerous Mousterian implements have been found above, in, and below London. Moreover, the various mammals mentioned by Prof. Elliot Smith as occurring at the Leadenhall Street site are mentioned among those found in this terrace ("Geology of the London District," 2nd ed., 1922, pp. 49-70; "Geology of North London," 1925, pp. 41-49).

If this view of the age of the deposits in which the skull was found is correct, its Neanderthal character, so far from suggesting "the possibility of the survival into Aurignacian times (in Britain) of a stray representative of the species *neanderthalensis*," is quite normal. Being responsible for the maps and memoirs alluded to, I should be glad to know on what grounds Prof. Elliot Smith assigns the deposit to the Low Terrace instead of the Middle, thereby involving himself in a difficulty as to the human species represented by his skull.

C. N. BROMEHEAD.

Geological Survey Office,
14A Parliament Street,
York.

I AM very grateful to Mr. Bromehead for directing my attention to the evidence for identifying the London Terraces. In reply to his query on what grounds I assign the deposit at Lloyd's to the Low Terrace instead of the Middle, I can only say that I have never claimed any competence to decide the geological points at issue; but, as I have already stated in public and in print on several occasions, have taken the opinions expressed when the ulna of the woolly rhinoceros (from the same level in the blue clay at Lloyd's) was exhibited at a meeting of the Zoological Society last March.

The decision of the age of the deposit, concerning which several geologists have written to me, has become of such crucial importance that last week the matter was referred to Prof. Boswell for his advice.

I need scarcely say that if Mr. Bromehead's opinion (which in private correspondence Prof. Sollas and Mr. Reid Moir had already suggested to me) should prove correct, it will facilitate my task of interpretation. For the London skull conforms much more nearly to the Neanderthal type than to the form that is usual in *Homo sapiens*. The fulness of the cerebellum, however, is in sharp contrast with the flattened Neanderthal type. The cranium is as thin as that of a modern woman's. In this respect, however, it agrees with the Neanderthal cranium found in 1911 at La Quina. Moreover, as Prof. Wingate Todd has pointed out (*Anat. Record*, vol. 27, 1924, p. 245), thickness of skull is so variable a feature as to have no decisive value as a specific criterion. Hence the points of difference between the London skull and the Neanderthal type are not necessarily significant. So that, if the blue clay can be shown to

be associated with the Mousterian phase of culture, the anatomical evidence can be interpreted more easily than would be the case if the deposit is Aurignacian.

The paradoxical evidence provided by the anatomical features of the skull renders the determination of the geological age a matter of fundamental importance. Hence Mr. Warren Dawson and I have taken the advice of many authorities in the hope of deciding this issue. Since this letter was written, Mr. Hinton, who examined the remains of the woolly rhinoceros and mammoth from the Lloyd's site last March, has again assured Mr. Dawson that "the blue clay in London is quite definitely post-Mousterian."

G. ELLIOT SMITH.

The Collection of Bryophytes by Scientific Expeditions.

MAY I ask the publicity of your columns for a matter concerning a rather limited branch of natural science, but one which we desire to ventilate as widely as possible in scientific circles?

The following resolution, passed unanimously at the annual meeting of the British Bryological Society held at Ross in August last, to a great extent explains itself:

"That it is desirable that in any future scientific expeditions promoted by British or Colonial public bodies, special attention should be given to the collection of bryophytes, the determination of which should be entrusted to British botanists."

The necessity for such a resolution arises from the fact that in most recent scientific expeditions bryophytes have received the scantiest attention or none at all. As an example may be cited the Mt. Everest Expedition, 1924. Although a special request was made that attention might particularly be paid to the collecting of bryophytes, not a single specimen was brought back by the official scientific staff, although at the altitudes at which most of the encampments were made it was obvious that cryptogamic plants might be expected to form far the highest percentage of the vegetation. This is evidenced by the fact that a certain number of cryptogams were individually collected by one of the climbing members of the expedition, and privately transmitted home, and these proved of great scientific interest (*cf. Journ. of Bot.*, 1925, pp. 189, 221)—including a moss from considerably the highest altitude from which any moss has hitherto been collected.

A recent scientific expedition to Australia, the West Australian and Islands Expedition, under Capt. Wilkins, sent out under the auspices of several of the principal scientific institutions and societies of Great Britain and Australia, returned with but a single example of the lower cryptogamous plants—a block of fossil diatomaceous earth. Bryologists have repeatedly the tantalising experience of hearing from returned explorers of the wealth of bryophytic vegetation traversed by them—lantern slides being sometimes especially prepared, for their particular delectation or exasperation, to illustrate the "dense masses of arboreal mosses" through which an expedition passed—only to find that among the botanical collections brought home the bryophytes are conspicuous by their absence.

The older botanical explorers knew better—Hooker in the Antarctic, Spruce on the Amazon, Schweinfurth in Africa, Wallich in Asia, and a host of others—and our knowledge of the world flora and of the factors of geographical distribution has been vastly increased thereby.

The facility of their collection further justifies our claim, since no plants demand less in the way of space or preparation. They simply require drying; and they may be usefully employed in filling up interstices and acting as packing for other specimens.

These arguments might easily be multiplied, but they would make a further demand on your space which would be, I fear, undue, and I hope superfluous.

Northampton.

The London Zoological Society's Aquarium.

IN NATURE of November 21, p. 767, in a report of the recent ornithological meeting in Berlin, "E. H." states that the Berlin Aquarium was "the model from which the larger London Aquarium has been built." This is entirely erroneous. Certainly we knew of and had inspected the Berlin Aquarium as well as many others whilst making our plans, but I do not know of any single feature, either mechanical or decorative, which we based on the Berlin Aquarium.

P. CHALMERS MITCHELL.

Zoological Society of London,
London, N.W.8,
November 23.

I AM glad Dr. Chalmers Mitchell corrects an error in my report. I understood that Mr. Boulenger had thoroughly inspected and measured the tanks in Berlin, which to me looked very much like those in the London Aquarium—but as I am not an expert on aquariums, I should not distinguish differences very clearly, and would notice similarities in all modern institutions of that kind. I have never had any doubt that the London Aquarium has great improvements on all others, as it is natural to improve on former establishments of the kind, when building a new one, by making use of the experience of others.

E. H.

Cyclops robustus, G. O. Sars.

Cyclops robustus is given by Prof. Sars as one of the rarer species, and to the best of my knowledge it has not been recorded previously for the British Isles.

Last July several specimens occurred in some tubs outside the biological laboratory at Marlborough College. The tubs in question are kept for the refuse from pond-life study. Some time afterwards, as the result of a fairly prolonged search, several ponds were found in Savernake Forest containing this species.

The reason why this species has not been recorded in the British Isles before must be, I think, that it has been overlooked on account of its resemblance to *Cyclops lucidulus*, Koch. That *Cyclops robustus* is really widely distributed in the British Isles is almost certainly proved by the fact that I found it so far north as Roineval in the Isle of Skye in September last.

It is interesting to note that Prof. Sars in "Crustacea of Norway" (vol. 6, p. 46) states that he has only found this species, in Norway, on the borders of the larger lakes. I have only found it in quite small ponds, if not puddles, especially those containing Sphagnum. Dr. W. Arndt has also found it in ponds in Bulgaria (*Zool. Anzeiger*, vol. 61, p. 298), though his specimens seem to differ somewhat from the original type.

The Nature of Man's Structural Imperfections.¹

By Sir ARTHUR KEITH, F.R.S.

I.

BETWEEN the activities of Archdeacon Paley and those of Élie Metchnikoff lies the greater part of the nineteenth century. At the beginning of that century we find the Archdeacon extolling the perfections of the human body—just as Celsus had done sixteen centuries before him.² By the close of the nineteenth century the alert and fearless brain of Élie Metchnikoff had discovered, or believed it had discovered, that the human body was blemished by many imperfections. The evangelist of this new and startling doctrine approached the study of man's body by an untrodden pathway, one made possible by the advancing science of his day. On his arrival at the Institut Pasteur in 1888, being then forty-three years of age, he set himself to investigate the means by which the human body combats and keeps at bay the swarming hosts of micro-organisms which find a natural habitat in its internal passages and recesses. He saw man's body as a battlefield—the scene of a perpetual warfare—and as his investigations proceeded, the conviction grew on him that the chances of the body's success were imperilled by a heritage of structures which had become out-of-date and useless. In the Wilde Lecture given before the Literary and Philosophical Society of Manchester, on April 22, 1901, he declared that man "was being killed by his intestinal flora," and that his great intestine had not only become useless but was also a positive and continual menace to the rest of his body. He believed that the stomach itself, and also part of the small intestine, could be dispensed with. Early in 1903 appeared "*Études sur la nature humaine*,"³ in which Metchnikoff greatly extended the list of man's structural imperfections.

Between the times of Paley and of Metchnikoff lie three great discoveries, and we must take note of them if we are to understand how it was possible for one to praise the perfection of man's structure at the beginning of the nineteenth century and the other to condemn its imperfections at the end. There was first the discovery that man's body was an aggregate or society of living microscopical units; it was Metchnikoff's fortune to approach the study of man's highly complex body through the simpler societies represented by the bodies of the lower invertebrates; it was thus he came by his discovery that certain units of such societies retain their freedom, thus permitting them to serve as scavengers or phagocytes. In the second place, there was Darwin's discovery; Metchnikoff was a convinced evolutionist. He therefore presumed that the alimentary outfit which served in an anthropoid phase of human evolution must be ill-adapted to deal with the dietary of civilised man. There was in the third place Pasteur's discovery, and so far as Metchnikoff's outlook was concerned, this was the most potent of the three. It was under the influence of Pasteur's discoveries that Metchnikoff came to think that the destiny of man lay in the issue of the everlasting contest which went on

between the living tissues of his body and the invading hosts of micro-organisms which threatened them. It is noteworthy that of the three men—Darwin, Pasteur, and Metchnikoff—who revolutionised in the 19th century our conception of man's body, and of the struggles to which it is subjected, not one of them was a professed anatomist; the anatomist stood too near to the subject of his study to see it in its true perspective.

Twenty-two years have come and gone since Metchnikoff's studies on "*La nature humaine*"⁴ first appeared, and I propose in this lecture to ascertain how far his doctrines of man's structural imperfections and functional disharmonies have stood the test of time. His thesis presumed that Darwin's theory of man's origin was true; that presumption has been supported by every discovery of the present century, and such evidence as we now have justifies us in believing that the rate of man's evolution has been more rapid than has hitherto been supposed.⁵ We realise to-day, more precisely than was possible when Metchnikoff wrote, that the most critical chapter in man's long history opened with the discovery of agriculture, a discovery of but yesterday if we reckon time on a geological scale. Agriculture revolutionised the conditions of human life; it made modern civilisation possible. We have reason to believe that this revolution in the condition of man's life was initiated either in Mesopotamia, Egypt, or adjacent lands not more than 8000 years ago. It is certainly not more than 5000 years ago since agriculture began to be practised in Western Europe. The vast majority of the people of the British Isles, probably 90 per cent. of them, are the descendants of men and women who, 200 generations ago, were dependent on the natural but precarious harvest which is provided by shore, river, forest, and moorland. City life is a new experiment for Europeans; most of us who live in London, if we could go back twenty generations, would find an ancestry which was living on the soil and of the soil; and now the poorest of us can add to our dietary produce brought from the ends of the earth. The alimentary system which was evolved to meet the needs of our primitive ancestors has now to accommodate itself to a modern dietary.

Beyond a doubt civilisation is submitting the human body to a vast and critical experiment. It is not only the alimentary system which is being subjected to new conditions; the bony and muscular framework of our bodies are also being subjected to novel stresses. Of the present manhood of Britain, half earns its bread by muscular labour; the other half lives sedentary lives. Our forefathers when they arrived in Western Europe were hunters; their bodies were unaccustomed to either manual labour or an indoor life; under the

¹ In 1907 Metchnikoff published a further work, of which an English translation appeared in the same year, edited by Dr. P. Chalmers Mitchell, under the title "*The Prolongation of Life*". In this Metchnikoff replied to his critics and produced more evidence in support of his thesis. Sir W. Arbuthnot Lane formed the opinion that the great intestine was a useless and dangerous structure independently of Metchnikoff; so also did Prof. Barclay Smith (see an article on the nature of the caecum and appendix by the present lecturer in the *Brit. Med. Journ.* 1912, vol. 2, p. 1599).

² See "*The Adaptational Machinery concerned in the Evolution of Man's Body*," *NATURE* (Special Supplement), August 18, 1923, p. 257; and "*Concerning the Rate of Man's Evolution*," *NATURE*, August 29, p. 317.

³ The Lloyd Roberts Lecture delivered to the Royal Society of Medicine on November 16.

⁴ See "*Evolution of Anatomy*," by Dr. Charles Singer (1925), p. 50.

⁵ An English translation, edited by Dr. P. Chalmers Mitchell, was published in 1904 under the title "*The Nature of Man*" (Hememann).

stress of civilisation the hunter's body has to serve modern needs. It says much for the adaptability of the human body that it stands these stresses so well as it does. Dr. J. D. Comrie,⁶ on examining 10,000 recruits for the army, found that 363 of them suffered from hernia and 113 from flat foot. Such breakdowns in the supporting system of the body do not occur with this frequency among hunting peoples. Civilisation has laid bare some of the weak points in the human body, but the conditions which have provoked them are not of Nature's ordaining but of man's choosing.

If modern civilisation is making new demands on our bones, muscles, and nerve controls, it is otherwise with another important system of our bodies. As our manner of living increases in comfort, the calls on our heat-regulating mechanism become fewer in number and less urgent in character. Our primitive forefathers lived in the open; their bodies, unhoused and scantily clad, were exposed to sun, rain, wind, and storm. Such a mode of life throws an increasing burden on the machinery which regulates body temperature—on skin, on respiratory mucous membrane, and on that elaborate system of reflexes which control the rate of internal combustion. Modern civilisation, so far as temperature is concerned, tends to make the human body a hot-house plant.

Metchnikoff perceived that civilisation had plunged man's body into a new environment, and that the rate of its progress had far outstripped the power of adaptive response which had carried man so far beyond the anthropoid stage. A belief grew within him—almost a grudge—that Nature was letting man down. He brought against the evolutionary powers which preside over the destiny of man both sins of omission and sins of commission. We shall deal with a sample of each. The first complaint on his list of omissions is that we have not shed from our skins the last remnants of an anthropoid pelage; hair on the body, he held, was useless and a source of disease. Whether or not a completely hairless body is desirable we may leave as a moot point; a hairless breed of dogs has been produced and no doubt a hairless race of man could be evolved. In this matter the Caucasian has been outstripped by the Negro and by the Mongol, the most hairless of races. It is more to the point to inquire how man has come by a comparatively hairless skin, and in the solution of this problem we have been making some advance. A hairless condition became possible with the evolution of the higher vertebrates; a foetus in the womb draws its heat from the mother's body; it has no need of a hairy covering until the period of birth arrives. There is in the Museum of the Royal College of Surgeons of England a chimpanzee foetus in the eighth month of development; the hair of its head and body has reached a stage identical with that of a newly-born child. A stage of development which is evanescent in the foetal anthropoid has become permanent in us. We have come by a new character through the inheritance of one evolved in foetal life. Many of our structural features have come to us in this way.⁷ The base of the human skull is greatly

flexed. In the foetal stage of all mammals the basicranial axis is bent, but in man only has this character been carried into adult years. Foetal inheritance becomes more and more possible for man because civilisation tends to make man's world into a protective womb.

As an example of a sin of commission, the introduction of a new and useless structure to the human body, Metchnikoff cites the case of the hymen. It is scarcely true to describe, as he does, the hymen as a new structure; it is present at a certain stage in the embryonic life of every higher mammal; it is only in the human species that it persists and forms a definite and substantial structure in the fully formed body. The hymen provides another example of the human body coming by a new character by retaining and modifying a structure which made its first appearance during embryonic or foetal life. When we seek to explain its use we must enter the purview of psychology, for round man's sense of sex has grown up a strange hinterland in his subconscious mind. Metchnikoff described the hymen as "an unpleasant impediment," but love, as the world has long recognised, thrives on impediments. The human prepuce, although not a new structure, was, in Metchnikoff's opinion, a useless and dangerous one; circumcision in one generation does not diminish the completeness of its development in the next. In this the prepuce resembles the hymen. Indeed, Metchnikoff said of the latter structure that the only purpose it had ever served was "the overthrow of the dogma of the inheritance-acquired characters."

The examples which I have cited above of the failure of man's body to adapt itself to present requirements are of little more than academic interest, but when Metchnikoff applied his analytical genius to the problems of man's alimentary system, he carried us into the realms where thought becomes the guide to action. "It would be no longer rash to say," so he wrote in 1903, "that not only the rudimentary appendix and the caecum, but the whole of the human large intestine are superfluous and that their removal would be attended with happy results." Since Metchnikoff penned this sentence, the operation of complete colectomy has been performed on many thousands of men and women, but I do not think that even the surgeons who have performed this operation most frequently and most successfully would maintain that a man or woman who has been rendered colonless enjoys that moderate share of health which falls to the average intact individual. If a finger becomes permanently fixed in an awkward position, the hand is improved by the amputation of the offending digit, but the relief thus gained does not restore the hand to its original capacity. The relief afforded by colectomy is of the same kind; the results of that operation in no wise bear out Metchnikoff's doctrine that the colon has become a superfluous organ in man's body. On the other hand, we have only to consult the pages of the medical press, to listen to tales which reach our ears daily, to note the ever-growing demand for patent purgatives, to be convinced that there is, as Metchnikoff maintained, a grave disharmony between the functional capacities of our great intestine and the dietary which modern civilisation has compelled us to adopt. The way out of our difficulties is not to call the colon a useless organ.

⁶ *Lancet*, 1910, 2, p. 959.
⁷ Prof. Louis Bolk, "The Part played by the Endocrine Glands in the Evolution of Man," *Lancet*, 1921, vol. 2, p. 588. See also Keith, "The Evolution of Human Races in the Light of the Hormone Theory," *Johns Hopkins Hospital Bulletin*, 1922, vol. 33, p. 195.

a "sewage pipe," a "cesspool," but to discover its original purpose and ascertain how far we can modify our mode of living to suit its inherited capacity. What that capacity is we have yet to discover, for we have no complete or exact knowledge of the uses of the great intestine in any animal whatsoever. So far as the human organ is concerned, surgery has stepped far in advance of physiology.⁸

Since Metchnikoff first promulgated his belief that the appendix, cæcum, and colon had become superfluous organs in man's body, our knowledge concerning the evolution of these structures, and of certain conditions which regulate their action, has increased. That increase of knowledge rehabilitates the ancient belief that Nature in her evolutionary mood exercises not only a surprising ingenuity but also the strictest economy. The ferments and catalysts elaborated by plants for their own use were made to serve in the animal body as vitamins. How necessary such substances are for the proper working of the great bowel has been shown by the recent researches of McCarrison⁹ and of Cramer.¹⁰ It was for the purposes of economy that the great bowel came into existence. In fishes, the earliest vertebrate forms known to us in the living state, potent digestive juices have to be produced at the expense of body tissues; with the evolution of land-living, air-breathing forms, much of this expenditure was saved by the utilisation of bacterial digestion. The great bowel was added to the original intestine for this purpose, the oldest part of this annex being the cæcum and appendix. The great bowel as we know it in fishes is a mere diverticulum from the

hinder end of the gut; it takes no part in the digestion of food. Its epithelium forms a glandular structure which has all the appearance of an organ designed for the supply of an internal secretion.¹¹ That secretion, whatever it may prove to be, is carried to the liver by the inferior mesenteric vein.

In the mucous membrane of the human great bowel, there are embedded in a stratum of reticular tissue—of reticulo-endothelium—some 15 millions of minute test-tube glands—the glands of Lieberkühn. No one who has noted the structure and setting of these glands, and the fine changes which their cells undergo in the course of action, can believe that their sole function is to supply a lubricating fluid for the intestine; they have all the appearance of also supplying an internal secretion, and the evolutionary history of the colon favours such an inference.¹² The reticular stratum of the colon, which Dr. Scott Williamson¹³ regards as the most important constituent of its mucous membrane, and in this I agree with him, represents a spleen of considerable size. Indeed, just as the liver and pancreas represent extrusions of highly specialised parts of the intestinal epithelium, the spleen represents a specialisation of the reticulo-endothelium of the alimentary canal; in cyclostomes¹⁴ the spleen is still intra-intestinal. Nor must we forget how greatly the large intestine is linked to the central nervous system—both by afferent and efferent pathways. When we take all these considerations into account, we must conclude that the great bowel of man is not a useless or superfluous organ, but one which we, in our ignorance, are maltreating.

(To be continued.)

High Frequency Rays of Cosmic Origin.¹

By Dr. R. A. MILLIKAN,

Director of the Norman Bridge Laboratory of the California Institute of Technology, Pasadena.

IT was so early as 1903 that the British physicists, Rutherford and McLennan, noticed that the rate of leakage of an electric charge from an electroscope within an air-tight metal chamber could be reduced by enclosing the chamber within a completely encircling metal shield or box with walls a centimetre or more thick. This meant that the loss of charge of the enclosed electroscope was not due to imperfectly insulating supports but must rather be due to some highly penetrating rays, like the gamma rays of radium, which could pass through metal walls as much as a centimetre thick and ionise the gas inside.

In view of this property of passing through relatively thick metal walls in measurable quantity, the radiation thus brought to light was called the "penetrating radiation" of the atmosphere and was at first quite naturally attributed to radioactive materials in the earth. But in 1910 and 1911 it was found that it did not decrease as rapidly with altitude as it should upon his hypothesis. The first significant report upon this

point was made by a German physicist, Gockel, who took an enclosed electroscope up in a balloon with him to a height of 13,000 feet and reported that he found the "penetrating radiation" about as large at this altitude as at the earth's surface, despite the fact that Prof. Eve, of McGill University, had calculated that it ought to have fallen to half its surface value in going up 250 feet.

In 1912-14 two other German physicists, Hess and Kohlhorster, repeated these balloon-measurements of Gockel's, the latter going to a height of 9 km., or 5.6 miles, and reported that they found this radiation decreasing a trifle for the first two miles and then increasing until it reached a value at 9 km., according to Kohlhorster's measurements, eight times as great as at the surface.

This seemed to indicate that the penetrating rays came from outside the earth, and were therefore of some sort of cosmic origin. The War put a stop to the world over to further studies of this sort, but so soon as we could get the proper instruments built after the War in the newly equipped Norman Bridge Laboratory of Physics, I. S. Bowen and myself went to Kelly Field,

¹ Address delivered before the National Academy of Sciences, Madison, Wis., U.S.A., on November 9.

near San Antonio, Texas, with four little recording electroscopes which we succeeded in the spring of 1922 in sending up in sounding balloons to almost twice the heights which had previously been attained. The highest flight reached the altitude of 15.6 km., or nearly 10 miles.

These instruments were interesting in that, though they were built to hold 300 cubic centimetres of air at 150 pounds pressure, and were provided each with a recording barometer, thermometer, and electroscope, also with three different sets of moving photographic films and the necessary driving mechanism, the total weight of the whole instrument was yet but 180 grams, or about 7 ounces.

In these experiments we expected, if the results previously reported were correct, to find very large rates of discharge; for our instruments went up to such heights that nine-tenths of the atmosphere had been left beneath them, and only one-tenth was left to cut down, by its absorption, the intensity of the hypothetical rays entering from outside. The results were contrary to this expectation. They proved conclusively, however, in agreement with the observations of Hess and Kohlhorster, that the penetrating radiation was greater at great altitudes than at the surface, but that the amount of the increase was not more than a fourth of that predicted from the results of the German observers. (Two years later they reduced their estimates, after further experiments, so that they were no longer in conflict with our measurements.)

VARIATION OF ABSORPTION WITH ALTITUDE.

Since the origin of the rays was still uncertain, with indications in favour of some cosmic source, Dr. Russell Otis and myself felt that the next step was to find out how penetrating the rays were; and since they were weaker at the surface than higher up, we went to the top of Pike's Peak in the summer of 1923, carrying up 300 pounds of lead and a big 6 ft. $\times$ 6 ft. $\times$ 6 ft. water tank for the sake of making absorption measurements on such rays as were found at that altitude.

We found that though our electroscopes discharged twice as fast on Pike's Peak as at the altitude of Pasadena, the rays were cut down so fast by our absorbing screens that it was certain that the greater part of them were not much, if any more, penetrating than the ordinary gamma rays emitted by radium. We found, further, that the rate of discharge of our electroscope was decreased by 10 per cent. by a heavy snowstorm which occurred during the week in which we were on the peak. This showed conclusively that the chief part, at least, of the rays with which we were experimenting on the peak were of local origin, and that they might be due to radioactive matter which in some unknown way got into the upper regions of the atmosphere.

The search for the cause of the increase with altitude in the intensity of these soft gamma-like rays became, therefore, quite as interesting as the question of the existence of a very penetrating radiation of cosmic origin, since this latter would produce at the most but a fraction, and no large fraction either, of the observed increase between Pasadena and Pike's Peak. Mr. Harvey Cameron and I therefore planned experiments for the summer of 1925 which were designed (1) to

settle definitely the question of the existence or non-existence of a small, very penetrating radiation of cosmic origin, and (2) to throw light on the cause of the variation with altitude of the softer radiation of the gamma ray type which we had found more than twice as intense on Pike's Peak as at Pasadena.

HIGH PENETRATING POWER.

To bring to light the very penetrating radiation, if it existed, it was necessary to find at very high altitudes very deep snow-fed lakes, for any radioactive contamination of the water through its seepage through the earth would vitiate the results obtained by sinking electroscopes to different depths beneath the surface of the lake.

We chose for the first experiment Muir Lake (11,800 feet high), a beautiful body of water hundreds of feet deep just under the brow of Mount Whitney, the highest peak in the United States. Here we worked for the last ten days in August, sinking our electroscopes to various depths down to 60 feet. Our experiments brought to light altogether unambiguously a cosmic radiation of such extraordinary penetrating power that the electroscope reading kept decreasing down to a depth of 45 feet below the surface. The atmosphere above the lake was equivalent in absorbing power to 23 feet of water, so that we had found rays, coming into the earth from outer space, so penetrating that they could pass through 45 plus 23 equalling 68 feet of water, or the equivalent of 6 feet of lead, before being completely absorbed. This represents rays much harder (more penetrating) than any which had before even been imagined. The most penetrating X-rays which we produce in our hospitals cannot go through half an inch of lead. Here were rays originating somewhere out in space at least a hundred times more penetrating than these.

Further, high penetrating power means, according to modern physics, simply high frequency or short wave-length. Our experiments indicate, then, that there is a region of frequencies as far up above the X-ray frequencies as are these latter above the frequencies of light waves. They show quite definitely, too, that these highest frequency rays are not homogeneous, but have a measurable spectral distribution, the shortest waves which we observed being a little less than twice the frequency of the longest, for the rays which we actually observed in Muir Lake changed hardness or frequency as they were filtered through greater and greater thicknesses of water, just as X-rays are successively hardened by passing through successive layers of lead. The experiments with the sounding balloons indicate that the frequencies of these cosmic rays do not extend over into the X-ray region of frequencies, else we should have obtained larger discharges in the experiments with sounding balloons when nine-tenths of the atmosphere had been left beneath us.

Further, we obtained good evidence that these cosmic rays shoot through space in all directions, this evidence being found in the fact that we could observe no change whatever in their intensity throughout day or night.

All the results obtained in Muir Lake were checked with wonderful completeness by another set of observa-

tions in another snow-fed lake—Arrowhead Lake—300 miles away from Muir, 7000 feet lower, and equally deep, where the Arrowhead Lake Development Company kindly put all their facilities at our disposal. Indeed, the absorbing power of the atmosphere between the elevations of Muir and Arrowhead Lakes is the equivalent of about two metres of water, and as a matter of fact, every reading in Arrowhead was practically identical with one taken in Muir at a depth two metres lower.

ORIGIN OF HIGH FREQUENCY RAYS.

We can draw some fairly reliable conclusions as to the origin of these very penetrating and very high frequency rays. The most penetrating rays that we have known anything about thus far, the gamma rays of radium and thorium, are produced only by nuclear transformations within atoms. This means that they are produced by the change of one atom over into another atom, or by the creation of a new type of atom. It is scarcely possible, then, to avoid the conclusion that these still more penetrating rays which we have here been studying are produced similarly by nuclear transformations of some sort. But these transformations must be enormously more energetic than are those taking place in any radioactive changes which we know anything about. For the frequency of any emitted ray is, according to our present knowledge, proportional to the energy of the subatomic change which gives birth to it. We can scarcely avoid the conclusion, then, that nuclear changes having an energy value perhaps fifty times as great as the energy changes involved in observed radioactive processes are taking place all through space, and that signals of these changes are being sent to us in these high frequency rays.

The energy of the nuclear change which corresponds to the formation of helium out of hydrogen is known, and from it we have computed the corresponding frequency and found it to correspond closely to the highest frequency rays which we have observed this summer. The computed frequencies of these rays also correspond closely to the energy involved in the simple capture of an electron by a positive nucleus. It is possible that this phenomenon is actually going on all through space. This is, I think, the most probable source of these rays. It is true that the formula underlying this computation of the frequencies of these rays from their absorption coefficient is of uncertain validity. It is a formula, nevertheless, that works well in the frequency range in which we can get independent checks upon it, namely, in that of the X-ray field and the gamma ray field.

According to this formula, the wave-length of the shortest waves which we have here investigated is 0.0004 Ångströms, or but one-fiftieth of that of the hardest gamma rays heretofore known, and but one-tenth millionth that of ordinary light. The longest wave-length which we have found is about five-thirds of the shortest, or 0.00067 Ångströms.

When these extraordinarily high frequency rays strike the earth, according to the now well-established Compton effect, they should be transformed partially into soft scattered rays of just about the hardness, or the wave-length, of the soft rays which we have

actually observed on Pike's Peak and Mount Whitney. The reason these soft rays were more plentiful on the mountain peaks than at Pasadena would then be found simply in the fact that there are more than twice as many of the hard rays to be transformed at the altitudes of the peaks than at that of Pasadena. This seems to be the solution of the second of our summer's problems.

But how can nuclear transformation, such, for example, as the formation of helium out of hydrogen or the capture of an electron by a positive nucleus, be going on all through space, the resulting rays coming apparently as much from one direction as from any other, and certainly not a whit more plentifully from the direction of the sun than from that diametrically opposite to it, as evidenced by the entire equality of our midday and midnight observations? The difficulty is not so insuperable, in view of the transparency even of large amounts of matter for these hard rays, combined with Hubble's recent proof at the Mount Wilson Observatory that some of the spiral nebulae are at least a million light years away. The centres at which these nuclear changes are taking place would then only have to occur at extraordinarily widely scattered intervals to produce the intensity of the radiation observed at Muir Lake.

The only alternative hypothesis to that above presented, of high frequency rays traversing space in all directions, might seem to be to assume that the observed rays are generated in the upper layers of the atmosphere by electrons shooting through space in all directions with practically the speed of light. This hypothesis might help in interpreting the mysterious fact of the maintenance of the earth's negative charge, but it meets with insuperable obstacles, I think, in explaining quantitatively the variation with altitude of the ionisation in closed vessels. In any case, this hypothesis is, in its most important aspect, very much like the one represented above, for it, too, fills space with rays of one sort or another travelling in all directions with the speed of light. From some such conception as this there now seems to be no escape. Yet it is a conception which is almost too powerful a stimulus to the imagination. Prof. MacMillan, of Chicago, will wish to see in it evidence for the condensation into matter, out somewhere in space, of the light and heat continually being radiated into space by the sun and stars, and the psychists will be explaining all kinds of telepathic phenomena by it.

In any event, our experiments seem to point to the following conclusions:

- (1) That these extraordinarily penetrating rays exist;
- (2) That their mass absorption coefficient may be so high as 0.18 per metre of water;
- (3) That they are not homogeneous, but are distributed through a spectral region far up above X-ray frequencies—probably 1000 times the mean frequencies of X-rays;
- (4) That these hard rays stimulate, upon striking matter, softer rays of about the frequency predicted by the theory of the Compton effect;
- (5) That these rays come into the earth with equal intensity day and night and at all hours of the day or night, and with practically the same intensity in all directions.

Current Topics and Events.

SOME progress is being made with the unifying of the electric supply undertakings in Great Britain, and electricians are beginning to look forward to larger generating stations and higher electric pressures of distribution. This is reflected by the activity of research in connexion with the dielectrics of cables for use with very high pressures. Both the Institution of Electrical Engineers and the Junior Institution of Engineers have discussed papers on this subject this year. In both these papers the progressive nature of a breakdown when it occurs is emphasised. There seems, however, to be some confusion as to what physicists mean by the electric strength of a homogeneous dielectric. This electric strength varies with temperature and mechanical pressure. The so-called "time lag" before the insulating material breaks down is due to the fact that its temperature is gradually rising and its electric strength is therefore diminishing. A spark or a brush discharge occurs when the electric strength becomes less than the maximum applied electric stress. To attempt to express "time lag" by a formula seems to us to be waste of time. There are many miles of 33,000-volt cable in use in Great Britain and some of them have been in uninterrupted operation for more than six years. Mr. Emanuelli of the Pirelli Cable Company said that a cable had been in successful operation in Italy for eighteen months at 130,000 volts. He attributed its successful operation to the fact that air and gas bubbles had been entirely eliminated from the insulation. The manufacture of cables which will withstand these enormous pressures is a very considerable step in advance, and, provided that the price is reasonable, it will affect very appreciably the trend of the development of electrical supply all over the world. The cost of the transmission cables in any large scheme of electricity supply is always the major part of the capital cost. As raising the pressure largely reduces this cost, it will cheapen the supply to the public.

THE problems of transport in tropical Africa, especially in relation to cotton-growing, are discussed in a memorandum prepared by the Mechanical Transport Sub-Committee of the Empire Cotton-growing Corporation. After a general survey of means of transport, it is pointed out that transport facilities are unlikely to develop along the same lines as in Great Britain. A network of branch railways or of modern macadamised roads is out of the question in the great spaces of thinly inhabited and sparsely cultivated Africa. Even if the volume of traffic warranted the construction of good roads, their upkeep would be prohibitive in regions of torrential rain. In the belief that for many years to come the roads in Africa will be unmetalled, the chief problem is to find what type of vehicle will inflict the least damage on the roads. With this end in view it is essential to maintain a low pressure per square inch of the road surface. After discussing the number, width, and diameter of wheels, the sub-committee

considers that the caterpillar or track system is a preferable alternative to the use of wheels. The most promising development of this device is the "half-track" system in which the front wheels are retained for steering purposes and the rear wheels are replaced by a flexible double track system. Trials with certain vehicles constructed on this principle hold out hope that the solution of the transport problem lies in that direction, although many improvements in the vehicles are still required.

IN order to commemorate the great services made to polar exploration by the late Dr. W. S. Bruce, leader of the Scottish National Antarctic Expedition, a fund has been raised by subscription, the proceeds of which will be awarded biennially "for some notable contribution to Natural Science, such as to zoology, botany, geology, meteorology, oceanography and geography, the contribution to be in the nature of new knowledge, the outcome of a personal visit to the polar regions on the part of the recipient." The award will consist of a medal, inscribed "Exploration of Polar Regions" and on the reverse "For Valuable Services," modelled on that designed by Dr. Bruce to commemorate the return of the *Scotia*, with in addition a sum of money. In the making of the award, preference will be given, other things being equal, to an explorer of Scottish birth or origin, and to one at the outset of his career as an investigator. The Royal Society of Edinburgh has been asked by the subscribers to accept and has accepted custody of the Bruce Memorial Fund, and awards will be made by a joint committee representing that society, the Royal Physical Society and the Royal Scottish Geographical Society. The first award will be made in 1926. For the purpose of increasing the money award of the prize, subscriptions may still be sent either to Mr. A. N. G. Aitken, S.S.C., 37 Queen Street, Edinburgh, or to the Treasurer of the Royal Society of Edinburgh.

IN a paper on the future of engineering, by Dr. W. B. Parsons, which appears in the August number of the *Journal of the Franklin Institute*, stress is laid on the fact that engineering as we now know it is little more than a century old. The main characteristics of the present epoch are the substitution of mechanical for animal power and the application of mechanical power to secure results obtainable in no other way. If the use of mechanical energy were abolished our much-vaunted civilisation could scarcely recover from the shock. The energy that we use and on which our civilisation mainly rests comes from the burning of coal and oil. From 1800 to 1860 the consumption increased ten times, from 1860 to 1920 it again increased ten times. More than a ninth of the total consumption of fuel is now due to oil. If we assume that the consumption doubles every 16 years, then in a little more than 200 years our total reserves will be exhausted. It is certain, therefore, that the rate of consumption of fuel cannot go on

increasing at the present rate and that the cost will go on increasing. Using excellent steam engines, only about 20 per cent. of the energy of combustion is converted into useful work and very little increase is possible with steam. To utilise our water power resources fully, we need some economical method of storing energy. This is one of the pressing problems of hydro-electric engineering. It is estimated that more than one-third of the potential horse-power of the world is to be found in Africa. When energy can be stored and transported or transmitted, the great sources of water power existing in the tropics would become available. But the total water power in the world falls far short of its needs. Atomic energy, the heat of the earth, tides and waves at present offer very little hope. Doubtless, as the need becomes more pressing, wind-mills, especially in those places where the trade winds flow fairly steadily, will be largely utilised. Solar heat appears, however, to be the most promising source. There is an urgent call to engineers with the aid of physics and chemistry to invent a more efficient power-producing engine than the steam generator, and a device to store energy that can be much more readily utilised than the electric accumulator.

"THE first epistle of Henry the Chemist to the Uesaniens" is the somewhat bizarre title of a characteristic article by Prof. H. E. Armstrong printed in the September issue of the *American Journal of Chemical Education*. Beginning with a very long epigraph, after the manner of a Pauline epistle, the author proceeds to express his opinions on topics connected with the ethics of belief, education, literature, chemistry, and culture. His incisive style reminds one of Shaw and Chesterton, who by wealth of hyperbole and paradox, lame aphorisms, and parodied proverbs, know well how to arrest attention, and also of the late Lord Morley, who, when asked for his opinion on the prose of Carlyle, replied that he preferred the English language. Prof. Armstrong denounces the modern Press, present-day teaching of science, the poor literary value of scientific writing, and the absence of cultural value in the science of to-day; but he reserves the vials of his wrath for the adherents of the hypothesis of ionic dissociation, who above all others appear to him to sin most against the Pauline injunction of "proving all things, and holding fast that which is good," the freedom to do which, he says, is the only intellectual freedom worth having. Through this excursive "epistle" runs a serious *leitmotif* that will appeal to all, namely, that dogmatism in science is the negation of science, a truth which is of wider applicability than is sometimes assumed.

A LONG-FORGOTTEN hoax and a controversy almost equally overwhelmed by oblivion is recalled by Dr. L. A. Gausman in an article, "The Figured Stones of Würzburg," which appears in the *Scientific Monthly*, vol. 21, No. 5. In the early years of the eighteenth century, when the origin and significance of fossils was being hotly debated, Dr. Johann Bartolomaeus Adam Beringer, doctor of medicine and philosophy

and professor of natural philosophy in the University of Würzburg, publicly committed himself to the belief that fossils were merely the capricious fabrications of God, who had committed them to the earth for some inscrutable purpose. Thereupon students and others made a number of fantastic "fossils" of clay, which they buried on a hill near Würzburg. They were discovered by Prof. Beringer and accepted as genuine and as supporting his views. The ground was then further "saled" with still more fantastic forms, inscribed in Hebrew, Babylonian, Syrian, and Arabic. In 1726, Prof. Beringer, notwithstanding the remonstrances of his friends, published his "results" in a quarto "Lithographia Würzburgensis," in which his methods of investigation and safeguards against error and fraud were fully described. The book was received with universal ridicule, and the author died shortly after, a broken man.

THOSE who regret the fact that a site of such importance in the history of palaeontological and archaeological studies in Great Britain as Kent's Cavern should not have been acquired by some public body to ensure its safe-keeping, will read with mixed feelings a sketch of the life and labours of the Rev. John MacEnery (1796-1841) by the Rev. Kevin Clark, of which instalments appear in the October and November issues of *Blackfriars*. MacEnery was private chaplain to the Carey family of Tor Abbey while carrying on his exploration of the cavern, and had no other financial resources. Consequently his valuable notes remained unpublished at the time of his death, and apparently disappeared when his collections were dispersed by auction. The manuscript describing his explorations was printed by the Devonshire Association in 1859; but his notes, which were to be worked up into the promised "Cavern Researches," but never appeared, would probably raise still further the reputation of the man whose opinions on the age of the stone implements found beneath the stalagmite have been vindicated by time as against those of his distinguished correspondents, Buckland and Cuvier.

IN the issue of *NATURE* of September 12, p. 396, Dr. A. Gaschler referred to experiments he had made, in which he had obtained by artificial means an increase of 1.4 to 20 times the normal yield of uranium X from the disintegration of uranium. In view of the significance of such a result, were it to be substantiated, the following remarks of O. Hahn and L. Meitner, which appeared in the issue of *Die Naturwissenschaften* for October 30, are of interest: "Dr. Gaschler has undertaken experiments at low potentials and with heavy currents in our laboratory and under our control. According to his previous communications he had, with this experimental arrangement, obtained a manifold increase in the activity of his uranium preparations. These experiments, according to our measurements, yielded absolutely negative results, and some failed in the preliminary stages. The experiments with high-tension currents were carried out elsewhere. The uranium preparation from such an experiment, undertaken in a

laboratory of the General Electric Company in Berlin, was handed over to us for examination by a gentleman interested in the phenomenon. Our measurements failed to reveal any detectable increase in the quantity of UX, although we should have been able readily to detect even an increase of only 1.4 times the normal amount. Owing to the importance of the problems involved, we feel it our duty to make this statement."

THE Report of the Meteorological Committee to the Air Council for the year ended March 31, 1925, has just been issued by H.M. Stationery Office (price 1s. 9d. net). This is the seventieth year of the Meteorological Office and the fifth year in which the cost of the Office has been borne on Air Ministry votes. A special feature of interest in the report is the establishment of a division to deal with questions concerning meteorology for airships, which has been rendered necessary by the decision of His Majesty's Government to proceed with the development of airships and ultimately to establish a regular airship service between Great Britain and India, and the formation of a permanent committee on agricultural meteorology in connexion with the Ministry of Agriculture. A general weather forecast covering all districts of the British Isles has been regularly sent to the British Broadcasting Company in place of the separate district forecasts previously supplied, and notifications when possible are issued of spells of settled weather. An important feature to improve weather forecasting during the year was the establishment by the Royal Air Force of a Meteorological Flight to obtain regular observations of upper air temperature by means of aeroplane flights. Gale warnings have proved very satisfactory. The study of atmospheric pollution has been continued, and an investigation into the effect of suspended impurity upon the incidence of bronchial diseases has been arranged in collaboration with the Ministry of Health. Marine meteorology continues to make good headway, and the many varied undertakings of the Meteorological Office show an increasing activity and general interest in the development of meteorology.

A BRIEF account of the visit of foreign men of science to Russia on the occasion of the celebration of the bicentenary of the Academy of Sciences, which appears in Bull. No. 14 of the U.S.S.R. Society of Cultural Relations with Foreign Countries, is supplemented by a survey of the various scientific and artistic activities which have been initiated or are being supported by the Soviets. Oriental studies have always formed an important part of the Academy's activities. Of these the most valuable was perhaps the "Buddhist Library" of 60 volumes, while the Tibetan collections were the richest in the world. These studies are now being continued by the publication of Pekarsky's Yakut dictionary, and important researches in Moslem culture are being carried on, the numismatic researches of Frein being specially noted. An expedition to investigate the condition of the workers in the Ural Mountains in the eighteenth and nineteenth centuries has already discovered a number of documents of importance for economic and social

studies and collected headgear of the nineteenth century, implements used in punishing the workers, cut glass and pictures painted by serfs. A botanical expedition has left for Persia, and will study an unexplored region on the outskirts of Nishpur. Songs of various Caucasian peoples are being studied and edited with a special view to their relation to ancient eastern cultures. A large number of objects belonging to the thirteenth and fourteenth centuries has been found in the course of excavations of tombs, Moslem chapels, and other buildings in the Crimea by Prof. Borogdin. These discoveries throw much light on the culture of the ancient Tartars. An account of the excavations is to be published shortly.

THROUGH the interest of Prof. William Trelease, of Illinois, U.S.A., who had personal relations with three generations of the distinguished botanists commemorated, the City of Geneva has marked their one-time residence at 3 Cour de St. Pierre with a tablet bearing the following inscription: "Ici ont vécu et travaillé pendant un siècle les botanistes genevois Augustin-Pyramus de Candolle, 1778-1841, Alphonse de Candolle, 1806-1893, Casimir de Candolle, 1836-1918; Augustin de Candolle, 1868-1920."

It is announced in *Science* that Dr. J. B. Whitehead, professor of electrical engineering and dean of the faculty of engineering of the Johns Hopkins University, Baltimore, has been awarded the triennial prize, for the year 1925, of the Fondation George Montefiore of Liège, Belgium, for the best original work contributing to scientific advancement in the technical applications of electricity. The prize is awarded for his series of papers entitled "Gaseous Ionisation in Built-up Insulation." The amount of the prize this year is 4000 francs. This is the second time that Dr. Whitehead has been awarded this prize.

THE Council of the Iron and Steel Institute makes annually a limited number of grants from the research fund founded by the late Mr. Andrew Carnegie in aid of metallurgical research work. The object of the scheme is to enable students, who have passed through a college curriculum or have been trained in industrial establishments, to conduct researches on problems of practical and scientific importance relating to the metallurgy of iron and steel and allied subjects. Candidates, who must be under thirty-five years of age, must apply before the end of next February on a special form to be obtained from the Secretary of the Institute, 28 Victoria Street, London, S.W.1. The value of the grant will not exceed £100 in any one year.

WE learn from *Science* of October 30 that an expedition to Greenland is being organised by Prof. W. M. Hobbs. The main object of the expedition, which will leave the United States in July next year, will be the establishment of a meteorological observatory on the inland ice at an altitude of 6000 to 7000 feet some hundred and fifty miles from the west coast. A staff will be maintained there for a year, and the data will be transmitted daily by wireless to the United States and Europe. Prof. Hobbs believes that this service will be of great value in

forecasting The expedition will co-operate with Dr L. Koch, who is to lead a Danish scientific party to Scoresby Sound on the east coast, and to cross the interior to Holstenborg on the west coast. This journey is expected to occupy about two months. A further object of Prof. Hobbs's inland station will be the investigation of the upper atmosphere by means of rubber balloons. It is also proposed to take two aeroplanes for reconnaissance work over the ice cap in various directions.

A BIBLIOGRAPHY of meteorological literature, No. 8, prepared by the Royal Meteorological Society with the collaboration of the Meteorological Office, has recently been issued by the Royal Meteorological Society (price 2s. 6d. to non-fellows). The bibliography was incorporated in the Meteorological Society's Journal from 1917 until 1920, but has since been issued as a separate publication in six-monthly parts. The publication is of considerable value to students of meteorology in all parts of the world.

THE British Museum (Natural History) has recently issued an illustrated brochure entitled "British Mosquitoes and their Control," which is obtainable

at the Museum or through booksellers for the low price of 6d. This pamphlet forms No. 4 of the Economic Series and is written by Mr. F. W. Edwards and Col. S. P. James, who are recognised authorities on their subject. Practically all the information commonly sought for by medical officers and the general public will be found readily available, in its pages. The distribution and habits of the twenty-six species of British mosquitoes are briefly, but clearly, described, and there is a useful account of remedial and control measures.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Assistant at the Low Temperature Research Station, Cambridge—Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (December 14). Chair of philosophy—Registrar, University, Bristol (February 1). Lectureships in botany and in domestic science—Secretary, Huguenot University College, Wellington, C.P., South Africa. Biochemist—British Association of Research for the Cocoa, Chocolate, Sugar, Confectionery and Jam Trades, 2 Dalmeny Avenue, N.7.

Our Astronomical Column.

THE NEW COMETS.—These have both been well observed. The orbit of Comet van Biesbroeck presented great difficulties owing to the apparent motion being slow and almost directly from the sun. The following orbit by J. Møller and B. Strömberg is the best available, but it is still very uncertain:

T	1925 Sept. 29 370 U.T.
ω	99° 10' 73"
Ω	334 46 45
i	46 57 15
log q	0.16043

EPHEMERIS FOR 0^h.

	R.A.	N. Decl.	log r .	log Δ
Dec. 2.	12 ^h 5 5 ^m	30° 13'	0.2310	0.1842
10.	12 7 1	27 55	0.2460	0.1751
18.	12 6 3	25 48	0.2929	0.1647

The brightness is slowly declining.

The following orbit of Comet Wilk-Peltier is from rather rough observations, but is fairly near the truth.

T	1925 Dec. 6.936 U.T.

THE ORIGIN OF THE STARS.—A letter by Dr. J. H. Jeans in the *Observatory* (November) is of interest as tracing the modifications of his views that have taken place as new determinations have been made of the distances of the spiral nebulae. In a paper in *Phil. Trans. Roy. Soc.* for 1902 he showed that condensations forming stars might be expected to appear in

gaseous masses of density 10^{-23} , their distance apart being 10 parsecs. In 1917 he concluded that this process might be going on in the spiral nebulae, the visible condensations being taken as the nuclei of stars. The distances were at first assumed from Van Maanen's measures, but the recent discovery of Cepheids in the spirals indicates a much greater distance for them, and the masses of the condensations are increased from 3 sun to 16 sun. The only revision of his earlier work that he finds necessary is to conjecture that the radiation of the nebula as a whole is governed by different laws from that of the stars formed from it. The new-born stars are not necessarily giants: if the density of the nebula is as high as 10^{-10} , they will be dwarfs. It is conjectured that the group of nebulae near the galactic pole R.A. 12^h 37^m, N. Decl. 14°, may be of this character.

A MASSIVE SPECTROSCOPIC BINARY.—Orbits of many spectroscopic binaries are appearing regularly in the Publications of the Victoria Observatory. Vol. 3, No. 6 deals with an interesting star, No. 216014 in the Henry Draper Catalogue: its R.A. is 22^h 44.2^m, N. Decl. 64° 32', magnitude 6.8: spectrum Bo. The period is 2.3 days, and the minimum masses are 14.23 and 12.37 in terms of the sun, the probable values being half as great again, placing the system among the six most massive ones. The absolute magnitude is given as -2.67, implying a distance of 3400 light-years. The radial velocity of the system is -23.10 km./sec. The H and K calcium lines are sharp, and give a constant radial velocity of -26.28 km./sec. The component of the solar velocity is only -11.40 km./sec., so that the calcium cloud is not stationary with respect to the stellar system, as in some cases. It is conjectured to belong to the binary system, but to be 40 or 50 astronomical units from the stars, at which distance it would not show an oscillation. The diameters of the stars are estimated as 5.4 times that of the sun, giving a density of 0.08 sun. The relative orbital velocity is nearly 500 km./sec.

Research Items.

THE INTERPRETATION OF PREHISTORIC "FINDS."

—An interesting example of the light which can be thrown upon prehistoric objects of doubtful use by ethnographic data is given by Dr. Paul Rivet in the *Compte rendu* of the Liège meeting (1924) of the French Association for the Advancement of Science. Count Bégouen found in the cave at Montesquieu-Avantès (Ariège) an object of stone of which the surfaces were pitted with holes, most of them pierced right through from side to side. The date was either Magdalenian or Neolithic, it was uncertain which. A second object similar in certain respects—the figure of a feline—was found in a Magdalenian stratum in the grotto of Isturitz (Basse Pyrénées). It is, like the object previously described, pierced with holes, five in number, and in addition it is engraved. Four of the engravings appear to represent stylised barbed harpoons. Dr. Rivet suggests a common purpose for these dissimilar objects. He compares them with certain objects of ivory in use among modern Eskimo and described by Culin in his study of the games of American Indians. These are used for a species of cup and ball game, not, however, purely for amusement. Eskimo children use these objects when the sun first reappears after the long winter, to hasten his complete return. The game is definitely magical. In the same way the piercing of the hole by a point of bone in the prehistoric specimens may have been a magical ceremony symbolic of the piercing of game and practised before a hunting expedition.

PLACE-NAMES OF THE VIRGIN ISLANDS.—Since the acquisition in 1917 of the Danish Virgin Islands by the United States, the Coast and Geodetic Survey has been active in the preparation of a modern map and in amplifying the survey of the coastal waters. Although the earliest map of St. Croix was so old as 1671, there was no modern map of the islands incorporating accurate surveys. The latest effort of the Coast and Geodetic Survey is a Geographic Dictionary of the Virgin Islands of the United States by J. W. McGuire (Special Publication No. 103). In this gazetteer all place-names are entered with a note of their situation and derivation, and an indication of those which are rejected as being misspelt, superfluous or obsolete. From the length of the list of works consulted, it is clear that no trouble has been spared in compiling a trustworthy and scholarly guide to the place-names of these islands. The pamphlet also contains an introductory geographical chapter.

THE CYTOLOGY OF CANCER.—The September issue of the *Journal of the Royal Microscopical Society* opens with an admirable account of the general and experimental cytology of cancer by Dr. R. J. Ludford. In order to traverse the wide field more rapidly, Dr. Ludford has summarised the observations and theories in the form of twenty-one diagrams, either original or based on published figures. He gives a brief account of the behaviour of the nucleus and of the cytoplasmic organs—mitochondria, the Golgi apparatus, and the much discussed Plimmer's or bird's-eye bodies—and of keratinisation, and the formation of fat and pigment, and appends a summary of the properties of cancer cells cultivated *in vitro*. In his conclusion Dr. Ludford points out that with present microscopic technique there is no means of distinguishing between a normal and a cancerous cell. The virus of cancer, cultivated by Gye and photographed by Barnard, is smaller than the largest colloidal particles in the cell, and too small to be seen with the microscopes in common use.

THE CONTINUITY OF THE VERTEBRATE NERVOUS SYSTEM.—Frances M. Ballantyne (*Trans. R. Soc. Edin.*, vol. 53, pp. 663-670) records observations on the development of sensory nerves in *Lepidosiren*, and states that the olfactory nerve, the auditory nerve, and the spinal sensory nerves are at first protoplasmic bridges—each being a continuous strand and not a chain of discrete cells—which become fibrillated and lengthen as the embryo forms. Careful observation of large motor neurones in the spinal cord has convinced the author that the terminals of the axons, instead of ending in a club on the surface of the next neurone, really penetrate into its substance, and their neurofibrillæ pass directly and without a break through the cell and along its axon. No sign of a network either in or around the cell could be observed, and the neurofibrils are straight and unbranched within the cell. The dendrites of the neurone are at first thick processes which branch repeatedly and end in tapering threads of cytoplasm which appear to be without neurofibrillæ. The axon branches penetrate either into the body of the cell or into the thick proximal part of the dendrites, and the author supports the view that the great development of the dendrites, with their many branches, is to increase the surface of the cell in order to facilitate the metabolic processes, that is, the function of the dendrites is nutritive rather than nervous.

LEAF-MINING DIPTERA.—Memoir 78 (August 1924) of the Cornell University Agricultural Experiment Station deals with the leaf-mining Diptera of North America. Its author, Mr. S. W. Frost, brings together a good deal of useful information which will appeal to the dipterist and to the economic entomologist. The leaf-mining habit is regarded as having developed from the scavenger habit. Larvæ, having first entered the plant as scavengers, became adapted to an existence within the living host, and finally migrated to the stems and leaves, where they are now miners. It appears that 287 genera, including 589 species of North American plants, are affected by leaf-mining Diptera. The fly *Agromyza curvipalpis* var. *texana* Mall., for example, mines 15 species of Compositæ, and *Cerodontha femoralis* Meig. mines 22 species of Gramineæ. On the other hand, *Agromyza pusilla* Meig. has been recorded from 17 different families of plants, while at the opposite extreme there are other Diptera only known from a single species of plant host. Altogether there are 11 genera, including 61 species of Diptera, recorded as having the leaf-mining habit in North America, and they pertain to six families only. These families are the Cecidomyiidae, Trypanidae, Agromyzidae, Drosophilidae, Ephydriidae, and Anthomyiidae. Biological and descriptive accounts of these various species occupy pp. 29-132, and there follow lists of the leaf-mining Diptera of the world classified both under plant names and insect names. These two catalogues are useful compilations and appear remarkably complete. At the end of the memoir there is a very full bibliography of the subject.

SUGGESTED ALTERNATION OF GENERATIONS IN THE RED ALGÆ.—Prof. R. W. Phillips has certainly resuscitated from the literature a very interesting problem connected with the alternation of generations in the genera *Phyllophora*, *Gymnogongrus*, and *Ahnfeldtia* (*New Phytologist*, vol. 24, pp. 241-255, 1925). Whilst a few species seem to show normal alternation of sexual and tetrasporic generation, in others the tetrasporic generation has not been recorded. But

in these others curious warts have been recorded, which prove to be of the nature of nemathecias, that is, fructifications consisting of threads in which the successive cells of the threads become converted into tetraspores. Schmitz thoroughly investigated these more than thirty years ago and convinced himself and his fellow-investigators that these fructifications were of parasitic nature, and not the tetraspores of the host. In that case, where is the tetrasporic generation of the host plant? Prof. Phillips recalls the curious habit these marine algae have of being parasitic on a nearly allied plant, and asks the pertinent question whether this is not a more striking example still of this with the parasite actually the tetrasporic generation of the same plant.

PRESERVATION OF PLANT TISSUES IN MUD.—Any hint as to the condition under which plant structures may be preserved in soil long enough to permit of their subsequent petrification may ultimately prove of value in the interpretation of fossil structure. It is well, therefore, to have placed on record such observations as those of R. E. Hunter and Winifred E. Mottram (*New Phytologist*, vol. 24, pp. 193-206, 1925), who noted that the moving shingle bank at Blakeney had left exposed some of the old marsh mud containing plant remains which, to judge from the rate of shingle movement, etc., were upwards of 200 years old. The authors have thus been led to undertake the troublesome task of trenching in the salt-pan of the marsh, after drainage. The results show that the roots of the living plants penetrate to considerable depths, and that, in certain circumstances, a plant such as *Triglochin* may decay at the base very slowly whilst the living crown continues active for a very long time. They concluded from the rate of accretion of the marsh that a plant of *Triglochin* examined was perhaps thirty-six years old. The plants exposed by movement of shingle were stems of *Statice Limonium*, and were *in situ*. Investigation of the actual marsh does not appear to have cleared up adequately their presence here, but it has shown that the conditions existing in certain types of "soft" salt-marsh pan certainly favour the preservation of plant remains.

BURMESE PERISSODACTYLA.—Dr. Pilgrim has published in a memoir of the Geological Survey of India (vol. 8, No. 3, 1925) an account of the Eocene Perissodactyla of Burma. These are represented by members of the Titanotheriidae, of the Amynodontidae, an aberrant family of rhinoceroses, and of the Tapiridae. The discovery of titanotheres in Burma is of great interest. The family is typically American, and the only other parts of the world in which it has so far been found are Transylvania, with the sole genus *Brachydiastematherium*, and the newly discovered forms obtained in Mongolia by the American Museum of Natural History expedition. Dr. Pilgrim describes a new genus, *Sivatitanops*, and also a form ascribed to the American genus *Eotitanotherium*. The memoir is well illustrated, but on the technical side the types used by the Publication Department of the Government of India need renewing and the type-setting a stricter supervision.

EARTHQUAKES IN NEW ZEALAND.—The report of the Dominion Observatory, New Zealand, 1924-25 (Bulletin No. 58), contains some notes on the earthquakes of 1924. The Milne seismograph was in operation throughout the year, and the Milne-Shaw seismograph from February 8. During the last ten months of the year, 62 earthquakes were recorded by the former, and 73 by the latter, instrument. Seventy earthquakes were felt during the year, sixty

in the North Island and ten in the South Island, none of which attained a destructive intensity. Maps have been prepared and will shortly be published showing in considerable detail the distribution and intensity of the earthquakes felt in New Zealand.

OBSERVATION OF EARTHQUAKES IN A RAILWAY TUNNEL.—It is well known that earthquakes are either not felt at all or felt only slightly in railway tunnels and mines, even when the shocks at the surface are very strong. In the great Japanese earthquake of September 1, 1923, the damage to tunnels was very slight, and occurred only a few yards from either end. To determine the rate at which the amplitude decreases with increase of depth, Mr. S. Nakamura (*Proc. Phys.-Math. Soc. of Japan*, vol. 7, 1925, pp. 127-130) placed two of Omori's tromometers, one in a transverse shaft connecting two parallel tunnels each $1\frac{1}{2}$ miles long at a depth of 375 feet below the surface and nearly 500 yards from the northern end, the other just outside the tunnel at that end. Comparisons were made for nine earthquakes during the first three months of the present year, and they show that, as a rule, the amplitude of the principal vibrations was less in the tunnel than outside, the ratio ranging from 0.19 to 1.93. Though the general variation in the ratios of the amplitudes with varying periods agrees approximately with that computed from the formula for the Rayleigh waves, the agreement is not close enough to allow the inference that the observed waves were the Rayleigh waves.

PRECIPITATION IN SCANDINAVIA.—A new rainfall map of Norway and Sweden, on a scale of 1 : 2,500,000, is published by H. W. son Ahlmann in *Meddelanden från Statens Meteorologisk-Hydrografiska Anstalt*, Band 3, No. 4, Stockholm. The Swedish part is taken from the map by A. Waltén which previously appeared in the same publication. The Norwegian part is based on the rainfall statistics of the Norwegian Meteorological Institute and the volume of water in the Norwegian rivers. The author has devised also a method of finding the relation between the amount of precipitation and the extent of glaciation in any region. Values of rainfall based on the flow of rivers are adjusted by the addition of certain coefficients of evaporation. The coefficient decreases with the amount of fall, since great falls are at high elevations when temperature is low and evaporation not active. The only region where data were insufficient was Finmark, where rainfall stations are few and there is little present glaciation and no measurement of the flow of rivers. The map shows in a striking way the great variations in rainfall in Norway and the rapid decrease in amount from the west to the east of the Scandinavian peninsula.

UPPER AIR IN SAMOA.—A tentative discussion of pilot balloon flights has been made for the twenty months, May 1923-December 1924, at Apia, Western Samoa, in latitude $13^{\circ} 48' S$, longitude $171^{\circ} 47' W$., by Mr. Andrew Thomson, Director of the Apia Observatory, to obtain the direction and velocity of the trade winds at various altitudes, the nature of the antitrades overlying them, and the variation of these great air movements with the season of the year. Further observations are in progress, but it is not believed that up to a height of 12 km. (7.5 miles) the figures now given will be materially altered. The coasts of South America lie 6200 miles to the eastward, and the continent of Australia 2500 miles to the west, and the expanse of the ocean is otherwise free from the influence of land except for numerous islands, the influence of which is said to be inconsiderable. Apia

lies slightly to the south of the centre of the South-east Trades. On the open ocean in the immediate vicinity of Samoa, winds from the quadrant south-east to north-east blow for 48 per cent. of the time during the months of December and January, and 85 per cent. during June to August. The velocities of the balloons for the two periods May to October (the dry season) and November to April (the wet season) are resolved for each 0.5 kilometre of altitude into north-south and east-west components. The north-south component is weak and approximately the same for wet and dry seasons. The east-west components show that the trade-wind movement of the air to the west decreases steadily with altitude and becomes zero at 3 km. (1.9 miles) in November to February and at 7.2 km. (4.5 miles) in May to August. The eastward motion of the Antitrades setting in at these levels continues to a height of 12 km. (7.5 miles).

DIELECTRIC CONSTANTS OF UNSATURATED COMPOUNDS.—In the *Journal of the American Chemical Society* for October 1925, C. P. Smyth and C. T. Zahn give the results of measurements of the dielectric constants of ethane, ethylene, acetylene and *n*-butylene carried out in order to investigate the structure of unsaturated bonds. Other experiments have indicated that a double bond in a hydrocarbon chain often gives rise to a moment in the molecule which can be determined from the dielectric constant of the substance. The moments of the ethane, ethylene, acetylene and acetylene molecules are zero, but *n*-butylene has a small moment. This evidence shows that the electrons of an unsaturated bond are symmetrically arranged, but have a stronger field of force than a saturated bond. If the unsaturated bond is not symmetrically placed in the molecule, the effect will be to give the substance a measurable moment.

DIMENSIONS OF MOLECULES.—By means of the Stephan-Maxwell-Jeans equation, calculations of the average cross-sectional areas for the molecules of substances can be made from their diffusion coefficients. The rate at which molecules diffuse through a gas depends not only on the absolute velocities of the molecules, but also on their size, since the possibility of collision increases with increasing size or cross-sectional area. In the *Journal of the American Chemical Society* for October 1925, E. Mack, Jr., describes a method of finding diffusion coefficients by direct weighing and gives values for several substances. The average cross-sectional areas of these were calculated from scale models in beeswax by shadow projection, and were in excellent agreement with the values found by the diffusion method, showing that the models of the molecules were of the correct shape. The experiments confirm the view that benzidene and diphenyl have a collapsed structure.

COMPUTATION OF SPECTRAL ENERGY.—The Department of Commerce of the Bureau of Standards has recently published a series of "Tables and Graphs for facilitating the Computation of Spectral Energy Distribution by Planck's Formula." The set consists of seven sheets each about 24 in. $\times$ 19 in., printed on stout paper, the price being the very reasonable one of 35 cents. Of the sheets, five are charts, the remaining two a sheet of explanations and a sheet of tables. Table 1, which will be of use to the general physicist, gives values of the intensity of radiation E_λ for different values of $\lambda\theta$ (λ =wave-length, θ =absolute temperature), expressed as fractions of the value at maximum, which occurs for $\lambda=\lambda_m$, where $\lambda_m\theta=2890$. The values are given to four significant figures. Tables 2A and 2B give values of E_λ for λ from 0.4 μ to

0.72 μ , and for θ from 1000° to 2800°, the ordinates being on such a scale (different for each temperature) that $E_\lambda=100$ at 0.59 μ in Table 2A, at 0.56 μ in Table 2B. The five charts provide graphs corresponding to the second of these tables, the scale being altered from chart to chart so as to provide an accuracy of 0.33 per cent. in the energy values, 0.1 per cent. in the temperatures. From such curves it is a very simple matter to deduce the colour-temperature of a radiator from observations of the relative energies at 0.56 μ and one other wave-length. The graphs are on millimetre paper, and are very clearly executed. The value $C_2=14350$ is chosen for the radiation constant occurring in Planck's formula, though work done by Coblentz at the Bureau of Standards gave $C_2=14320$. It is shown, however, that this makes a negligible difference to the accuracy required, and in any case it is easy to use the charts in such a way as to allow for the difference.

METALLURGY IN ANCIENT MEXICO.—The method employed by the ancient Mexicans in the manufacture of certain metal objects has been repeatedly investigated with no very conclusive result. Strebel holds that although these objects have the appearance of wound wire welded or soldered together—and some were undoubtedly made by this process—the usual method employed was that of *la cire perdue*. They had not hitherto been submitted to microscopic examination. Dr. Axel Hultgren, however, has now applied this method of investigation to three exactly similar bronze bells from Nochistlan in Central Mexico, and has published the result in vol. 17, N.S. of the *Journ. des Américanistes de Paris*. Externally these bells have a grooved appearance suggesting that they have been made by winding a metal wire and subsequent welding, but internally they are perfectly smooth. An analysis of their composition gave copper 92.40, tin 6.95, lead 0.02, phosphorus 0.05, antimony less than 0.1, iron and aluminium less than 0.1. The microscopic examination showed the dendritic structure typical of cast alloys, and such as would be in accord with the chemical composition. The branches of the dendritic structure are the first formation of crystals in a falling temperature, and contain less tin than the material intervening between them which solidifies later. This proves, therefore, beyond question that the bells were cast. Had they been made from wire, the dendritic formation would have been distorted.

CONSTITUTION OF GLASS.—Prof. W. E. S. Turner has summarised the more important sections of our present knowledge of the nature and constitution of glass in a paper presented to the Society of Glass Technology and published in the Society's quarterly journal (September 1925). He has applied the Ramsay and Shields equation to the study of the molecular complexity of glasses with the aid of some data on surface tension and density, and has shown the fluid glass "molecules" to be of high molecular weight. Further investigation of the molecular complexity is developed by the application of indirect evidence. The existence of chemical compounds in glass has received attention, and the relation between percentage oxide content and the properties of thermal expansion, density, tensile strength, compression strength, etc., suggests that the oxides retain their individuality. The existence of breaks in the curves of composition—specific volume, etc., is taken as evidence of the presence of compounds. Much more investigation of physical and physico-chemical character is necessary before definite conclusions can be drawn. The same issue contains important communications from other authors on the constitution of glass.

Anniversary Meeting of the Royal Society.

IN his address on the occasion of the anniversary meeting of the Royal Society, held on November 30, the retiring president, Sir Charles Sherrington, referred to the heavy toll which death has taken of the Society since the last anniversary meeting. Brief mention was made of the lives and work of no less than twenty-three fellows and two foreign members who died during the past year. The president also spoke of the retirement of Sir William Hardy, biological secretary of the Society since 1915, on the completion of his statutory term of office.

The substance of the remainder of Sir Charles Sherrington's address is printed below.

The generous bequest of 10,000*l.* received last year from an anonymous donor for the promotion of medical research has this year, on the recommendation of the Tropical Diseases Committee of the Society, been resorted to for prosecuting investigation into the disease kala-azar, endemic in India and the Orient. At the instance of the Society, Major Patton and Dr. Hindle started for Northern China in June last in pursuance of that object. From the same generous and anonymous source a further munificent bequest has been received of something over 28,000*l.*, to be applied on the same terms and under the same condition of anonymity.

The Society, at the request of the Government, again organised, through a committee appointed for the purpose, an exhibition of pure science at the British Empire Exhibition. The catalogue of last year's exhibition was revised, enlarged and republished under the title "Phases of Modern Science." It is estimated that the Pure Science Exhibition was visited this year by at least 120,000 persons.

From the fund accruing to it in 1921 by the bequest of Miss Foulerton, the Society has this year been able, in pursuance of its scheme for advancing natural knowledge by the establishment of research professorships, to institute a further Foulerton Professorship, and the new Foulerton Professor appointed is Prof. A. Vivian Hill. Prof. Hill is already universally known as a most distinguished and fruitful investigator in animal physiology. He has placed the knowledge of muscular contraction upon a new footing. Taking up the problem from the viewpoint which chemical researches had at that time reached, Hill, by his own experiments, and experiments in conjunction with his pupils and others, has carried its study much further, especially in its physical aspects. The technique devised and the lines of analysis pursued have been masterly. He has attained preciser measurements, both of the energy changes and their time relations, and of the mechanical work realisable. Examining under various conditions the several ratios existing between these quantities, he has thrown fresh light upon the intimate mechanism of muscle. Not always has it been entirely welcome news that Prof. Hill has brought us about our muscles; we learn from him that they are sadly viscous machinery, but to that he reconciles us by pointing out compensatory advantages arising from that property. Deeper acquaintance with the principles underlying that function should enable better advantage to be taken of it. Some of Prof. Hill's results already touch practical issues. He is determining decisive factors concerned in the performance and maintenance of physical effort, and is tracing physiological characteristics underlying the skill and endurance of the athlete. Such researches promise information of value in regard to the management of muscular effort—and its application on a wholesale scale to industrial

labour. They also promise further insight into what may be termed manual skill. Prof. Hill's researches concern, therefore, questions of large practical as well as of theoretical importance.

As regards the biological papers brought before the Society during the past year, one feature which they display is that at this present time the growth of what one may term the experimental biological sciences—physiology, pathology, bacteriology, and pharmacology—is in some measure a convergent growth. Their individual boundaries seem more and more to merge. They are individual in their application rather than in their essential nature, and an advance made by one is of immediate advantage to all. Of any particular paper it would be often difficult, were it desirable, to say under which of these individual sciences it might best be singly classified or catalogued. Nor, under the elastic working of the Society, does that create difficulty; and that again affords evidence of the practical efficiency of our working arrangement.

With certain stages of growth there goes, on the other hand, increasing independence of an individual science. This seems so to-day for psychology viewed under the rubric of experimental biology. That psychology is rapidly growing is evident—not least so from its enhanced and successful application to practical problems lying before it in the sphere of industrial management and conditions of labour. Psychology as a part of experimental biology possesses, of course, recognised ties with the physiology and pathology of the nervous system; but on them it no longer explicitly leans to the extent it did. Its discipline becomes more intrinsically its own. This is, to my mind, well, and of favourable augury for its immediate progress as an experimental science. Concurrently with that tendency in psychology it is noteworthy that physiologists, Prof. Pavlov and his school, with, in Great Britain, Dr. Anrep, are pursuing analyses of complex behaviour of the higher animals under systematic avoidance of all reference, even by implication, to such psychical reactions as accompany that behaviour. Their method applies to animal behaviour in wider ambit than hitherto, the principles of reflex action. To illustrate by one example:—In his admirable Croonian lecture last June, Prof. Magnus described analyses by himself and his colleagues of the pure reflex behaviour of the cat without cerebral hemispheres. He showed how, for example, a moving mouse before the eyes of such a cat attitudinises the whole mechanism of the animal, exciting from it appropriate posture and direction in readiness for the final spring upon its prey. After that, "all the cat has to do is to decide to jump."

To jump or not to jump, that becomes the question. At such a point it is that the work of Pavlov and his school dovetails on to the work of Magnus and his school. Pavlov shows how in the intact animal such a final turning-point in its train of reactive behaviour—for example, "jump" or "not-jump"—can be studied as what is termed a "conditioned reflex"; he shows how that turning-point can be examined as the outcome of a balance between physiological impulsions and restraints, dependent partly on conditions under which the act is called for at the moment, partly on conditions under which it has been called for in the past—that is to say, the physiological history of the act in the individual, the mutual time-relations of the dominant stimuli, and so on. The result is thus treated as a sum of physiological factors, positive and negative, interacting under physiological rules, which can be determined, therefore, as obtaining from the

cerebral cortex. In this way is pursued a physiological study of higher nervous functions of the animal brain, without appeal to psychical reactions, of which, indeed, the method affirms nothing and denies nothing. To my thinking this line of attack is a gain both for physiology and for psychology, since psychology and physiology thus tread an essentially common terrain, yet do so each untrammelled by the other and without explicit reference to the eternal psycho-physical problem.

But it would be a far step, and a difficult, and of questionable gain, to carry such divorce of psychology and physiology into the study of fields such, for example, as human speech with what that connotes for reaction in the human brain. There it would seem better, as in Dr. Head's analysis of aphasia, to treat the anatomical, physiological and psychical data together. This seems the better, possibly the only, course of approach to those highest conjoint physiologico-psychological problems than which there can be few scientific problems which are of greater or more special interest to man.

PRESENTATION OF MEDALS.

THE COPLEY MEDAL: PROF. ALBERT EINSTEIN.

The name of Einstein is known to every one through the theory of relativity which he originated in 1905 and extended by a notable generalisation in 1915. Einstein realised that the time and space with which we are so directly acquainted by experience can be no other than the fictitious *local* time and space of the moving system—the motion in this case being that of the earth; we have no means of determining, nor can physical science be concerned with, any absolute reckoning of space and time. After this Einstein was led to the identification of mass with energy—another result of far-reaching importance, which allows us to know the exact amount of the store of energy so tantalisingly hidden within the atom.

There was a feeling that this theory of relativity for uniform motion must be a particular case of something more general; but observational knowledge seemed to oppose a decisive negative to any extension. It was Einstein again who found the way to the generalisation by bringing gravitation into his scheme.

Einstein's general theory of relativity is remarkable alike for the brilliance of conception and the mastery of the mathematical implement required to develop it. The new law of gravitation must be reckoned the first fundamental advance in the subject since the time of Newton. It involves an interaction between gravitation and light, which had indeed been suspected by Newton and almost taken for granted by Laplace, though it dropped out of scientific speculation when the corpuscular theory of light gave way to the undulatory theory. The three crucial astronomical tests of Einstein's theory have all been verified—the motion of perihelion of Mercury, the deflexion of light, and the red-shift of the spectral lines. The last-named proved the most difficult to test, but there is now general agreement that it is present in the solar spectrum. More recently Einstein's theory of gravitation has appealed to astronomers not merely as something which they are asked to test, but as a direct aid to the advancement of astronomical research. Invoked to decide the truth of a suspicion of transcendently high density in the "white dwarf" stars, it has decided that in the companion of Sirius matter is compressed to the almost incredible density of a ton to the cubic inch.

The other direction in which modern physical theory has broken away altogether from the ideas of the nineteenth century is in the quantum theory. Probably no one would claim that he really understands the quantum theory. For such illumination as we do possess we are in great measure indebted to Prof. Einstein. In 1905, almost at the same time as he published his first work on relativity, he put forward the famous law of the photo-electric effect, according to which the energy of a single quantum is employed in separating an electron from an atom and endowing it with kinetic energy. This was, perhaps, the first recognition that the development of the new quantum mechanics was not to be tied to classical mechanics by pictures of quasi-mechanical oscillators or other intermediate conceptions, but was to proceed independently on radically different principles. Noteworthy contributions followed on the theory of ionisation of material, and on the problem of the specific heats of solids. In 1917 Einstein reached another fundamental result—namely, the general equation connecting absorption and emission coefficients of all kinds. This gives deep insight into the origin of Planck's law of radiation, besides providing new formulæ with the widest practical applications.

A ROYAL MEDAL: PROF. WILLIAM HENRY PERKIN.

The science of organic chemistry owes a debt to Prof. Perkin, as instanced in recent years by his monograph on cryptopine and protopine, a record of chemical research rarely equalled in experimental skill and precise reasoning. He has revealed the constitutions of the alkaloids harmine and barmaline; he is nearing the solution of the structures of strychnine and brucine, two alkaloids which have hitherto resisted all attempts to determine their structural formulæ. His work on berberine has left few questions unanswered concerning the constitution of this important substance. He has developed new methods of attack on the chemistry of these natural products, and has faced many problems in structural organic chemistry. He succeeded, during a period of twenty years at the University of Manchester, in building up there a notable school of chemical research. During the past twelve years, in the University of Oxford, he has again organised and developed a similar research school.

A ROYAL MEDAL: PROF. ALBERT CHARLES SEWARD.

Prof. Seward's work has been conspicuous on account of the way in which he has extended and reduced to order our knowledge of the palæobotany of Gondwanaland, especially in India, South and Central Africa, Antarctica and the Falkland Islands. The lower stages of the Gondwana system are characterised by evidences of a glacial climate; and in order more completely to understand the conditions of life that existed, Prof. Seward has visited Greenland and otherwise paid special attention to the effect of climate and light in explaining the rise and luxuriance of the *Glossopteris* flora in the Southern Hemisphere. In addition to its direct stratigraphical value to geologists, his work has added greatly to our knowledge of plant migration, and especially of the way in which the *Glossopteris* flora invaded the Northern Hemisphere previously occupied by the groups familiar to us by our Coal Measure plants.

THE DAVY MEDAL: SIR JAMES IRVINE.

The constitution of the simpler sugars (monosaccharoses) was based on a sure foundation by the classical researches of Emil Fischer. Taking up the

investigation where Fischer had left it, Sir James has carried the inquiry into the more complex field of the disaccharoses, and by means of new processes, which he has been able to evolve and apply, to assign definite chemical structures to many of these most important natural products. He has also studied the constitutions of the still more complex polysaccharoses, starch and inulin, incidentally gaining an insight into the manner in which the plant forms and utilises these fundamental reserve materials.

THE SYLVESTER MEDAL: PROF. A. N. WHITEHEAD.

Always primarily interested in the foundations of mathematics, it is in the logical analysis of these foundations that Prof. Whitehead's reputation has been won. The great work, "*Principia Mathematica*," written in collaboration with Bertrand Russell, contains the most systematic and the most profound analysis to which the foundations of the subject have yet been submitted.

From pure mathematics both Prof. Whitehead and his collaborator have turned independently to physics. In his more recent books Whitehead has endeavoured to apply the spirit of "*Principia Mathematica*," and in particular the principle which he calls "extensive abstraction," in the more complicated and more con-

troversial field of physical existence. That a point, whether in the older physics or the modern physics of space-time, is a class, or a class of classes, of events, that an electron is a systematic correlation of the characters of all events throughout all Nature, are doctrines at which the unsophisticated may be tempted to scoff, but the tendency of modern scientific thought is to the conclusion that, if the world of physics is indeed ultimately capable of any rational interpretation, it must be interpreted in some such way.

THE HUGHES MEDAL: MR. F. E. SMITH.

Mr. Smith began work on the realisation of the fundamental units of electrical measurement in 1902; and such further experiments as have been made since have served only to confirm his results. Other important investigations by Mr. Smith have dealt with the measurement of terrestrial magnetism. The recording magnetometers which he designed have proved of great value, while more recently he constructed, at the suggestion of Sir Arthur Schuster, a horizontal force magnetometer of extreme accuracy. During the War his services to the nation were of great importance, and since the Armistice, as Director of Research at the Admiralty, he has been responsible for a number of valuable investigations.

The Conference on Solid Smokeless Fuel in Sheffield.

A CONFERENCE on solid smokeless fuel was held in the Department of Applied Science at the University of Sheffield on Friday November 20. To point the moral, a tasty fog prevailed throughout the proceedings. The meeting was under the joint auspices of the Society of Chemical Industry, the Institution of Chemical Engineers, the Institution of Gas Engineers and the Midland Institute of Mining Engineers.

The objects of the meeting were to discuss methods of improving the quality of high-temperature coke and the alteration to present equipment and to plant which is required for the purpose. Dr. C. H. Lander contributed a general résumé, and papers were read by Dr. E. W. Smith on "The Qualities Requisite in a Solid Smokeless Fuel for Domestic Use," Prof. R. V. Wheeler on "The Production of Free-burning Solid Smokeless Fuel at High Temperatures," Mr. E. V. Evans on "The Combustibility and Reactivity of Coke," Mr. D. Rider on "Coke Quenching," and Mr. F. M. Birks on "Coke Handling, Screening and Breaking." There were about three hundred present, and the meeting was highly successful. In addition to the papers, investigations under the direction of Prof. Wheeler in the Fuel Department were inspected. There was also a demonstration of ordinary coke burning in open grates and in a closed one.

Low-temperature processes have been discussed with some thoroughness, and consequently the position as to these is fairly well known. Briefly, there is no low-temperature process. Many are the systems on paper, few are on works-sized concrete foundations, none show appreciable returns to the owners. It may be said of all, that none have mastered their engineering difficulties, few know even part of the chemistry of their products, whilst the efforts of all the systems have made no impression on the fuel question. It is clear that a low-temperature process will have to pass through the difficulties attending the evolution of the high-temperature process without any of the advantages attaching to these statutory bodies.

Such being the case, and assuming a demand for a free-burning solid smokeless fuel, can anything be done to render high-temperature coke more combust-

ible and thus suitable for the domestic grate? If this can be done, then remembering that gas-works and coke-ovens together have an output of about 20 million tons of coke and that the domestic consumer consumes more than 40 million tons of coal per annum, the field for expansion is obvious. With regard to this scheme, it may be said that gas-works and coke-ovens do possess carbonisation technique, of a sort, capital has certainly been expended on them, they are old and tried servants.

If this were all, and provided high-temperature processes provide a free-burning fuel, then coke-ovens and gas-works have it. But it has yet to be proved that they can and will provide a coke that is easy to ignite, easy to keep alight, free from ash, low in moisture, clean and free from dust. But assuming that all this could be done and assuming that the combined output went to the domestic consumer—a very far-fetched assumption—only half of the domestic coal consumption would be displaced. A doubling of plant cannot reasonably be visualised within the next ten years.

Consequently there is still plenty of scope for low-temperature carbonisation, if the processes could be put on a commercial footing. Considerable interest was taken in low-temperature processes owing to the probable oil obtainable under these conditions. But a good deal more oil seems probable by the use of hydrogenation methods, the one process being yet as problematical as the other. Little is known of the composition of the liquid products of low-temperature processes. It is for this reason that low-temperature processes are desirable. It may well be that new classes of compounds may be brought to light with new properties and new uses. New drugs, new dyes, may be obtained, new substances with yet unknown benefit to mankind. Whatever the financial results from low temperature, the probable scientific results should be known.

The technical contributions to the subjects of the conference may be summed up in a short space, as was done by Prof. Wheeler. Fine grinding followed by blending, and the mixture of coals thus produced to be carbonised in narrow ovens under high-tempera-

ture conditions, the charge to be pushed when the centre of the coke reaches 700°C. , seem likely to produce a more combustible coke. This opinion is based on some theory, on a fair amount of careful laboratory experiments, with but little large-scale confirmation, however.

Of scientific contributions there were naturally few; naturally, because of the newness, vastness and difficult character of the field. Concerning carbonisation, profound ignorance prevails. As to treatment and events beyond the hydraulic main there is still room for discussion—witness the recent contribution to this by Dr. Smith and Mr. Finlayson—but in respect to treatment and events, from the cold coal to the hydraulic main, there is no useful discussion. We do not know. There is much methane in coal gas, the methane has presumably been at 1000°C. or so. At this temperature methane deposits carbon and produces hydrogen. The shiny carbon—termed methane carbon—is accompanied by at least two, if not more than two, physically different forms of carbon. Moreover, from the deposit, it is almost as easy to pick out pieces of naphthalene as it is pieces of carbon.

At the Conference the terms reactivity and combustibility were used as synonyms. Korrevar has shown that they are as synonymous as silica and glass. Mr. E. V. Evans brought forward a new method for the determination of the combustibility of coke, as regards the utility in the open grate, and the method promises much. But as to reactivity, that intrinsic property of carbon, not much was said. The reactivity of carbon, which lies at the basis of the combustibility of that impure substance, coke, depends on the physical condition of the carbon, and at once we are back to the carbon deposits from methane cracking. If we know nothing concerning these deposits of

carbon, what are we to say of our real knowledge of coke?

As Dr. H. M. Travers pointed out, at almost every stage of the carbonisation some very pertinent and unanswerable questions may be put. Why is primary tar formed at all—what is the mechanism of it? Why does coke at the later stages of carbonisation evolve hydrogen for the most part, and that in bursts with rise of temperature? He also put in a plea for research into fundamentals of fuel utilisation; if this be undertaken, then the Conference may well be a momentous one. He considers that the universities should undertake the work rather than, for example, the Fuel Research Board. His opinion is that progress is not likely to follow the permutations and combinations of well-known works processes. A difficulty is created, however, by the financial position of most of the universities of Great Britain. Many public-spirited industrialists know this, and there may be those, whether individuals or corporations, who would care to contribute towards the cost of research into fundamentals of this character.

Should means become available for the prosecution of the fundamental researches indicated, then a plea might be entered for the University of Sheffield, where there is a well-established school of fuel research. The list, distributed at the meeting, of work in progress, served to indicate the varied and extensive character of its activities. One could pass from Fuel Research Board apparatus, solvent resolution, to spontaneous combustion, momentary heating of coal, desulphurisation, combustion, coal constitution, synthetic ulmins, hydrogenation, flame work and microscopic work.

The Conference adjourned until February for a meeting at Manchester. S. L. B. ETHERTON.

The Early Nilotic, Libyan, and Egyptian Relations with Minoan Crete.

THE Huxley Memorial Lecture of the Royal Anthropological Institute for 1925 was delivered by Sir Arthur J. Evans at the rooms of the Royal Society on Tuesday, November 24. The chair was taken by Prof. C. G. Seligman, president of the Institute.

Sir Arthur Evans said Crete might be described as a half-way house between three continents, Europe, Asia, and Africa. Its fortunate situation marked it as the point where the primitive culture of our continent was first affected by the older civilisations of Egypt and the East. The most ancient geographical relations of Crete lay with Anatolia and the East. Man entered Crete from the Anatolian side; he may even have found the dwarf hippopotamus surviving from the times of the land-bridge of Miocene and Pleistocene times; but Palæolithic discoveries in Crete are still wanting and human remains from Neolithic times are still to seek. From Middle Minoan times a brachycephalic element is perceptible, mixed with the older dolichocephalic inhabitants, which may be due to an intrusion of "Armenoids" from Asia Minor, for which a portrait on a Middle Minoan seal supplies an argument. Archaeological, religious, and linguistic evidence all point to a root connexion between Crete and Anatolia. The primitive female steatopygous figures from the Neolithic strata of Knossos find remarkable parallels from Asia Minor and so far afield as the Euphrates and Caspian. Stone maces and monochrome pottery show similar affinities. The pre-Hellenic language is related to old Carian and its kindred tongues.

It has been supposed that Egyptian relics found in connexion with Minoan and Mycenaean Crete arrived

by the Syrian or Anatolian route, but this is unsupported by any evidence as regards the earlier contact of Crete with the Nile Valley. There is abundant proof that early man was not averse from deep-sea voyages. It is natural to suppose that in the East Mediterranean navigation began in the Aegean island world. Neither the Syrian nor the Libyan coast was favourable to its rise. Of Cretan vessels, the earliest representation is a clay model from Palaikastro of the First Early Minoan Period, which may be compared with the Nile craft such as those shown on the pottery of Naqada. There was a general use of sailing craft from an early date, and vessels with a single mast are of constant recurrence at the beginning of the Second Early Minoan Period in the first half of the third millennium B.C.

Evidence accumulating since 1890 of early relations between Crete and Egypt going back to the fourth Dynasty received remarkable confirmation from the beginning of the excavations at Knossos, in the form of imported Egyptian stone vessels of late prehistoric and protodynastic age and, more important, in derivative native Cretan forms in softer stone such as steatite and serpentine. In a Neolithic house of rectangular form found under the Central Court of the original Palace of Knossos, with fixed hearth of Anatolian type, was found among objects of pure Stone Age tradition a copper axe which must be regarded as an importation, not improbably from the Nile Valley. Two finds of special importance from this site were a gallipot-like vessel with clear traces of tubular drilling closely resembling a type of late predynastic and protodynastic Egyptian vessels, and two fragments of vessels of variegated stone which,

although like nothing found in Egypt or elsewhere, appear to be exotic and show that the Nilotic usage of stone vessels wrought in decorative materials had taken root at Knossos in the late Neolithic phase.

Among other elements of Cretan culture showing affinities to the early culture of the Nile and of the indigenous inhabitants of the opposite Libyan coasts, are the large stone ossuaries in the beehive form of the Messara plain on the southern border of the island, contrasting with the rectangular habitations of Crete. Stone idols from Hagia Triada curiously recall those found in predynastic Egypt. They show the high head and pointed beard of the Nilotic race, and possibly passed to Crete from Libya. The Cretan mode of head-dress and the type of loin clothing show either a resemblance or a general analogy with that of the Libyans. The Libyan Delta goddess appears to have been, in part at least, incorporated in the Cretan mother goddess, as is shown in the form of bow, arrows, and shield which are the attributes of the former. In

the stone ossuaries, the discovery of palettes of stone similar to those used by the predynastic Egyptians for antimony and malachite to adorn the person are peculiarly significant.

These striking correspondences in forms and usage, and especially in the contracted burials of the vaulted tombs of Messara, the dolichocephalic skulls, and the recurrence of foot-shaped amulets of stone, suggest a settlement of a proto-Libyan element in the southern foreland of Crete. These tombs are of a true beehive type, but they differ from the Mycenæan examples in their entrance system. They represent a sepulchral type which has a wide diffusion in the old Libyan region of North Africa. This proto-Libyan settlement became entirely assimilated in the Old Cretan population, but the engrafting of this artistic element on the indigenous island stock may well have contributed to the later bloom of Minoan culture.

At the conclusion of the lecture, the president of the Institute presented the Huxley Medal to Sir Arthur Evans.

The Flame Spectra of Carbon Monoxide and Water Gas.

TWO papers by Mr. F. R. Weston, recently published in the *Proceedings of the Royal Society* (A, vol. 109, 1925, pp. 176-186 and 523-526), embody the results of researches into the flame spectra of carbon monoxide, hydrogen, water gas, etc., which he has conducted at the Imperial College of Science and Technology under the joint supervision of Profs. W. A. Bone and A. Fowler. The object of the researches was to elucidate certain aspects of the combustion of carbon monoxide, and notably whether or not this gas interacts *directly* with oxygen in flames, a point which has been much disputed amongst chemists during the past forty years, but now seems to be in the way of being definitely cleared up by the spectroscopic

The spectrum of a flame of undiluted carbon monoxide burning in air (or oxygen) at atmospheric pressure is shown to consist of a banded radiation, extending from 5000 Å.U. in the visible region to 2200 Å.U. far in the ultra-violet, upon which a continuous spectrum is superimposed. Both the banded and continuous parts of the spectrum, which are associated with the characteristic colour and actinic properties of a carbon monoxide flame, are most probably due to *direct* interactions between carbon monoxide and oxygen molecules in the flame, without any intervention of steam. At the same time, unless both the carbon monoxide and oxygen are previously dried before combustion, the spectrum shows some characteristic "steam lines," due to interactions between CO and OH₂ molecules in the flame, which proceed simultaneously with, and independently of, the CO and O₂ interactions.

As the carbon monoxide in the burning gas was progressively replaced by hydrogen, both the banded and continuous parts of the spectrum rapidly faded away, until with an equimolecular (that is, 50 CO + 50 H₂ by volume) mixture of the two combustible gases

(water gas) only "steam lines" remained visible in the spectrum, the characteristic CO-radiation and flame-colour having almost entirely disappeared.

When a flame of undiluted carbon dioxide was burnt (undried) in oxygen under reduced pressure, the banded part of the spectrum became more distinct and the continuous part less intense as the pressure was diminished, the "steam lines" were invariably present in the spectrograms. When a flame of carbon monoxide, previously dried by passage through strong sulphuric acid, was burnt at atmospheric pressure in oxygen, similarly dried, the "steam lines" in the resulting spectra had almost disappeared (they were only faintly visible), whereas the intensity of the continuous part of the spectrum remained undiminished.

The conclusion drawn from the experiments is that in the flame of pure (undried) carbon monoxide two sets of independent interactions occur simultaneously, namely: (a) direct interactions between carbon monoxide and oxygen, exciting radiations which give rise to the continuous and banded parts of the spectrum, and to the characteristic blue colour of the flame, and (b) interactions between CO and OH₂ molecules, which originate the "steam lines" in the spectrum. When hydrogen is gradually added to the burning gas the relative proportions of the first-named interactions diminish rather rapidly and proportionately more of the carbon monoxide is burnt by interaction with OH₂-molecules, until when an equimolecular mixture of carbon monoxide and hydrogen is reached, the carbon monoxide-steam interactions occur to the practical exclusion of the carbon monoxide-oxygen interactions. These experiments have afforded the first clear evidence that in an ordinary carbon monoxide flame both sets of interactions are going on independently and simultaneously.

School Natural History Societies

THE Marlborough College Natural History Society is interesting as a school institution which has had an unbroken existence since 1864, when it was founded under the auspices of the then headmaster, later Dean Bradley of Westminster; it now issues its seventy-third printed report. Marlborough is situated in an unique position for this study, with some primeval forest in Savernake on one side and the

open savannahs of the Downs on the other. Between the two runs the Kennett, here quite a small sluggish stream noted for its excellent trout-fishing, with beds of willows and water meadows by its sides. Near its head waters, from six to seven miles away, lie Silbury Hill and Avebury, the latter with its immense stone circles. The Downs show dolmens and tumuli, most of the latter probably of much later age, and there

are numerous remains in camps, etc., of Roman times. The Report contains an account of excavations on the Wansdyke where it approaches Savernake Forest, and Mr. A. C. Brentall contributes a description of Martinsell, an old camp or cattle enclosure, three to four miles away, on the top of a chalk hill which falls precipitously to some of the richest agricultural ground of Wilts. Flint implements are common everywhere, as shown in an article by J. G. D. Clark, comparing 2000 specimens collected within two years at Marlborough and Seaford.

The permanent value of the whole series of reports lies, however, mainly in their descriptions of the natural history of one of the richest areas of the British Isles. The foundations of these were laid by such men as Preston and Hart-Smith in botany, Warde Fowler and Im Thurn (of British Guiana fame) in ornithology, and, above all, by Edward Meyrick in entomology, the latter not only a genius in his scientific work, but also in his task as a schoolmaster of developing the individuality of his pupils. Of the same type would appear to be Mr. A. G. Lowndes, who has written an illustrated article on that peculiar shrimp-like freshwater Cheirocephalus, a relic of the primary period; he also contributes notes on other freshwater forms that he and his class are studying, while there are references to vacation parties taken to the Isle of Purbeck and to the laboratory of the Marine Biological Association at Plymouth.

Of other work we might refer to meteorological observations carried on for sixty years, to the flowering dates of plants and to the dates of capture of insects, regular features of the report. In these a boy, A. G. P. Michelmores, seems to be prominent, and he, too, is largely responsible for revised lists of several groups of insects within a ten-mile radius of Marlborough, really the record of 663 species of that very difficult group, the Diptera or flies, is extraordinary for a school natural history society.

In this age of systematised school games—organised exercise would be a better term—we particularly welcome a report such as this, showing individuality, sacrifice and keenness in both masters and boys. Nothing gives a greater zest and interest to one's later life than the art of observation of all one's surroundings, both large and small, taught perhaps best in natural history. We are, indeed, happy to see that in this great school there must be opportunities for healthful and profitable recreation apart from the compulsion of "games."

University and Educational Intelligence.

CAMBRIDGE.—Mr. F. B. Smith has been reappointed reader in estate management for five years as from October 1.

The Raymond Horton Smith prize for 1924-25 has been divided between Dr. J. H. Burn, of Emmanuel College, whose thesis was written on the effects of denervation of a limb, and Dr. G. A. Harrison, of Gonville and Caius College, who dealt with insulin and diabetes mellitus.

The University Commissioners have published a list of amendments to their recently proposed statutes. The department of forestry is to be grouped with agriculture in a joint faculty. The Financial Board is to have power at its discretion to require that a departmental imprest account shall be administered by some one other than the head of the department. This might prove to be a valuable controlling factor in the case of any department the finances of which did not at any time appear to be administered in the best interests of the University. A special exception to the statute which requires professors to retire at the

age of sixty-five years is to be made in the case of Sir Humphry Rolleston, Bart., who accepted office at a time when the commissioners had intimated that they proposed to institute a retiring age of seventy years.

The Special Board of Agriculture and Forestry has presented a report of progress for the year 1924-25. The considerable number of students who obtained Imperial and commercial appointments is of great interest. Accounts are appended detailing the expenditure on research of about 38,000*l.* from the Development Fund of the Ministry of Agriculture.

LIVERPOOL.—Some relatives and friends of the late Sir William A. Herdman have founded a memorial scholarship at the University. This is open to graduates of British universities who are prepared to carry on research in marine zoology at Liverpool and at any British marine biological station. The scholarship has a present value of about 50*l.* per annum. Applications should be made to the Registrar before the first day of the summer term.

We learn from the Paris correspondent of the *Times* that degrees of doctor *honoris causa* have been conferred at the Sorbonne upon the following, among others: Sir Ernest Rutherford, Cambridge; Mr. Noguchi, Rockefeller Institute, New York; Prof. I. P. Pavlov, Leningrad; M. Charles de la Vallée Poussin, Louvain; and Prof. Ettore Pais, Rome.

THE Committee of Award of the Commonwealth Fund announces that it is now prepared to receive applications for the fellowships to be awarded in 1926. The fellowships will normally be tenable at an approved American university for two years and are open to persons of British birth domiciled in England, Scotland, Wales, and Ireland who are graduates of recognised universities and are unmarried and not more than thirty years of age. Women as well as men may apply. Provision amounting to approximately 600*l.* per annum will be made for the total expenditure involved during the tenure of a fellowship. Applications must be forwarded through the authorities of the university or college of which the candidate is or was a member. The form of application can be obtained from the Secretary to the Committee, Mr R. H. Simpson, 50 Russell Square, London, W.C.1. Applications must reach the Secretary by February 20 next.

THE effect of continuation classes on mill personnel was discussed at a luncheon meeting of the Lancashire Section of the Textile Institute on October 9. Mr. John Crompton, of Messrs. Burgess, Ledward and Co., Ltd., read a paper on this subject, which is published in the October number of the Institute's journal. Mr. Crompton makes out a strong case for the general adoption of the system of continuation classes, concurrent with workshop practice, for which the "Fisher Act" provides. The data on which he bases his arguments are derived chiefly from the experience of his own and other firms in employing boys and girls attending the continuation classes held in the Worsley Technical School, Walkden. He explains in detail how he has met the difficulty arising from machines being vacated by one set of operatives and requiring to be tended by others. He points out that at Rugby, the only town in England where day continuation schools are compulsory for all employees under the age of sixteen years, there is no juvenile unemployment, 90 per cent. of the employers pay wages for school attendance, 75 per cent. of the young persons attend voluntarily evening school activities in addition to the compulsory day classes, and these classes are proving the best method of establishing contact and oversight of a considerable

proportion of the population after the school-leaving age. "The managers of several works declare that the day continuation school is the best form of welfare effort, and that the humanising influence of real education is the only true welfare work."

THE annual meeting of the Geographical Association will be held on January 7-9 at the London School of Economics, under the presidency of Mr. W. G. A. Ormsby Gore, who will take as the subject of his presidential address "The Economic Geography of the British Empire." The very full programme includes lectures by Prof. J. L. Myres, on "Wayside Geography," by Sir John Russell, on "Cotton and the Nile," by Sir Halford Mackinder, on "The Teaching of Geography," and by Prof. P. M. Roxby, on "The Concept of Natural Regions in the Teaching of Geography, with special illustrations from China." University teachers of geography will hold a discussion on the compatibility of the training of the geographer with the acquisition of a university degree in geography, to be opened by Mrs. Ormsby, on the first day of the meeting, while on the last day there will be the following four concurrent discussions, the opener's name in each case being given in brackets: The place of geography in a two period a week geography course (Mr. C. G. Beasley), detail in geography lessons (Mr. C. Daryll Forde), geography in relation to other school subjects (Major A. G. Church), and geography for the younger children in primary schools (Miss R. M. Fleming). The afternoon of January 9 will be given over to excursions; arrangements have been made for (1) a walk across Hampstead Heath and a visit to the geography rooms of the William Ellis and Henrietta Barnett Schools, (2) a visit to the Science Museum, South Kensington, and (3) beating the bounds of the City of London under the guidance of Mrs. Ormsby. A publishers' exhibition of books of maps has also been arranged.

FROM the International Federation of University Women we have received a copy of the report of the Council meeting held at Brussels in July last. The list of constituent national federations comprises 23 countries, those with the largest membership being the United States of America (22,000), Great Britain (2000), Canada (1500), Australia (600), Ireland (350), South Africa (326), France (290), Switzerland (260), and New Zealand (250). Germany is not included. An application for affiliation has been received from Ukrainian university women, some of whom are in the Soviet Republic of the Ukraine and some in Poland. The most valuable of all the Federation's efforts for promoting intercourse are, says the president (Dean Gildersleeve of Barnard College, Columbia University), plans for fellowships and club-houses. For fellowships a campaign has been started for a "Million Dollar Fund." Awards have recently been made to Dr. Ethel McLennan of Australia, who is undertaking research work at Rothamsted, and to Dr. Elsa Mahler of Switzerland, who is continuing at Rome, Florence, and Arezzo, her work on Megarian bowls. For 1927 the Australian Federation offers two fellowships of 500*l.* each, one to be awarded to a non-British member of the International Federation and the other to a British member (excluding residents in Australia or New Zealand). There are international club-houses at which special privileges are offered to all travelling members of the Federation from other countries at Baltimore, New York, Philadelphia, Washington, Brussels, Montreal, Paris, Lyons, and London. The biennial conference of the Federation will be held in 1926 at Amsterdam and will include discussions of academic research, application of research to social problems, adult education, etc.

Early Science at Oxford.

December 7, 1683. Glass is found to be electrically only in ye cold, not by ye fire.

Dr. Plot gave an account of severall sorts of seeds, roots, leaves &c. brought from ye East Indies, and presented to ye Royal Society by Captain Knox. It having been affirmed, that probably seawater may be sweetened by being distilled from salt of Tartar, it was ordered to be tried how far ye distillation of brine from salt of Tartar might go towards ye sweetening of ye brine. It was ordered to be tried, whether Iron-ore melted, and cast into an ingot, lying north, and south, will acquire a verticity? As also whether water will bubble, after that a fire has, for some considerable time, been made over it, in like manner as it does when it boils by reason of a fire under it.

A letter was read from Dr. Antony Nuck, Anatomy Reader at the Hague, to Mr. Benbrig; wherein he promises to communicate to the Society, what Curiosities fall under his observation.

1686. An observation of ye Reverend Mr. Peck, Minister of Mayfield in Sussex, concerning a Gentleman who had been long in the East Indies, and about a month after that he took ship from thence, was taken with a fainting *feaver*, and various indisposition, had a vein opened; the *bloud* was squeezed out, and did accumulate like drops of melted wax: this gave releif, but about 3 weeks or a month after, his distemper returned; he was bled again; and thus his distemper and his bleeding continued for some years. In ye intervals he was well. He was cured by chewing Rhubarb.

December 8, 1685. Dr. Plot presented a piece of Ebony from St. Christopher's; it is yellow after ye saw, and blackish after ye plane, and is ye heaviest wood, we have yet seen.

There being some discourse concerning ye antiquity of weighing things in air and water, Dr. Bernard was pleased to informe ye Society, that that method is mention'd in ye Misna.

Dr. Plot also shew'd ye Society some little stones found by Mr. Lloyd on a bank by ye wayside south of Islip Church; they are ye same with those described by Dr. Lister, only these had no side indented.

The Circulation of ye blood appearing most evident to sense in some partes of ye *Lacerta Aquatica* viewed through a microscope (which we must in justice own to have receiv'd first from ye minutes of ye Dublin Society) the tryall of this experiment before this Society was recommended to Mr. Hoy.

December 9, 1684. A Paper was presented, by Mr. Desmastes, making mention of ye Trial of some Experiments found in Kunckel, vizt: That spirits of wine and syrup of violets make a green;

That Spirit of wine, and Milk, in equall parts, curdle; and

That a few drops of Water and Spirit of wine, heat perceptibly

A sheet of paper was presented ye Society, made of ye Asbestos-Stone by Mr. Lloyd, Register to the Chymicall courses of ye Laboratory of Oxford. The paper was made thus.

Mr. Lloyd received a parcell of this stone from the Isle of Anglesey, part of which he pounded (crude as it was) and carrying it to a paper-mill, had it mixt with water in their troughs for that purpose; then taken up, like their other matter for paper, it ran together. But ye lint being heavy, and quickly subsiding they were forc't to stirr it often, and be very quick in their operation. It was thought it might be made much finer and whiter, if it could be made stronger and tough, so as to be fit for any use.

Societies and Academies.

LONDON.

Geological Society, November 4.—N. E. Odell: Preliminary notes on the geology of the eastern parts of central Spitsbergen; with especial reference to the problem of the Hecla Hook formation. Approximately, the area amounts to 2000 square miles, but only a relatively small portion of this could be actually examined. It consists of a mountainous tract much of which is submerged under "highland ice" and glaciers, and is therefore lacking in direct rock-evidence. But through this ice-covering break many "nunatakkar," and, on the west of the region, a high range of mountains—the Chydenius Range—of which Mount Newton (5445 feet) is claimed to be the culminating point of Spitsbergen. The rocks encountered include representatives of the metamorphic basement complex, the Hecla Hook formation (which is intimately associated with that complex), the Carboniferous system, and intrusive acid and basic igneous facies. No evidence was found of rocks earlier in age than the Hecla Hook series, and an Archæan formation must be presumed absent. The greatest acid intrusions are those of the pink and grey granites in the Mount Newton and Mount Chernishev massif, both of the pre-Carboniferous (and presumably pre-Devonian) age. They would appear to have been intruded at the time of the Caledonian folding, and though towards its close, yet prior to the earliest Devonian sedimentation. Except in the south, on the Nordenskiöld Glacier, the Devonian strata are entirely absent, having been eroded from the interfolded Hecla Hook sediments and granites before the transgression of the Upper Carboniferous sea. The Carboniferous is confined to the coast of Hinlopen Strait, from Cape Fanshawe so far south as Bismarck Strait, while Triassic deposits were not seen north of the latter.—K. S. Sandford: The geology of North-East Land (Spitsbergen). North-East Land is separated by a narrow strait from the main island of Spitsbergen, and is about 8000 square miles in area. A great part of the coast and the whole of the interior are completely hidden by ice, which forms a dome rising to about 2400 feet. The northern area consists of Older Palæozoic rocks, granite, and gneiss; the last two being probably younger than the ancient sedimentary rocks. A pink granite penetrates them, and has been found extensively developed in the southern part of this "northern oldland." An important discovery in 1924 was the south-eastern corner of this pink granite, in the middle of the east coast, which previously had been known only as an unbroken and precipitous ice-front over 100 miles long. The southern area of the Island is delimited from the northern by an east-and-west fjord. This is an area of undisturbed Upper Carboniferous and Permian-Carboniferous clays and cherts, to a visible thickness of more than 1000 feet: the fauna belongs to the Russian Province. The history of the Island has been one of quiescence and immunity from folding, in an area of shallow seas. It has been affected by vertical movements, also by acid intrusions (Palæozoic) and by basic intrusions (Cretaceous).

Royal Anthropological Institute, November 10.—J. P. T. Burchell: The "shell-mound" industry of Denmark as represented at Lower Halstow, Kent. The stratified finds made during 1924 in the coastal sections between Swalecliffe and Reculver upon the north coast of Kent consisted of a medieval midden

of the fifteenth century containing roughly worked flint instruments for the purpose of opening up the shells of the oyster, cockle, whelk, and winkle; a midden of the Roman period containing pottery fragments, in addition to a series of occupation sites of the Early Iron Age in which were found several types of the pottery of that period accompanied by a few flint implements and flakes. A flint implement of Early St. Acheul times was found in the underlying Pleistocene gravels. This is the first instance of an implement being found *in situ* in these particular gravel sections. Further excavations were carried on during the current year. The site in question is on the western side of a tongue of land running out northwards into the centre of the Upchurch Marshes. Here, resting upon the surface of the London Clay, is a factory site of the Shell Mound period. This site consists of a series of circular patches 3 feet to 4 feet wide and 3 inches to 4 inches deep. They are composed of blackened earth and calcined flints. The implements occur most freely in these patches. The characteristic implements of the industry are the adze and "shell mound" axe or tranche, whilst flakes, cores, core scrapers, core dressings, chisel-ended flakes, blades, discs, borers, points and scrapers of the end, round, side and hollow types, are well represented. A round quartzite pebble with both faces countersunk and two opposing ends much bruised was also found.

Optical Society, November 12.—S. A. Emerson: Some recent improvements in modern ophthalmic lenses. The paper discusses the limitations inherent in the usual forms of fused bifocal lenses, and the methods now being adopted for overcoming these limitations. In the newer bifocals the glass used for the reading segment has the same relative dispersion as that of the major lens. The fused lens has thus no more chromatic aberration in the reading portion than has an ordinary single lens of the power of the reading portion made from either glass. In the fused bifocals as usually made there is very limited control of the centering of the reading portion. By using suitably shaped reading portions, this difficulty has been largely overcome. For medium and high-power lenses, a reduction in weight and an improvement in appearance, together with an increase in the field of view, have been obtained.—W. Swaine: Relation of visual acuity and accommodation to ametropia. Artificially produced results on the author's own eye are compared with his theoretical table showing how degrees of ametropia affect visual badness (*i.e.* inverse of acuity).—H. H. Emsley: Irregular astigmatism of the eye—effect of correcting lenses. Experiments to test the grating acuity of the eye in different meridians reveal the presence of irregular acuity, or irregular astigmatism as it is called.—E. F. Fincham: Some causes of apparent astigmatism of the eye, other than cylindrical errors of refraction. Measurements of visual acuity of a hypermetropic eye were made with a grating test. These showed that although the eye was able to make the necessary adjustment of the accommodation to correct the hypermetropic error for any meridian, the acuity varied considerably in different meridians. Variations of acuity in different meridians can be explained upon the assumption of the presence of "veins" of unequal refractive index in the media, or the striated character of the crystalline lens. Owing to the hexagonal packing of the foveal cones, the separation of their outer extremities (presumably the sense organs) is different in different meridians. The separation is least in the three meridians in which lie the centres of adjacent hexagons.

DUBLIN.

Royal Dublin Society, October 27.—L. B. Smyth: A contribution to the geology of Great Orme's Head. Great Orme's Head in North Wales consists of at least 1230 feet of Carboniferous limestone. The uppermost 180 feet are nearly barren, cherty limestones. They rest upon 50 feet of dark limestones and shales, the Bishop's Quarry beds, with a considerable fauna, including *Productus giganteus* (Mart.) in prodigious numbers, and *Posidonomya becheri* (Bronn.). Correlation is suggested with "Upper D₂" (Lamellibranch beds) of Garwood and Goodyear in the Craven district. The next 700 feet consist of pale to white limestones, graduating below to dark brown, with a few shales at the base. The latter have a fauna containing D₁ and D₂ forms. Below these shales all the limestone is dolomitised and no identifiable fossils were obtained. The thickness of the dolomite exposed is apparently 700 feet, but, owing to faults, may be only 300 feet. The base is hidden. One new species, *Chsiophyllum delicatum*, is described. Contemporaneous erosion is indicated at five horizons by the occurrence of local unconformities, limestone conglomerate, and current-bedded limestones and sandstones. The anomalous position of a mound of cherty limestone is probably due to transport by ice.

EDINBURGH.

Royal Society, November 9.—J. W. Gregory: (1) Scottish drumlins. Kames and drumlins are two of the most familiar features in Scottish scenery due to glacial deposits. Drumlins are elongated mounds of boulder clay which generally occur in parallel series and each has a steep broad bluff at one end, and tapers gently at the other. This form has been often attributed to the direct action of the ice by the deposition of the clay around a core of closely packed boulders. It is generally stated that drumlins are parallel to the direction of the ice movement. The Scottish drumlins have no such boulder core, and they are generally oblique to the ice movement, and are often at right angles to it. They are parallel to the prevalent wind direction as shown by the bending of the trees upon their crests. They are regarded as the characteristic form developed by boulder clay under the combined action of wind and rain. Some drumlins rest upon a core of rock which then determines their alignment; in these cases the effect of wind erosion is often shown by the development of secondary drumlins on the sides of the major drumlins. (2) Scottish kames. Kames are ridges of sand and gravel deposited during the melting of the ice sheets of the glacial period. They have been often identified with the Swedish osar and attributed to deposition in rivers flowing under or through glaciers. The distribution of the Scottish kames—excluding formations so-called which are moraines, drumlins, or banks left by the denudation of sheets of gravel—gives no support to this view, but shows that, like the ordinary Irish eskers, the American kames and similar formations in Finland, they were deposited as banks of gravel on the margin of an ice sheet melting in water. The chief Scottish kames occur at intervals along a line through eastern Scotland from Caithness to Berwickshire. They are all earlier than the 100-ft. raised beach except one at Dornoch. They are absent from the Highland Plateau, on which they would be expected to occur if due to sub-glacial rivers.—J. M. Wordie: Notes on the geology of Jan Mayen: The bulk of the island consists of lavas of basaltic composition, for the most part trachy-basalts; but among the early eruptions trachytes and andesites are found. In

places there are great thicknesses of tuff, and sills of basic constitution are everywhere prominent. Beerenberg (8090 ft.) has never been active in historic times.—G. W. Tyrrell: The petrography of Jan Mayen. The Jan Mayen lavas consist of a mildly-alkalic series ranging from ankaramite (ultrabasic olvine-basalt), through trachy-basalts of various types, trachyandesites, to trachytes, of which seven new chemical analyses have been made. The suggested sequence of eruption is trachyte, trachy-basalt, and ankaramite, due to the downward freezing of a gravity-stratified magma.—Martin A. Peacock: The geology of Videy, S.W. Iceland; a record of igneous action in glacial times. The basement-rocks of Videy are a disturbed, downward succession of palagonite-tuff and breccia with included glacial blocks, "globular basalt" (akin to pillow-lava), and fine-grained, shattered basalt. Their structural and petrographic peculiarities may be explained by assuming that they were formed by "sub-glacial extrusion."

PARIS.

Academy of Sciences, October 19.—J. Costantin: An unsuspected case of plant pathology.—d'Arsonval; F. Bordas and F. Touplain: The determination of the régime of mineral springs. A description of automatic instruments used for recording the temperature and output of the spring, and for taking a sample when a determined temperature is attained.—Riquier: Some problems relating to the partial differential equation $(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2})u = 0$.—A. Calmette,

J. Valtis, L. Nègre and A. Boquet: Experimental infection through the placenta by the filtrable elements of the tubercular virus. Under certain experimental conditions the filtrable virulent elements arising from tuberculous products or from cultures of Koch bacilli, inoculated under the skin of guinea-pigs, can pass through the placenta, infect the fetus and determine tuberculous lesions.—Paul Mentré: The simultaneous projective deformations of a congruence and of its two focal surfaces.—André Roussel: The method of adjunction of the calculus of variations.—Const. Parvulesco: The distribution of the stars in the globular clusters M.9, M.10, M.12, and the kinetic theory of gases.—Georges Fournier: The period of decay of radium E. The values found by the author, 4.86 days and 4.84 days, confirm the earlier results of Thaller (4.85 days), and are not in agreement with the recent figure of 4.98 days found by Bastings.—Jean Jacques Trillat: A method, using X-rays, by means of which the course of certain chemical reactions (the oxidation of unsaturated fatty acids) can be followed. A thin layer of the unsaturated acid was placed on a sheet of lead, and X-ray spectrographs taken at intervals. By this method the steps in the oxidation of oleic, linoleic and linolenic acids can be studied. The oxidation is brought about by successive additions of the same quantity of oxygen; and is accompanied by a molecular elongation of the order of 6 or 7 Å.U. This elongation renders the system unstable and is followed by polymerisation.—Fred Viès and Mlle. Madeleine Gex: The behaviour of benzene in the presence of aqueous solutions: the ultra-violet absorption as a function of the pH. The experimental results are given as a curve, showing the ratio of the absorptions $[\lambda 260]/[\lambda 254]$ as a function of the pH. The benzene molecule is not inert towards the hydrogen ions of the solution.—H. Forestier and G. Chaudron: The points of magnetic transformation in the system ferric oxide-magnesia. The study of the relation between temperature and

the magnetic properties of mixtures of ferric oxide and magnesia prove the existence of magnesium ferrite, $\text{MgO} \cdot \text{Fe}_2\text{O}_3$. Ferrites of nickel, lime and cadmium, which are attracted by a magnet, have also been prepared.—A. Boutaric and Mlle. G. Perreau: The influence of some stable colloids on the flocculation of sols and of suspensions.—J. L. Costa: The mass spectra of some light elements. The values found are for hydrogen 1.0074 (positive ion) or 1.0079 (neutral atom); lithium 6.009 and 7.012.—Francis Perrin: The Brownian movement of rotation.—Picon: The action of a vacuum and of heat on the neutral and basic nitrates of bismuth. The estimation of the water of constitution and of nitric acid in these salts.—Const. A. Ktenas: The eruption of the volcano of Santorin. The morphological characters.—René Souèges: The embryogeny of the Crassulaceæ. Development of the embryo in *Sedum acre*.—Marc Bridel: The presence of two new ferments, primeverosidase and primeverase, in the emulsion of almonds.—G. Rivière and G. Pichard: The posterity of *Amygdalopersica Formontii*.—René Hazard and L. J. Mercier: The action of tropanol on the heart.—Armand Dehorne: Indications on the inome of some cellular categories.—M. and Mme. Georges Teissier: The embryonic growth of *Chrysaora hysocella*.—Samec: The enzymatic hydrolysis of natural and synthetic amylophosphates.—Agasse Lafont and Roger Douris: The subcutaneous injection of gaseous substances such as oxygen.

SYDNEY.

Royal Society of New South Wales, September 2 — A. R. Penfold: The essential oil of *Eriostemon myoporoides*. This Rutaceous plant occurs along the coast to tableland districts of New South Wales, Victoria and Queensland, being very abundant at Emu Plains in the former State. The leaves and terminal branchlets yielded 0.75 per cent of a very mobile yellow oil. Its principal constituents proved to be d-a-pinene (75-85 per cent), ocimene, Ledum camphor, m.pt. 104° C., a sesquiterpene resembling aromandendrene, methyl anthranilate, a paraffin of m.pt. 64°-65° C., with traces of a phenolic body.—Sir George Knibbs: The human sex-ratio and the reduction of masculinity through large families. The live births in all western countries show an excess of males, and still births an even greater excess. Multiple births show greater femininity than ordinary. In Australia the proportion of females increases with the size of the family; thus in families of 1 to 3 there are 391 more boys than girls in 10,000 children; in families of 4 and 5 only 317 more; in families of 6, 7, 8, and 9 only about 246 more; in families of 10, 11, and 12 only 235 more. Taking the size of family given in "Who's Who," and using about half of the entries, the proportion is almost exactly what could have been predicted solely from the methods of probability, assuming equal chances for males and females. For example, in families of seven, the numbers for 7 boys, 6 boys and 1 girl, 5 boys and 2 girls, 4 boys and 3 girls, etc., were actually as on the top line

1	5	15	26	23	21	6	1
1	5	16	27	27	16	5	1

The bottom line shows what might have been expected from probability. The masculinity, however, while it falls on the whole, is somewhat variable. There is a difference in the relative number of males in the living and deceased issue of families of from 1 to 9. The Australian results are based on 81,375 families and 454,372 children.—G. J. Burrows and A. E. James: Molecular solution volumes and association. A comparison of the solution volumes

of several solutes in benzene, toluene, methyl alcohol and acetone suggests that the molecular solution volume is always greater in non-associated liquids such as benzene than in associated liquids such as methyl alcohol. When the solute is not associated the difference is small, but in the case of an associated solute there is a marked difference between its volume in benzene or toluene and that in alcohols or acetone. The molecular solution volume of a non-associated solute in any of these liquids does not differ very much from the molecular volume of the solute in the liquid condition, whereas an appreciable difference is observed in the case of an associated solute dissolved in an associated solvent.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 11, No. 10, October).—Francis G. Benedict and Elizabeth E. Crofts: The fixity of basal metabolism. For a normal subject, half an hour's repose is sufficient to establish a condition giving trustworthy measurements of basal metabolism on any individual day. Even when exposure has reduced the skin temperature considerably, oxygen consumption measurements indicate that heat production is unchanged and thus independent of heat loss.—Tracy Yerkes Thomas: (1) Announcement of a projective theory of affinely connected manifolds. (2) On the equi-projective geometry of paths. Most of the theorems have their counterpart in the affine geometry of paths.—H. P. Robertson: Transformations of Einstein spaces.—Otto Oldenberg: On fluorescence radiation of nitrogen. A condensed spark arrangement is included inside a bulb containing the gas at very low pressure, and a ray from the spark excites faint fluorescence along its path. The fluorescence has a pure band spectrum containing bands due to the fluorescing ion and the fluorescing molecule.—A. H. Compton and R. L. Doan: X-ray spectra from a ruled diffraction grating. The grating was ruled on speculum with comparatively large grating spaces ($D = 2.000 \times 10^{-3}$ cm.), and light ruling and very small glancing angles were used. Wave-lengths measured thus agree well with those obtained by reflection from a crystal.—Ralph D. Bennett: An attempt to test the quantum theory of X-ray scattering. Simultaneous registration of a recoil electron and a scattered X-ray quantum, at the angles predicted by Compton's theory, would be favourable evidence. Using Geiger point discharge counters and a solid, or hydrogen or air as a scattering target, co-incident effects were obtained, but they occurred in groups.—P. W. Bridgman: (1) The viscosity of liquids under pressure. For water, at low temperatures viscosity decreases with rising pressure to a minimum and then increases. This minimum disappears above about 25° C. All other liquids examined show uniform increase of viscosity with pressure, at first linearly but above 1000 kgm./sq. cm., the rate of increase grows rapidly, and generally the logarithmic curve becomes nearly straight. The temperature coefficient of viscosity also increases with pressure. (2) Thermal conductivity and thermo-electromotive force of single metal crystals. Thermal conductivity and thermo-electromotive force for bismuth, zinc, cadmium, and tin crystals for the range room-temperature to 100° C. were measured as a function of direction in the crystal. The results lead to the conclusion that there is a reversible absorption of heat within the crystal on changing the direction of the current (internal Peltier heat effect).—H. B. Wahlin: The aging effect in the mobility of positive ions.—J. H. Van Vleck: On the quantum theory of the polarisation of resonance radiation in magnetic fields.—H. C. Urey: The structure of the hydrogen molecule ion.

The energy is calculated of the steady state of lowest energy of the hydrogen molecule ion, when the electron vibrates in a straight line perpendicular to, and through the mid point of, the line joining the nuclei.—Albert L. Raymond: The mechanism of carbohydrate utilisation. The steps in alcoholic fermentation are, briefly, hexose monophosphate ester, cleavage into two triose groups, one containing all the phosphorus, the latter becoming hexose diphosphate and the former yielding alcohol and carbon dioxide; and the hydrolysis of the diphosphate back to hexose. Carbohydrate metabolism in the animal is believed to be similar.—William D. Harkins: The separation of chlorine into isotopes (isotopic elements) and the whole-number rule for atomic weights. By diffusion through the walls of clay pipe-stems, hydrogen chloride was obtained containing chlorine of atomic weight 35.477, as compared with 35.4574 for ordinary chlorine. It is hoped to investigate with this light fraction the spectral shift due to isotopes as found for ordinary lead and the lead produced by disintegration of uranium.—William D. Harkins and W. G. Guy: The radio-activity of potassium, rubidium, and other elements. The natural leak of a large ionisation chamber is balanced against that of a small chamber containing uranium oxide covered with aluminium foil to exclude α -radiation. The salts examined were placed in the large chamber, and the activities of rubidium and potassium found are as 1:39:1.00. It is concluded that the disintegration of an isotope is the source of the radiation from potassium.—William D. Harkins and Norvil Beeman: The oriented wedge theory of emulsions. If the oil-like or non-polar end of the soap molecule is smaller than the polar end, the emulsion will be one of oil in water; if the reverse be the case, the droplets will be of water. The size of the greatest number of drops is so much greater than the size of the sodium oleate molecule that it cannot be expected that the molecule should determine the size of the drop. Emulsifying agents, the molecules of which have larger non-polar or polar ends, are required to test the theory.—Williams D. Harkins and J. W. Morgan: Polymolecular and monomolecular films. Young's modulus for steel being about 12,000, that of a monomolecular film such as stearic acid on water is 39; a polymolecular film is generally much weaker. Films of mixed substances each giving a monomolecular film are also monomolecular.—William D. Harkins and S. B. Stone: The isotopic composition of the element chlorine in the meteorites: the atomic weight of meteoric and terrestrial chlorine (see NATURE, September 19, p. 426).—George L. Clark, P. C. McGrath, and M. C. Johnson: The effect of X-rays on the platinum catalyst in the contact sulphuric acid reaction. X-rays do not improve the yield if dry air is used. With moist air, an enormously greater conversion is obtained which is further increased, but only temporarily, by radiation of the catalyst.—Wm. H. Gates: The Japanese waltzing mouse, its origin and genetics. Both the waltzing and non-waltzing form of the Japanese mouse are derivatives of *Mus wagneri*, a native of Central Asia, and not of the common house mouse. In a cross with the latter, the characters of the waltzer tended to remain together in the F_2 generation.—A. J. H. Russell: A statistical approach to the epidemiology of cholera in Madras Presidency. The monthly mortality figures for the period 1902–21 are used, and the population dealt with numbers 43 millions. There is an annual and a six-yearly periodicity and a varying relationship in different areas with rainfall.—Harold Hotelling: The distribution of correlation ratios calculated from random data.—E. W. Stearn, B. F. Sturdivant, and A. E. Stearn: The life-history of a micro-parasite isolated from carcino-

matous growths. Cultures or extracts of carcinomatous tissue give an organism the life-history of which seems to include rods, thread-like forms with tapering ends, cocci of various sizes, and large sporing bodies. The optimum temperature is 37° – 41° C. In fluid from the tissue it is almost invisible and passes filters, but can be detected as a loosely coiled spirillum. In cultured colonies, under certain conditions, orthorhombic crystals appeared.

(Un nouveau phénomène électrocinétique: étude de l'électrocapillarité de l'oxide tellureux fondu.) Napsal A. Šimek a H. Kadlcová. Pp. 21+2 tab. Čís. 62: Rhamphorhynchus Gemmingeri, H. v. Meyer. Napsal Fr. Rikovsky. Pp. 14. Čís. 63: O absorpci plyného chlorovodíku v kyselině sírové. (The Absorption of Gaseous Hydrogen Chloride by Sulphuric Acid.) Napsal Václav Čupr. Pp. 13. (Brno.)

Diary of Societies.

MONDAY, DECEMBER 7.

- ROYAL SOCIETY OF EDINBURGH, at 4.30.—W. J. M. Menzies: Salmon (*Salmo salar*) of the River Moisie, Eastern Canada.—Fred. J. Symon: The Diffusion of Salt Vapours in a Bunsen Flame.—William Cooper: Note on Copper-tinted Flame Caps.—F. A. E. Crew: Prenatal Death in the Pig, and its Effect upon the Sex-Ratio.—E. L. Ince: Researches into the Characteristic Numbers of the Mathieu Equation.—T. M. MacRobert: The Addition Theorem for the Legendre Functions of the Second Kind.—Sir Thomas Muir: The Theory of Continuants from 1900 to 1920.
- VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—G. B. Michell: Scientific Criticism of the Bible.
- BIOCHEMICAL SOCIETY (in the Biochemical Laboratory, Imperial College of Science and Technology), at 5.—H. W. Buston and S. B. Schryver: The Isolation of some Further Undescribed Products of the Hydrolysis of Proteins.—H. Martin and S. B. Schryver: The Action of an Electric Field on Egg Albumin.—H. Chick: Sources of Error in the Biological Method of Investigating Fat-soluble Vitamins.—W. V. Thorpe: The Action of Enzymes on the Oxytocic Principle of the Pituitary.—R. K. Cannan: Potentiometric Studies in Biological Oxidation-Reductions.—D. T. Harris: The Action of Light on Blood.
- SOCIETY OF ENGINEERS (at the Geological Society), at 5.30.—H. E. I. Taylor: The Growth of the Gothic Church Window.
- BRITISH PSYCHOLOGICAL SOCIETY (Education Section) (Annual General Meeting) (at London Day Training College), at 6.—Prof. T. P. Nunn: Some Notes of a Visit to American Educational Institutions.
- INSTITUTION OF STRUCTURAL ENGINEERS (Students' Meeting) (at Abbey House, 2 Victoria Street), at 6.—E. F. Michells and others: Discussion on How to pass Examinations.
- ROYAL INSTITUTION, at 7.—General Meeting.
- INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—C. L. Lipman and others: Discussion on Design and Performance of Protective Relays.
- INSTITUTION OF AUTOMOBILE ENGINEERS (Loughborough Graduates' Meeting) (at the College, Loughborough), at 7.
- NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Graduate Section) (at Middlesbrough), at 7.30.—W. Goldsborough: Testing of Turbo-Blowers.
- OPTICAL SOCIETY (at Imperial College of Science), at 7.30.
- INSTITUTION OF STRUCTURAL ENGINEERS (Midland Counties Branch) (at Birmingham), at 7.30.
- ARISTOTELIAN SOCIETY (at University of London Club), at 8.—C. R. Morris: Judgment as the Fundamental Act of Knowledge.
- ROYAL SOCIETY OF ARTS, at 8.—Dr. R. Lessing: Coal Ash and Clean Coal (Cantor Lectures, III.).
- SURVEYORS' INSTITUTION, at 8.—Col. C. H. Bressley: Modern Methods of Roadmaking.
- ROYAL GEOGRAPHICAL SOCIETY (at Aeolian Hall), at 8.30.—Prof. L. W. Collet: The Lakes of Scotland and of Switzerland.
- BIOCHEMICAL SOCIETY (at Imperial College of Science).
- SOCIETY OF CHEMICAL INDUSTRY (London Section) (Joint Meeting with the Institute of Chemistry, London and South-Eastern Counties Section) (at Institution of Mechanical Engineers), at 8.—W. J. U. Woolcock: Five Years of Progress in the Fine Chemical Industry.

TUESDAY, DECEMBER 8.

- MANCHESTER GEOLOGICAL AND MINING SOCIETY, at 4.
- INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—J. H. S. Dickenson, B. Gray, and F. E. Cherry: The Selection and Properties of Steels used for Oil Well Boring Equipment.
- INSTITUTE OF MARINE ENGINEERS, at 6.30.—M. L'Hermier: Powdered Fuel Developments.
- INSTITUTION OF ELECTRICAL ENGINEERS (East Midland Sub-Centre) (at the College, Loughborough), at 6.45.—F. J. Mollatt: Address.
- INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—Prof. S. P. Smith: An All-Electric House.
- ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—T. Thorne Baker and F. L. Davidson: A New Physical Method for the Examination of Gelatine.—E. L. Turner and C. D. Hallam: The Basis of the Image in Photo-Lithography.—F. J. Tritton: On the Theory of the Carbro Process.
- INSTITUTION OF ELECTRICAL ENGINEERS (Scottish Centre) (at Royal Technical College, Glasgow), at 7.30.—Major E. I. David: Electricity in Mines.
- INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Centre) (at Broadgate Cafe, Coventry), at 7.30.—General Meeting.
- PHARMACEUTICAL SOCIETY, at 8.—Dr. A. W. Crossley: Cotton (Lantern Lecture).
- ROYAL ANTHROPOLOGICAL INSTITUTE (Indian Section), at 8.15.—Capt. A. M. Hocutt: The Buddha's Illumination.
- INSTITUTION OF MECHANICAL ENGINEERS (Swansea Branch) (at Swansea).—

WEDNESDAY, DECEMBER 9.

- ROYAL SOCIETY OF ARTS (Indian and Dominions and Colonies Sections), at 4.30.—Dr. H. M. Leake: The Imperial College of Tropical Agriculture.
- RADIO SOCIETY OF GREAT BRITAIN (at the Institution of Electrical Engineers), at 6.—A. B. Bawtree: The Acoustics of the Headphone and Loud-Speaker.
- NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Graduate Section) (at Bobbe Hall, Newcastle-upon-Tyne), at 7.—T. B. Davison: Modern Transport.
- INSTITUTION OF ENGINEERS-IN-CHARGE (at St. Bride's Institute, Bride Lane), at 7.30.—J. V. Stevens: Oil Fuel for Commercial Purposes.
- INSTITUTION OF CHEMICAL ENGINEERS (at the Chemical Society, Burlington House).—Col. B. I. Rolling: Magnetic Separation.

INSTITUTION OF MECHANICAL ENGINEERS (Sheffield Branch) (at Sheffield).—H. F. L. Orcutt: Characteristics and Uses of Ground Gears.

THURSDAY, DECEMBER 10.

- LONDON MATHEMATICAL SOCIETY, at 5.—H. Levy: The Analysis of an Empiric Function into its Quasi-Periodic Constituents.—J. C. Burkill: The Expressions in Stieltje's Integrals of the Inversion Formulae of Fourier and Hankel.—W. L. Ferrar: (1) On the Summability (C, k) of Series of the Type $\sum a_n n^k$; (2) Necessary and Sufficient Conditions for Summability (C, r).—T. Stuart: (1) Fermat's Last Theorem: Arguments against a Solution; (2) The Diophantine Equation $X^4 + Y^4 + Z^4 = A W^4$ where $A = 1$ or 3 .—G. H. Hardy and J. E. Littlewood: Two Theorems concerning Fourier Series.—T. Vijayaraghavan: A Tauberian Theorem.
- CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. R. Langdon-Down: The Teaching of Shorthand as Part of a General Education.
- INSTITUTION OF STRUCTURAL ENGINEERS (Yorkshire Branch) (at Great Northern Hotel, Leeds), at 6.30.—E. F. Sargeant: Concrete Granary at Hull.
- INSTITUTE OF METALS (London Local Section) (Joint Meeting with the Institution of British Foundrymen) (in the Rooms of the Institute of Marine Engineers), at 7.30.—J. B. Hoblyn: Commercial Aluminium Alloys from the Users' Point of View.
- SOCIETY OF CHEMICAL INDUSTRY (Bristol Section) (at Bristol University), at 7.30.—S. H. Piper: The Use of X-rays in Chemistry.
- INSTITUTE OF CHEMISTRY (Edinburgh and East of Scotland Section) (Jointly with Society of Chemical Industry, Edinburgh and East of Scotland Section) (at North British Station Hotel, Edinburgh), at 7.30.—R. B. Pilcher: Alchemists and Chemists in Art and Literature.
- INSTITUTION OF ELECTRICAL ENGINEERS (Dundee Sub-Centre) (at University College, Dundee), at 7.30.—J. K. Murray: Some Features of Telegraph Engineering.
- OPTICAL SOCIETY (at Imperial College of Science), at 7.30.—Col. H. S. Winterbotham, Lt.-Col. M. N. MacLeod, and Lt. M. Hotine: Photogrammetric Surveying.
- INSTITUTION OF ELECTRICAL ENGINEERS (Irish Centre) (at Trinity College, Dublin), at 7.45.—J. Lindsay: The Mechanical Winning of Peat (Lecture).
- SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall, Essex Street, Strand), at 8.—Mme. A. Rieder: Population Problems in the Near East.
- OIL AND COLOUR CHEMISTS' ASSOCIATION.

FRIDAY, DECEMBER 11.

- ROYAL ASTRONOMICAL SOCIETY, at 5.—O. Struve: A Study of the Nature of Spectroscopic Binaries.—A. S. Williams: A New Variable Star in Andromeda.
- PHYSICAL SOCIETY OF LONDON (at Imperial College of Science), at 5.—Dr. E. A. Owen and G. D. Preston: On the Effect of Rolling on the Crystal Structure of Aluminium.—R. S. Burdon: The Spreading of One Liquid on the Surface of Another.—J. T. Combridge: On the Advance of the Perihelion of Mercury.
- MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society), at 6.
- INSTITUTION OF MECHANICAL ENGINEERS, at 6.
- INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 6.15.—F. J. Lane: The Rotary Converter Automatic Sub-Station.
- SOCIETY OF CHEMICAL INDUSTRY (Glasgow Section) (at 39 Elmbank Crescent, Glasgow), at 7.—Open Night.
- INSTITUTE OF METALS (Swansea Local Section) (in the Metallurgical Department, University College, Singleton Park), at 7.15.—Prof. J. H. Andrew: Modern Metallurgy.
- INSTITUTE OF METALS (Sheffield Local Section) (in the Non-Ferrous Section of the Applied Science Department of the University, St. George's Square), at 7.30.—Prof. F. C. Thompson: Nickel Silver.
- JUNIOR INSTITUTION OF ENGINEERS (at Royal Society of Arts), at 7.30.—J. S. Highfield: Presidential Address.
- INSTITUTION OF MECHANICAL ENGINEERS (Yorkshire Branch) (at Leeds).—Prof. G. F. Charnock: Chairman's Address.

SATURDAY, DECEMBER 12.

- BRITISH PSYCHOLOGICAL SOCIETY (at University College, London), at 3.—J. J. Strassheim: A New Method in Mental Testing.—Miss A. M. Jenkin: Eidetic Imagery.
- MINING INSTITUTE OF SCOTLAND (at Glasgow).
- PHYSIOLOGICAL SOCIETY (at Bedford College for Women).

PUBLIC LECTURES.

SATURDAY, DECEMBER 5.

- HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Travel and Transport in Ancient Egypt.

MONDAY, DECEMBER 7.

- SCHOOL OF ORIENTAL STUDIES, at 5.30.—(In French) J. Hackin: Les Monuments bouddhiques et les antiquités musulmanes de l'Afghanistan. (Succeeding Lectures on December 8 and 9.)
- UNIVERSITY OF LEEDS, at 8.—Sir Henry Hadow: Chamber Music, illustrated from Beethoven and Modern Composers.

THURSDAY, DECEMBER 10.

- KING'S COLLEGE, LONDON, at 5.15.—A. D. Lindsay: Benedict Spinoza.

SATURDAY, DECEMBER 12.

- HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. H. G. Cannon: Floating Life in the Sea.

Supplement to NATURE

No. 2927

DECEMBER 5, 1925

Atomic Theory and Mechanics.¹

By Prof. N. BOHR, University of Copenhagen.

THE CLASSICAL THEORIES:

THE analysis of the equilibrium and the motion of bodies not only forms the foundation of physics, but for mathematical reasoning has also furnished a rich field, which has been exceedingly fertile for the development of the methods of pure mathematics. This connexion between mechanics and mathematics showed itself at an early date in the works of Archimedes, Galileo, and Newton. In their hands the formation of concepts suitable for the analysis of mechanical phenomena was provisionally completed. Since the time of Newton, the development of the methods for treating mechanical problems has gone hand in hand with the evolution of mathematical analysis; we need only recall such names as Euler, Lagrange, and Laplace. The later development of mechanics too, based on the work of Hamilton, proceeded in very close association with the evolution of mathematical methods, the calculus of variations, and the theory of invariants, as appears clearly in recent times also in the papers of Poincaré.

Perhaps the greatest successes of mechanics lie in the domain of astronomy, but in the mechanical theory of heat an interesting application was also found in the course of the last century. The kinetic theory of gases, founded by Clausius and Maxwell, interprets the properties of gases to a large extent as results of the mechanical interactions of atoms and molecules flying about at random. We wish to recall especially the explanation of the two principles of thermodynamics given by this theory. The first principle is a direct result of the mechanical law of conservation of energy, while the second principle, the entropy law, can, following Boltzmann, be derived from the statistical behaviour of a large number of mechanical systems. It is of interest here that statistical considerations have permitted the description not only of the average behaviour of atoms, but also of the fluctuation phenomena, which have led by the investigation of the Brownian motion to the unexpected possibility of

counting atoms. The proper tools for the systematic development of statistical mechanics, to which especially Gibbs contributed, were furnished by the mathematical theory of canonical systems of differential equations.

The development of the electromagnetic theories in the second half of last century, following the discoveries of Oersted and Faraday, brought about a profound generalisation of mechanical concepts. Although, to begin with, mechanical models played an essential part in Maxwell's electrodynamics, the advantages were soon realised of conversely deriving the mechanical concepts from the theory of the electromagnetic field. In this theory the conservation laws are explained by considering energy and momentum to be localised in the space surrounding the bodies. In particular, a natural explanation of radiation phenomena can be obtained in this way. The theory of the electromagnetic field was the direct cause of the discovery of electromagnetic waves, which to-day play so important a part in electrical engineering. Further, the electromagnetic theory of light founded by Maxwell provided a rational basis for the wave theory of light, which goes back to Huygens. With the aid of the atomic theory it afforded a general description of the origin of light and the phenomena taking place during the passage of light through matter. For this purpose, the atoms are supposed to be built up of electrical particles which can execute vibrations about positions of equilibrium. The free oscillations of the particles are the cause of the radiation, the composition of which we observe in the atomic spectra of the elements. Further, the particles will execute forced vibrations under the forces in the light waves and thus become centres of secondary wavelets which will interfere with the primary waves and produce the well-known phenomena of reflection and refraction of light. When the frequency of vibration of the incident waves approaches the frequency of one of the free oscillations of the atom, there results a resonance effect, by which the particles are thrown into specially strong forced vibrations. In this way a natural account was obtained of the phenomena of resonance radiation and the anomalous dispersion of a substance for light near one of its spectral lines.

¹ This article represents substantially the contents of an address delivered, on August 30, before the sixth Scandinavian Mathematical Congress in Copenhagen. It should be mentioned, however, that the present elaboration of the text has been notably influenced by the appearance, since the delivery of the address, of an important paper by Heisenberg, to which reference is made below.

Just as in the kinetic theory of gases, it is not merely the average effect of a large number of atoms that comes into consideration in the electromagnetic interpretation of optical phenomena. Thus, in the scattering of light the random distribution of the atoms makes the effects of the individual atoms appear in such a way that a direct counting of the atoms is possible. In fact, Rayleigh estimated from the intensity of the scattered blue light of the sky the number of atoms in the atmosphere, obtaining results in satisfactory agreement with the counting of atoms obtained by Perrin from a study of the Brownian motion. The rational mathematical representation of the electromagnetic theory is based on the application of vector analysis, or more generally tensor analysis of higher dimensional manifolds. This analysis founded by Riemann offered the proper means for the formulation of Einstein's fundamental theory of relativity, which introduces concepts that go beyond Galileo's kinematics, and may perhaps be considered as the natural completion of the classical theories.

THE QUANTUM THEORY.

In spite of all the successful applications of mechanical and electrodynamical ideas to atomic theory, further development revealed profound difficulties. If these theories really provide a general description of thermal agitation and of the radiation connected with motion, then the general laws of heat radiation must be capable of a direct explanation. Contrary to all expectations, however, a calculation on this basis could not explain the empirical laws. Going beyond this, Planck demonstrated, retaining Boltzmann's account of the second law of thermodynamics, that the laws of heat-radiation demand an element of discontinuity in the description of atomic processes quite foreign to the classical theories. Planck discovered that in the statistical behaviour of particles which execute simple harmonic oscillations about positions of equilibrium, only such states of vibrations must be taken into account the energy of which is an integral multiple of a "quantum," ωh , where ω is the frequency of the particle and h a universal constant, the so-called Planck's quantum of action.

The more precise formulation of the content of the quantum theory appears, however, to be extremely difficult when it is remembered that all the concepts of previous theories rest on pictures which demand the possibility of a continuous variation. This difficulty was especially emphasised by the fundamental researches of Einstein, according to which essential features of the interaction between light and matter suggest that the propagation of light does not take place by spreading waves but by "light-quanta,"

which, concentrated in a small region of space, contain the energy $h\nu$, where ν is the frequency of the light. The formal nature of this statement is evident, because the definition and measurement of this frequency rests exclusively on the ideas of the wave theory.

STRUCTURAL UNITS OF THE ATOM.

This inadequacy of the classical theories was brought into prominence by the development of our knowledge of atomic structure. One formerly hoped that this knowledge might be gradually enlarged by an analysis of the properties of the elements based on the classical theories, which had been fruitful in so many respects. This hope was supported shortly before the birth of the quantum theory by Zeeman's discovery of the effect of magnetic fields on spectral lines. As Lorentz showed, this effect corresponds in many cases to just that action of magnetic fields on the motion of oscillating particles which is to be expected from classical electrodynamics. Besides, this account allowed conclusions to be drawn about the nature of the oscillating particles which agreed beautifully with the experimental discoveries of Lenard and Thomson in the field of electric discharges in gases. As a result, small negatively charged particles, the electrons, were recognised as units common to all atoms. It is true that the so-called "anomalous" Zeeman effect of many spectral lines caused profound difficulties for the classical theory. These were similar to those which showed themselves in the attempts with the aid of electrodynamic models to explain the simple empirical regularities among the spectral frequencies, which were brought to light through the work of Balmer, Rydberg, and Ritz. In particular, such an account of the spectral laws could scarcely be reconciled with the estimate of the number of electrons in the atom which Thomson obtained from observations on the scattering of X-rays by a direct application of the classical theory.

These difficulties could for a time be attributed to our imperfect knowledge of the origin of the forces by which the electrons are bound in the atom. The situation was, however, entirely changed by the experimental discoveries in the field of radio-activity, which furnished new means for the investigation of atomic structure. Thus, Rutherford obtained convincing support for the idea of the nuclear atom from experiments on the passage through matter of the particles ejected by radio-active substances. According to this idea, the greatest part of the atomic mass is localised in a positively charged nucleus, exceedingly small compared with the dimensions of the atom as a whole. Around the nucleus there move a number of light negative electrons. In this way, the problem of atomic structure took on a great similarity to the

problems of celestial mechanics. A closer consideration, however, soon showed that, nevertheless, there exists a fundamental difference between an atom and a planetary system. The atom must have a stability which presents features quite foreign to mechanical theory. Thus, the mechanical laws permit a continuous variation of the possible motions, which is entirely at variance with the definiteness of the properties of the elements. The difference between an atom and an electrodynamic model appears also when one considers the composition of the emitted radiation. For, in models of the sort considered, where the natural frequencies of motion vary continuously with the energy, the frequency of the radiation will change continuously during emission according to classical theory and will therefore show no similarity to the line spectra of the elements.

QUANTUM THEORY OF ATOMS.

The search for a more precise formulation of the concepts of the quantum theory which might be capable of overcoming these difficulties led to the enunciation of the following postulates:

1. An atomic system possesses a certain manifold of states, the "stationary states," to which corresponds in general a discrete sequence of energy values and which have a peculiar stability. This latter shows itself in that every change in the energy of the atom must be due to a "transition" of the atom from one stationary state to another.

2. The possibility of emission and absorption of radiation by the atom is conditioned by the possibility of energy changes of the atom, in such a way that the frequency of the radiation is connected with the energy difference between the initial and final states by the formal relation

$$h\nu = E_1 - E_2.$$

These postulates, which cannot be explained on classical ideas, seem to offer a suitable basis for the general account of the observed physical and chemical properties of the elements. In particular, an immediate explanation is given of a fundamental feature of the empirical spectral laws. This feature, the Ritz principle of combination of spectral lines, states that the frequency of every line in a spectrum can be represented as the difference between two terms of a manifold of spectral terms characteristic of the element; in fact, we see that these terms can be identified with the energy values of the stationary states of the atom, divided by h . In addition, this account of the origin of spectra gives an immediate explanation of the fundamental difference between absorption and emission spectra. For, according to the postulates, the condition for selective absorption of a frequency which corre-

sponds to the combination of two terms is that the atom is in the state of smaller energy, while for emission of such radiation, it must be in the state of greater energy. In short, the picture described is in very close agreement with the experimental results on the excitation of spectra. This is shown especially in the discovery of Franck and Hertz as to impacts between free electrons and atoms. They found that an energy transfer from the electron to the atom can take place only in amounts which are just the energy differences of the stationary states as computed from the spectral terms. In general, the atom is simultaneously excited to emit. Similarly, the excited atom can, according to Klein and Rosseland, lose its emissive power through an impact, and the colliding electron experiences a corresponding increase of its energy.

As Einstein has shown, the postulates also furnish a suitable basis for a rational treatment of statistical problems, especially for a very lucid derivation of Planck's law of radiation. This theory assumes that an atom, which can undergo a transition between two stationary states and is in the higher state, shows a certain "probability," depending only on the atom, of jumping spontaneously to the lower state in a given interval of time. Further, it assumes that external illumination with radiation of the frequency corresponding to the transition gives the atom a probability, proportional to the intensity of the radiation, of going from the lower to the higher state. It is also an essential feature of the theory that illumination with this frequency gives the atom in the higher state, besides its spontaneous probability, an induced probability of jumping down to the lower state.

QUANTUM THEORY OF RADIATION.

While Einstein's theory of heat radiation gives support to the postulates, it accentuates the formal nature of the frequency condition. For from the conditions for complete thermal equilibrium, Einstein draws the conclusion that every absorption and emission process is accompanied by a transfer of momentum of amount $h\nu/c$, where c is the velocity of light, just as the idea of light quanta would lead one to expect. The significance of this conclusion has been emphasised in a very interesting way by the discovery of Compton that the scattering of homogeneous X-rays is accompanied by a change of wave-length in the scattered radiation depending on the direction of observation. Such a change in frequency follows in a simple way from the light-quantum theory if in the deflexion of the quantum one takes into account the conservation of momentum as well as energy.

The constantly growing contrast between the wave theory of light, apparently required for the explanation

of optical phenomena, and the light-quantum theory, which represents naturally so many features of the interaction between light and matter, suggested that the failure of classical theories may even affect the validity of the laws of conservation of energy and momentum. These laws, which hold so central a position in the classical theory, would, then, in the description of atomic processes, be only statistically valid. However, this suggestion does not offer a satisfactory escape from the dilemma, as is shown by the experiments on the scattering of X-rays which have been undertaken recently with the beautiful methods permitting a direct observation of individual processes. For Geiger and Bothe have been able to show that the recoil electrons and photo-electrons which accompany the production and absorption of the scattered radiation are coupled in pairs just as one would expect from the picture of the light-quantum theory. With the method of the Wilson cloud chamber, Compton and Simon have even succeeded in demonstrating, besides this pairing, the connexion demanded by the light-quantum theory between the direction in which the effect of the scattered radiation is observed and the direction of the velocity of the recoil electrons accompanying the scattering.

From these results it seems to follow that, in the general problem of the quantum theory, one is faced not with a modification of the mechanical and electro-dynamical theories describable in terms of the usual physical concepts, but with an essential failure of the pictures in space and time on which the description of natural phenomena has hitherto been based. This failure appears also in a closer consideration of impact phenomena. In particular, for impacts in which the time of collision is short compared to the natural periods of the atom and for which very simple results are to be expected according to the usual mechanical ideas, the postulate of stationary states would seem to be irreconcilable with any description of the collision in space and time based on the accepted ideas of atomic structure.²

THE CORRESPONDENCE PRINCIPLE.

Nevertheless, it has been possible to construct mechanical pictures of the stationary states which rest on the concept of the nuclear atom and have been essential in interpreting the specific properties of the elements. In the simplest case of an atom with only one electron, such as the neutral hydrogen atom, the orbit of the electron would be in classical mechanics a closed ellipse, obeying Kepler's laws, according to which the major axis and frequency of revolution are

connected in a simple way with the work necessary for a complete separation of the atomic particles. Now if we regard the spectral terms of the hydrogen spectrum as determining this work, we see in that spectrum evidence of the steplike process through which the electron under emission of radiation is gradually bound more and more firmly in states visualised as orbits of smaller and smaller dimensions. When the electron is bound as firmly as possible, and the atom can therefore emit no further radiation, the normal state of the atom has been reached. The orbital dimensions estimated from the spectral terms have values for this state of the same order of magnitude as the atomic dimensions obtained from the mechanical properties of the elements. From the nature of the postulates, however, such features of the mechanical pictures as frequency of revolution and shape of the electronic orbits are not open to comparison with observations. The symbolic character of these pictures can scarcely be more strongly emphasised than by the fact that in the normal state no radiation is emitted, although according to the mechanical picture the electron is still moving.

Nevertheless, the visualisation of the stationary states by mechanical pictures has brought to light a far-reaching analogy between the quantum theory and the mechanical theory. This analogy was traced by investigating the conditions in the initial stages of the binding process described, where the motions corresponding to successive stationary states differ comparatively little from each other. Here it was possible to demonstrate an asymptotic agreement between spectrum and motion. This agreement establishes a quantitative relation by which the constant appearing in Balmer's formula for the hydrogen spectrum is expressed in terms of Planck's constant and the values of the charge and mass of the electron. The essential validity of this relation was clearly illustrated by the subsequent test of the predictions of the theory regarding the dependence of the spectrum on the nuclear charge. The latter result may be considered as the first step towards the fulfilment of the programme presented by the concept of the nuclear atom, to account for the relationships between the properties of the elements solely by means of the integer which represents the number of unit charges on the nucleus, the so-called "atomic number."

The demonstration of the asymptotic agreement between spectrum and motion gave rise to the formulation of the "correspondence principle," according to which the possibility of every transition process connected with emission of radiation is conditioned by the presence of a corresponding harmonic component in the motion of the atom. Not only do the frequencies of the corresponding harmonic components agree

² For a closer discussion of these problems reference may be made to a recent article of the writer; compare in particular the addendum (*Zs. für Phys.* 34, 142, 1925).

asymptotically with the values obtained from the frequency condition in the limit where the energies of the stationary states converge, but also the amplitudes of the mechanical oscillatory components give in this limit an asymptotic measure for the probabilities of the transition processes on which the intensities of the observable spectral lines depend. The correspondence principle expresses the tendency to utilise in the systematic development of the quantum theory every feature of the classical theories in a rational transcription appropriate to the fundamental contrast between the postulates and the classical theories.

THE RULES OF QUANTISATION.

The development was considerably furthered by the fact that it seemed possible to formulate certain general laws, the so-called rules of "quantisation," by means of which the mechanical motions associated with the stationary states were to be chosen from the continuous manifold of such motions. These rules concern atomic systems for which the solution of the mechanical equations of motion is simply- or multiply-periodic. In these cases the motion of every particle can be represented as a superposition of discrete harmonic vibrations. According to the rules of quantisation which were considered to be a rational generalisation of Planck's original result for the possible energy values of an harmonic oscillator, certain components of action which characterise the solution of the mechanical equations of motion are put equal to integral multiples of Planck's constant. By means of these rules a classification of the stationary states results in which a set of integers, the "quantum indices," is ascribed to every state. Their number is equal to the degree of periodicity of the mechanical motion.

In formulating the rules of quantisation the modern development of the mathematical methods of dealing with mechanical problems was of decisive importance. We need recall only the theory of phase integrals utilised in particular by Sommerfeld, as well as the property of adiabatic invariance of these integrals emphasised by Ehrenfest. The theory was given a very elegant form by the introduction of the uniformising variables of Stäckel. In this form the fundamental frequencies determining the periodicity properties of the mechanical solution appear as the partial derivatives of the energy with respect to the components of action to be quantised. The asymptotic connexion between the motion and the spectrum as calculated from the frequency condition is secured in this way.

With the help of the rules of quantisation, many finer details of spectra seemed to be accounted for naturally. Of especial interest was Sommerfeld's demonstration, that the small deviations from a Keplerian motion,

which result from the modification of Newtonian mechanics demanded by the relativity theory, offer an explanation of the fine-structure of the hydrogen lines. Furthermore, we would recall here the explanation given by Epstein and Schwarzschild of the splitting up of the hydrogen lines in an external electric field which Stark discovered. We are here dealing with a mechanical problem, the treatment of which was much improved in the hands of mathematicians like Euler and Lagrange, until Jacobi stated his famous elegant solution by means of Hamilton's partial differential equation. Especially after the utilisation of the correspondence principle—by which not only the polarisation of the Stark effect components was interpreted, but also, as Kramers showed, the peculiar intensity distribution of these components—can we say that in this effect every trait of Jacobi's solution can be recognised, although hidden under a quantum theory mask. In this connexion it is of interest to mention that with the help of the correspondence principle, the effect of a magnetic field on the hydrogen atom could be treated so as to show a far-reaching similarity with Lorentz's account of the Zeeman effect on the basis of classical electrodynamics, especially in the form given by Larmor.

STABILITY OF ATOMIC STRUCTURE.

While the last-mentioned problems represent direct applications of the rules of quantisation, we meet, in the problem of the structure of atoms with several electrons, a case where the general solution of the mechanical problem does not possess the periodic properties which seem to be necessary for the mechanical picturing of the stationary states. It suggested itself, however, that this further limitation of the applicability of mechanical pictures in the study of the properties of atoms with several electrons, beyond that in the study of atoms containing only one electron, is directly connected with the postulate of the stability of stationary states. In fact, the interaction of the electrons in the atom presents a problem which is quite analogous to the problem of a collision between an atom and a free electron. Just as no mechanical explanation can be given for the stability of an atom in the collision, so we must suppose that already, in the description of the stationary states of the atom, the special part which every electron plays in its interaction with the other electrons is secured in an entirely unmechanical way.

This view is in general conformity with the spectroscopic evidence. An important feature of this evidence is the discovery of Rydberg, that in spite of the more complicated structure of the spectra of other elements compared to that of hydrogen, the same constant as that in the Balmer formula appears in the empirical formulæ of the series spectra of all elements. This discovery is simply explained by regarding the series spectra as evidence of processes by which an electron is added to an atom, its binding becoming more firm step by step with the emission of radiation. While the character of the binding of the other electrons remains the same, the steplike strengthening of the binding of this electron is visualised by orbits which at first are large compared with usual atomic dimensions, and become smaller and smaller until the normal state

of the atom is reached. In the case when the atom has a single positive charge before the capture of the electron, the attraction of the electron by the rest of the atom will, on this picture of the binding process, at first coincide closely with the attraction of the particles in the hydrogen atom. It is therefore clear why the spectral terms representing the binding of the electrons show an asymptotic convergence to the terms of the hydrogen spectrum. In the same way one obtains a direct explanation of the general dependence of a series spectrum on the state of ionisation of the atom, brought to light so beautifully through the work of Fowler and Paschen.

Typical evidence of the way in which the electrons are bound in the atoms is also afforded by the study of the X-ray spectra. On one hand, the fundamental discovery of Moseley, of the striking similarity of the X-ray spectrum of an element to the spectrum that corresponds to the binding of a single electron by the nucleus, can be easily understood if it is remembered that in the interior of the atom the direct influence of the nucleus on the nature of the binding of each individual electron exceeds greatly the mutual influence of the electrons. On the other hand, the X-ray spectra show certain characteristic differences from the series spectra. These originate from the circumstance that in the former we do not witness the binding of an additional electron in the atom, but the reorganisation of the binding of the remaining electrons upon removal of one of the electrons previously bound. This circumstance, which has been especially emphasised by Kossel, was well suited for bringing to light new and important features of the stability of atomic structure.

THE ANALYSIS OF SPECTRA.

To account for the details of the spectra, a closer study of the interplay of the electrons in the atom is, of course, required. Disregarding a strict application of mechanics, an attack was made on this problem by assigning to every electron a motion of such periodic properties that a classification of the spectral terms by means of quantum indices could be accomplished. In the hands of Sommerfeld, in particular, a number of regularities of spectra were simply explained in this way. Further, these considerations afforded a fruitful field of application for the correspondence principle. In fact, this gave an account of the peculiar limitations in the possibilities of combining spectral terms, the so-called selection rules for spectral lines.

On these lines, it has recently been possible by making use of the evidence from series spectra, as well as from X-ray spectra, to draw conclusions about the grouping of electrons in the normal state of the atom. This grouping explained the general features of the periodic system of the elements in conformity with the ideas of chemical activity of atoms as developed especially by J. J. Thomson, Kossel, and G. N. Lewis. Progress in this field has been intimately connected with the great enrichment during the last few years of spectroscopic evidence, and, not least, by the investigations of Lyman and Millikan, the gap has been almost bridged over between the optical spectra and the region of X-rays, where great advances have been

made in recent years by Siegbahn and his collaborators. In this connexion the work of Coster on the X-ray spectra of heavy elements may be mentioned as affording beautiful support for the account of essential features of the periodic system.

The analysis of the finer details of the spectra, however, has brought to light a number of features which could not be interpreted with mechanical pictures on the basis of the theory of periodicity systems. We refer in particular to the multiplet structure of spectral lines and the effect of magnetic fields on these structures. These latter phenomena, which are generally known as anomalous Zeeman effects and, as mentioned above, had already led to difficulties in the classical theories, fitted, it is true, in a natural way into the scheme of the fundamental postulates of the quantum theory. For, as Landé showed, the frequencies of the components into which each spectral line is split up by the field can, like the original lines, be represented as combinations of terms. The manifold of these magnetic terms is obtained by replacing each original spectral term by a set of values which differ from it by small quantities depending on the field intensity. In fact, the beautiful experiments of Stern and Gerlach, by which a direct connexion was established between the force which acts on an atom in a non-homogeneous magnetic field and the energy values of the stationary states in the field calculated from the magnetic terms, may be regarded as a most direct support of the fundamental ideas of the quantum theory.

Landé's analysis discloses, however, a strange difference between the interactions of the electrons in the atom and the coupling of mechanical systems. In fact, we are forced to assume the presence of a mechanically undescrivable "strain" in the interaction of the electrons which prevents a unique assignment of quantum indices on the basis of mechanical pictures.³ In the discussion of this problem a general condition of thermodynamic stability introduced by Ehrenfest played an important part. When applied to the postulates of the quantum theory, this condition states that the statistical weight attributed to a stationary state is a quantity which cannot be changed by a continuous transformation of the atomic system. Moreover, it has recently been recognised that this same condition leads, even for atoms with only one electron, to difficulties which point to a limitation of the validity of the theory of periodicity systems. In fact, the problem of the motion of point charges admits of certain singular solutions which must be excluded from the manifold of stationary states. This exclusion artificially restricts the rules of quantisation, but at first this restriction did not obviously contradict experimental evidence. Difficulties of an especially grave nature, however, were brought to light by the interesting analysis by Klein⁴ and Lenz⁵ of the problem of a hydrogen atom in crossed electric and magnetic fields. Here it was found impossible to satisfy Ehrenfest's condition, since suitable variation of the external

³ Compare an article of the writer (*Ann. d. Phys.* 71, 228, 1923) which contains a general survey of the results regarding the explanation of spectral evidence on the basis of mechanical pictures of stationary states. In this article detailed reference to the earlier literature on the subject may be found, and we therefore have confined ourselves here to quoting papers which have appeared since then.

⁵ W. Lenz, *Zs. für Phys.* 24, 197, 1924.

forces would gradually transform orbits depicting stationary states which could not always be excluded from the manifold of these states, into orbits where the electron falls into the nucleus.

Apart from these difficulties, the analysis of the finer details of the spectra has considerably furthered the quantum theory interpretation of the laws of the relationship between the elements. In fact, an extension of the ideas regarding the grouping of the electrons to which the quantum theory has led has recently been suggested by Dauvillier,⁶ Main Smith,⁷ and Stoner,⁸ taking various kinds of evidence into consideration. Notwithstanding the formal nature of these suggestions, they exhibit a close connexion with the spectral regularities disclosed by Landé's analysis. In this direction important progress has recently been made, especially by Pauli.⁹ Notwithstanding that the results thus obtained constitute an important step towards the above-mentioned programme of accounting for the properties of the elements solely on the basis of the atomic number, it must be remembered, however, that the results do not allow of a unique association with mechanical pictures.

QUANTUM THEORY AND OPTICAL PHENOMENA.

A new era in the development of the quantum theory has been opened up during the last few years by a closer study of optical phenomena. While, as mentioned above, the classical theory had such great successes in this field, the postulates at first gave no direct clue. From experiment, it is true, one could conclude that an atom, when illuminated, caused a scattering of the light essentially analogous to the classically computed scattering of elastically bound electrical particles, the natural frequencies of which are the same as the frequencies corresponding to the transition processes which the atom can perform under the influence of external radiation. In fact, on the classical theory such harmonic oscillators would, when excited, emit a radiation of just the same constitution as that of atoms transferred to a higher stationary state.

The possibility of obtaining a unified description of optical phenomena with this concept of oscillators conjugated to the transitions was essentially advanced by an idea of Slater,¹⁰ according to which the emission of radiation from an activated atom may be regarded as "cause" for the spontaneous transitions, in analogy to the effect of incident radiation in producing transitions. Ladenburg made a first important step towards a quantitative description of dispersion by suggesting a definite connexion between the scattering activity of the oscillators and the probabilities of the corresponding transitions in Einstein's theory. Decisive progress, however, was made by Kramers¹¹ by an ingenious transcription in harmony with the correspondence principle of the effects which, according to classical theory, are brought about in an electro-

dynamical system by illumination with light waves. Just as the radiation frequencies are calculated in the classical theory, on one hand, and the quantum theory on the other hand,⁶ it is typical in this transcription, that differential quotients are replaced by differences, in such a way that in the final formulæ only quantities open to direct observation appear. Thus in Kramers' theory the scattering of an atom in a certain stationary state is quantitatively connected with the frequencies corresponding to the different transition processes to other stationary states as well as to the probabilities of the appearance of these transitions under the influence of illumination.

It is an essential feature of the theory that in calculating the anomalous dispersion near a spectral line, one has to take into account two opposite kinds of resonance effects depending on whether the spectral line corresponds to a transition of the atom to a state of larger or smaller energy. Only the first of these corresponds with the resonance effects which have been utilised previously in accounting for dispersion on the basis of the classical theory. It is also very interesting that the further development of the theory by Kramers and Heisenberg¹² gave a natural quantitative description of additional scattering effects with changed frequencies, the existence of which had been predicted by Smekal¹³ from considerations based on the theory of light quanta, which thereby again has shown its fertility.

While this description of optical phenomena was entirely in harmony with the fundamental ideas of the quantum theory, it soon appeared that it stood in strange contradiction to the use of the mechanical pictures previously employed for an analysis of the stationary states. In the first place, it is impossible on the basis of the scattering activity of illuminated atoms demanded by the dispersion theory to construct an asymptotic connexion between the reaction of an atom in alternating fields of smaller and smaller frequency and the reaction in constant fields as calculated from quantisation rules of the theory of periodicity systems. This difficulty strengthened the doubts about this theory to which, as already mentioned, the problem of the hydrogen atom in crossed electric and magnetic fields had led. Secondly, it had to be regarded as especially unsatisfactory that the theory of periodicity systems was apparently helpless in the problem of the quantitative determination of the transition probabilities on the basis of the mechanical pictures of stationary states. This was felt all the more, as it was possible in several cases to obtain a quantitative formulation of the general statements of the correspondence principle as regards these transition probabilities with the help of viewpoints suggested by an analysis of the optical behaviour of electrodynamic models.¹⁴ These results stood in excellent agreement with measurements on the relative intensities of spectral lines, as they have been developed especially in Utrecht

during the last few years, but they could only in a very artificial way be included in the schemes governed by the rules of quantisation.

AN ATTEMPT AT A RATIONAL QUANTUM MECHANICS.

Quite recently Heisenberg,¹⁵ who has especially emphasised these difficulties, has taken a step probably of fundamental importance by formulating the problems of the quantum theory in a novel way by which the difficulties attached to the use of mechanical pictures may, it is hoped, be avoided. In this theory the attempt is made to transcribe every use of mechanical concepts in a way suited to the nature of the quantum theory, and such that in every stage of the computation only directly observable quantities enter. In contrast to ordinary mechanics, the new quantum mechanics does not deal with a space-time description of the motion of atomic particles. It operates with manifolds of quantities, which replace the harmonic oscillating components of the motion and symbolise the possibilities of transitions between stationary states in conformity with the correspondence principle. These quantities satisfy certain relations which take the place of the mechanical equations of motion and the quantisation rules.

That such a procedure actually leads to a self-contained theory sufficiently analogous to classical mechanics depends essentially on the fact that, as Born and Jordan¹⁶ were able to show, there exists in Heisenberg's quantum mechanics a conservation theorem analogous to the energy law of classical mechanics. The theory is built up in such a way that it is automatically in harmony with the postulates of the quantum theory. In particular, the frequency condition is fulfilled by the values for energies and frequencies derived from the quantum mechanical equations of motion. Although the fundamental relations which take the place of the quantisation rules involve Planck's constant, quantum indices do not appear explicitly in these relations. The classification of stationary states is based solely on a consideration of the transition possibilities, which enable the manifold of these states to be built up step by step. In brief, the whole apparatus of the quantum mechanics can be regarded as a precise formulation of the tendencies embodied in the correspondence principle. It must here be mentioned that the theory fulfils the requirements of Kramers' dispersion theory.

Owing to the great difficulties of the mathematical problem involved, it has not yet been possible to apply Heisenberg's theory to questions of atomic structure. From the above brief description it will be understood, however, that a number of results, which, like the expression for Rydberg's constant, had formerly been obtained on the basis of mechanical pictures by the aid of the correspondence principle, will retain their validity.¹⁷ Moreover, it is of the greatest interest that

already in the simple cases for which up to now a treatment on the basis of Heisenberg's theory has been carried out, the new theory leads, besides, to a quantitative calculation of the transition probabilities and to energy values for the stationary states, which differ systematically from those obtained by the quantisation rules of the older theory. One may therefore hope that Heisenberg's theory will be helpful in the struggle with the puzzling difficulties, mentioned above, in the study of the finer details of the spectra.

Earlier in this paper mention was made of the fundamental difficulties involved in the construction of pictures of the interaction between atoms either by means of radiation or by collisions. These difficulties seem to require just that abandoning of mechanical models in space and time which is so characteristic a feature in the new quantum mechanics. As yet, however, the formulation of this mechanics takes no account of the coupling of transition processes in pairs which shows itself in those interactions. In fact, only those quantities which depend on the existence of the stationary states and the possibilities of transitions between them occur in the new theory, which definitely avoids any mention of the times at which transitions take place. This restriction, however, which is typical of the attack on the problem of the constitution of the atom based on the postulates of the quantum theory, allows only some aspects of the analogy between the quantum theory and the classical theories to come to light. These aspects belong principally to the radiative properties of atoms, and just here Heisenberg's theory represents a real advance. In particular it allows us, in the phenomena of scattering, to recognise the presence of electrons bound in atoms in a way completely analogous to the classical theories,¹⁸ which, as stated above, in the hands of J. J. Thomson enabled the number of electrons in an atom to be counted from measurements of scattering of X-rays. The problems arising out of the validity of the conservation laws in atomic interaction involve, however, quite other aspects of the correspondence of the quantum theory with the classical theory. These are equally essential in the general formulation of the quantum theory and it is impossible to avoid discussing them when the reaction of atoms to swiftly moving particles is more closely studied. It is just here indeed that the classical theories have contributed so fundamentally to our knowledge of atomic structure.

It will interest mathematical circles that the mathematical instruments created by the higher algebra play an essential part in the rational formulation of the new quantum mechanics. Thus the general proofs of the conservation theorems in Heisenberg's theory carried out by Born and Jordan are based on the use of the theory of matrices, which go back to Cayley and were developed especially by Hermite. It is to be hoped that a new era of mutual stimulation of mechanics and mathematics has commenced. To the physicists it will at first seem deplorable that in atomic problems we have apparently met with such a limitation of our usual means of visualisation. This regret will, however, have to give way to thankfulness that mathematics, in this field too, presents us with the tools to prepare the way for further progress.

¹⁶ M. Born and P. Jordan, *Zs. für Phys.*, to appear shortly. The writer is obliged to the authors for the opportunity of seeing their paper in proof.

¹⁷ Note added in proof. Dr. Pauli has very kindly informed me of his success in making the new theory account quantitatively for the Balmer formula for the hydrogen spectrum as well as the influence on this spectrum of electric and magnetic fields. This is a very important result, since Pauli's analysis shows how the new theory avoids the difficulty involved in the older account of the spectral evidence in the necessary exclusion of the stationary states corresponding to singular solutions of the electronic motion.

Co-operative Research.

AT the first meeting of the British Association, held in 1831, the Rev. W. Vernon Harcourt proposed that the Association should "employ a short period of every year in pointing out the lines of direction in which the researches of science should move; in indicating the particulars which most immediately demand attention; in stating problems to be solved and data to be fixed; in assigning to every class of mind a definite task; and suggesting to its members that here is a shore of which the soundings should be more accurately taken, and there a line of coast along which a voyage of discovery should be made." This early suggestion adumbrating the organisation of scientific research met, apparently, with no response, and academic research continued to be conducted entirely on individualistic lines until a few years ago, when a Government department undertook the organisation of certain investigations which were realised to be of fundamental and national importance. In applied science the picture is a different one. Whereas the field for academic research is so vast and so ever-widening that the fear of duplication or mutual interference seldom arises, the problems of applied science, though very numerous, are more restricted in range, and therefore more amenable to organisation. For a long time past, organised research has been carried out by a few large manufacturing firms, but it was not until the British nation recognised, early in the War, that its existence depended upon certain industries which were based upon science, that steps were taken by Government to organise industrial scientific research.

If our ancestors, who were reared on the doctrines of *laissez-faire* and self-help, could see us to-day, they would marvel at the developments which have sprung Minerva-like from the bitter experiences of the War. As Sir Thomas Holland recently reminded us in his excellent address to the Royal Society of Arts on "The Organisation of Scientific Research throughout the Empire," the seeds of State-aided organisation of science were sown well back in the nineteenth century, but the credit for having transformed "an amorphous mob of scientific workers" into something resembling "an organised army" belongs to the Department of Scientific and Industrial Research. This Department, acting under a committee of the Privy Council, has never looked back since it was established in 1915, and the annual record of its activities has become a document equally important and interesting to the man of science and to the student of public affairs.

The latest report, covering the year 1924-25, of

which a summary is given elsewhere in this issue, deals with a large variety of topics, which are far too numerous to discuss in a single article, and it is therefore proposed to confine attention mainly to a matter which is becoming more and more important: the position of the research associations. These associations, it will be recalled, were founded with the direct object of assisting the industries of the country; a sum of 1,000,000*l.* (called the Million Fund) was allocated for this purpose, and disbursements from it were planned on the excellent principle that the State should help only those industries which can help themselves. Grants were to be made on the basis of 1*l.* for every pound subscribed by the industry concerned, and they were to be continued for a maximum period of five years, after which, it was anticipated, the associations would be self-supporting.

Experience has shown not only that this basic idea was thoroughly sound, but also that it has been admirably applied by the Department. The only rift in the lute is the general conviction that the limitation of State aid to a period of five years was a miscalculation. To what extent this error is admitted by the authorities, we do not know, but the fact that grants to many of the associations have been extended on a reduced scale (block grants of diminishing amount) seems to show that they share the general conviction. There is no doubt that the five-year period is inadequate. Devising a programme of research and planning its details, collecting an efficient staff, providing laboratory and other accommodation, are all slow processes; but the time required for these purposes is in most cases almost insignificant compared with that required to convince the manufacturer of the value of scientific research both to him and to the nation. It must, however, in fairness be stated that many manufacturers came in promptly. The success achieved in this direction can only be surmised, and it is to be hoped that the Department will publish figures showing not only the percentage of firms in each industry that have joined its association, but also the percentage of capital invested in the industry that is represented in the association.

Of the twenty-one research associations now in active operation, those connected with scientific instruments and photography have probably obtained the greatest measure of numerical support from the manufacturers concerned, and these are followed by the associations attached to the cotton and woollen industries; but the comparative non-success of other associations in no way reflects upon their management or upon the Department. Conditions vary very widely in the different industries, and some associations have encountered more opposition or reluctance than others from firms the refusal

of which to co-operate has been matched only by abiding faith in empiricism and trade secrets. No one can envy directors of research who meet with opposition of this kind, and the fault lies with the supineness of the nation to science in general rather than with individuals.

The Department, we understand, has been very successful in directing the choice of directors of research, upon whom so much depends, and in allowing them a free hand. The director has not only to organise and direct research, to conduct the business affairs of his association, but also everywhere to be in contact with the human factor, in the handling of his own staff, and in maintaining amicable relations with the personnel of his constituent firms: it is all-important that he should be on the best terms with the scientific heads of these firms, for this is a vital link in the chain of efficiency. His task is also influenced by the composition of his subscribing firms: an association of which the membership consists of one or two powerful corporations and a few small firms is much more difficult to direct than one of which the constituents are homogeneous, and the difficulties may be said to vary directly with the disproportion between the percentage of invested capital represented in the association and the percentage of firms in the industry that have joined it.

As we have said above, experience has shown that a research association cannot become self-supporting in five years; in view of this fact, of the comparatively small cost incurred (about 100,000*l.* per annum), and of the success already achieved, it is unthinkable that Government will cease to give adequate support after the exhaustion of the Million Fund. At the present and prospective rates of expenditure, the balance that remains (518,200*l.*) will not last for more than a few years. The interest on the unexpended balance has recently been spent on other projects—a possible point of criticism—but it has now been decided to carry forward for future expenditure the sums accruing under this head, although the precise way in which they are to be spent is not specified. Sir Thomas Holland (*Journal of the Royal Society of Arts*, Nov. 20, 1925) has done good service in showing how small, in comparison with the values of the trades concerned, are the sums required to continue the work of the associations; thus, the annual cost of research on cotton, wool, and rubber would be covered by adding $\frac{1}{4}$ *d.*, 1*d.*, and $\frac{1}{2}$ *d.* respectively to each *l.*'s worth of imported raw material. Given adequate support on existing lines, there is every prospect that the research associations will establish themselves as indispensable adjuncts of the industries with which they are connected.

Of the more distant future, one can speak with less assurance and with less optimism. For years past there has been a marked tendency for industrial firms to amalgamate, or to pool their resources and interests in other ways, the latest development in this direction being the unification of all the large German chemical companies into a huge corporation with a capital of about 32,000,000*l.* To what extent such aggregations are desirable from the points of view of the home consumer and the nation is a matter of opinion, but there is no doubt that large corporations can, and do, dispense with extraneous aid in carrying out all the research work they require, whether it be fundamental or incidental.

An interesting feature of the annual reports of the Department are the occasional references to matters of wider import than those which come strictly within its purview. In the present report it is stated that "the embarrassments and losses that the staple industries of the country are suffering are, in our belief, not primarily due to the neglect of science." Approval or disapproval of this statement will depend upon the connotations of the words "science" and "primarily." Most of our recent troubles, including unprecedented taxation, can be traced directly to the War, the occurrence and persistence of which were strongly favoured by lack of scientific foresight and scientific knowledge (*e.g.* of the basic materials glycerin, cotton, etc.), and not least, by the impotence of science, and other purely intellectual disciplines, to restrain or subliminate those primitive instincts of pugnacity and accretion which are "primarily" responsible for war.

There will be less diversity of opinion concerning the truth of the Prime Minister's statement (quoted in the report) that our trade will never be able to cope with unexpected emergencies, at home or abroad, until scientific method and scientific men occupy a better position in industrial affairs. Why the position of the scientific man is inferior to that of the financier and administrator, to what extent he himself is responsible, and how far it is due to the inherent and uncorrected perversity of others, are questions outside our present scope, but they all seem to centre around the larger problem of how to bring home to the people a sense of the actual and potential value of science in the maintenance and perfection of human life. Much of that value lies in research; and just as Malebranche declared that if he held truth captive in his hand, he would let it escape, so that he might pursue and capture it again, so we may say that if we held world supremacy in science and industry, we would let it go, so that we might be forced to use research in the struggle to regain it.

The Question of Race and Hormones.

Process of Physical Growth among the Chinese. By S. M. Shirokogoroff. Vol. 1: The Chinese of Chekiang and Kiangsu, measured by Dr. V. Appleton. Pp. vi+137. (Shanghai: The Commercial Press, Ltd., 1925.) 6 dollars.

THIS well-printed volume, dealing with a comparison of the process of bodily growth in two groups of Chinese, is one of a series of valuable studies of eastern Asiatic peoples undertaken by the anthropologist of the Museum of the Russian Academy of Sciences. Before he left Russia in 1917, Mr. Shirokogoroff was investigating the non-Chinese population of northern Asia: but when the circumstances of the times created obstacles that made it impossible for him to measure the children of Tungus, Manchu and Mongolian peoples, he transferred his attention to China. Dr. V. Appleton not only placed at his disposal her observations and measurements of 900 children made in the mission schools of Ningpo and Hangchow in Chekiang province, and at Shanghai in Kiangsu province, but also provided technical assistance for making the laborious statistical calculations. Dr. Appleton examined and measured the children of both sexes, and girls up to twenty years of age. Mr. Shirokogoroff made the measurements of adult men, for the interpretation of the process of whose growth he used the figures relating to the boys in his colleague's series.

The bulk of the volume is a collection of data rather than an argument that a reviewer can summarise. The author claims that the process of growth in the Chinese differs from that of other "ethnic groups"—he objects to the use of the word "race" and protests against the phrase "Mongol race" as "a baseless hypothesis." According to him, the Chinese differ from all other ethnic groups in the very pronounced and abrupt retardation of growth at the age of fifteen to sixteen years, and an equally distinctive acceleration four years earlier. His arguments are backed up by many tables of measurements and comparisons with data relating to other peoples, and statistical studies of the figures.

As Mr. Shirokogoroff explains in his introduction, the problem of interpreting the nature of physical growth is the real aim of his treatise; and he sets out to solve it by claiming that the "process is regulated, on one hand, by the interaction of the glands of internal secretion and metabolism which depend on heredity, and on the other hand, by the conditions of environment." He has made no observations of the endocrine glands. The argument is: the Chinese differ from other peoples in certain physical characters and mental aptitudes; therefore their ductless glands must be functioning in a different way from those of other people; hence

the physical characters and mental aptitudes of the Chinese have distinctive qualities! It is enough for him to accept without question Sir Arthur Keith's gay theories (*NATURE*, November 13, 1919; and *Johns Hopkins Hospital Bulletin*, 1922, pp. 155 and 195) as though they had been proved by observation or experiment, instead of being mere suggestions, which have never been seriously investigated or substantiated.

Mr. Shirokogoroff devotes a whole chapter to the "endocrine differences of the Chinese," which he sums up in the statement that "the endocrine complexes define not only the process of physical growth, but the psychic behaviour of ethnical units, so that the peculiarities of Chinese psychology and behaviour may be explained as the result of their glandular complexes." But when he becomes more explicit the fanciful nature of his argument is more clearly revealed. The longer legs of the Chinese infant, which the comparison of his measurements with those of other races indicates, are claimed to be due to the fact that "the pituitary gland is not inhibited by the thymus or pineal or sexual glands so intensively as among other ethnical groups. Among the Chinese of Chekiang it seems to be more active during the early period than among the Chinese of Kiangsu. Among both Chekiang and Kiangsu males this period is preceded by retardation (*vide supra*), which, we suppose, may be due to the inhibiting character of the sexual glands." In this strain of uncontrolled speculation Mr. Shirokogoroff devotes three pages to the process of building up a wonderful house of cards!

These statements are made without citing any evidence in support of them, or any data to suggest that there is any recognisable difference in the endocrine organs or their functional activities of the Chinese people. The only justification he offers for this vast claim is the reference to Sir Arthur Keith's views (which are also unsubstantiated by any control of experiment or observation) and Prof. Shellshear's observation that the thymus often persists throughout life in the Chinese. It is not uncommon to find an apparent persistence of the thymus in European adults; but as a rule histological examination reveals the fact that in such cases the distinctively thymic tissue has disappeared. Hence, until it has been checked, Shellshear's claim—the only anatomical fact so far adduced in support of the endocrine hypothesis—cannot be accepted as conclusive evidence.

In recent years the endocrine glands have been so widely exploited in applied medicine and in biological speculation, that one views with increasing suspicion the appeal to hormones to solve any difficulties for which no adequate explanation can be found. In such circumstances, Sir Michael Foster's maxim that a hypo-

thesis not tested by observation or experiment is of no value in science should be applied with the utmost stringency. As my colleague, Prof. T. R. Elliott, said some years ago with reference to this very subject of the interrelationships of endocrine organs: "Medicine owes no debt of gratitude to those who teach to her theories without proof." Probably in all processes of growth and development hormones are exerting a regulating influence; but crude analogies between the effects of disease on the thyroid, pituitary, or suprarenal organs and the differentiation of races will not promote but hinder the progress of science, unless the serious attempt is made to collect evidence in proof (or disproof) of the claims made for such specific endocrine influence.

Perhaps the only coherent argument in support of such an evolutionary factor was made by Prof. Bolk, of Amsterdam, when he attempted to interpret (*Lancet*, 1921, vol. 2, p. 588) the derivation of the distinctively human traits from those of an ape by the restraining influence of the hormones, in virtue of which man retained the characters of the simian infant into adult life. His argument was pursued with such logical intentness that he seemed not to be abashed at the paradoxical conclusion. For, according to Prof. Bolk, the human brain, man's distinctive attribute, was acquired not by the active growth of a progressively developing organ, but simply by the inertia of a tissue that retained the relative proportions it had in the foetal ape!

In all these speculations, fascinating by the very fact that they are so obviously fantastic, it seems to have been overlooked that while endocrine activity may influence the structure and metabolism of an individual and control his desires and behaviour, there is, as yet, not a scrap of evidence to prove that it plays the part of the determining factor in evolution which Mr. Shirokogoroff so confidently assumes.

The value of his volume depends wholly upon the new data he and his collaborator have so laboriously collected. Those whom he thanks in his preface for help in his "struggle with English" have not earned the gratitude he so generously bestows.

G. ELLIOT SMITH.

Sound Signalling.

The Principles of Sound Signalling. By Morris D. Hart and W. Whately Smith. Pp. v+139. (London: Constable and Co., Ltd., 1925.) 12s. 6d. net.

THE problem of sound signalling over considerable distances has a most important application to the question of safety of ships at sea in thick and foggy weather. This application, in the case of a maritime country like Great Britain, is probably more important than any other application of sound signalling.

From the time when Tyndall made his celebrated experiments on the transmission of sound signals through the atmosphere, much attention has been paid to the subject, but more particularly during the last ten or twenty years. Tyndall found, and it is now common knowledge, that the radius at which a sound may be heard is largely dependent on the state of the atmosphere. Apart from the effects of wind, large areas of silence have been observed in different directions and at different distances (sometimes small) from a source of sound. The loudness of the received sound, therefore, is no criterion of the distance from the source. The direction of the sound as perceived is not necessarily that of the actual source.

In view of these facts, both of serious import to ships in fog, a new system of sound signalling has originated in which the medium of transmission is no longer the fickle atmosphere but the much more homogeneous medium—the sea. Sound signals will travel great distances in the sea with little attenuation (when compared with that in the atmosphere) and with no observable change of direction. In the sea, areas of silence are unknown, and accuracy of directional reception is very great, within one or two degrees.

Both systems of sound signalling are in regular use around the coasts of Great Britain as well as those of other European countries, Canada, and North and South America. In addition to these systems of signalling, radio-direction finding is now rapidly increasing in its use and may ultimately supersede the older acoustic methods. A combination of radio-acoustic signalling, which gives a ship its exact position at sea, has also been tried with success by the Admiralty and by Trinity House.

The volume under consideration, although assuming the comprehensive title “The Principles of Sound Signalling,” deals only with the case of atmospheric transmission of sound. The principles discussed are, therefore, applicable only to sounds in air, and are in general quite unsuited to the problem of sound signalling in water. These important points might, with advantage, have been indicated in the title or the preface of the book.

The first chapter deals with the question of “efficiency” in acoustics. Here the authors are somewhat pedantic regarding the popular use of the word. They appear to overlook the fact that the popular meaning is correct; it was in daily use *before* the engineer and physicist employed the word in its narrower sense, namely, “the ratio of power-output to power-input.”

The processes of production, transmission, and reception of sound are each analysed and the efficiency of each subdivision, more than ten in all, is indicated by a special symbol. Although the authors may have found

it convenient to employ these numerous efficiency symbols, the reader may find them somewhat bewildering. Regarding the principles and methods of reception of sound, dealt with in the second chapter, very scanty consideration is given to the better known forms of receiver. The authors apparently consider that all forms of receiver other than the unaided ear and the Tucker hot-wire microphone are of no importance. It is made quite clear that the hot-wire microphone in conjunction with a suitable Helmholtz resonator is particularly suitable for low frequency sounds, but no alternative is given for reception at higher frequencies. A statement is made later, on p. 121, that most sound-signalling apparatus is intended to work in conjunction with the ear, but no apparatus is described (other than the recognised amplifying and collecting devices by mirrors, resonators, and trumpets) which can assist the ear at the higher frequencies at which it is most sensitive and where the hot-wire microphone becomes more and more insensitive. A hot-wire microphone and reflecting galvanometer, however valuable for research purposes, would be of doubtful assistance to a navigator in a fog—the sound signal must be heard and an approximate direction perceived.

The two chapters on transmission of sound are very interesting, the deductions relative to the size and intensity of sources of sound being of considerable practical value. The second chapter on transmission deals with the fundamental difficulty of sound signalling in air, namely, the capricious effect of atmospheric conditions. In addition to the refraction effects produced by wind, temperature gradients, fog banks, and patches of dry air, are other important causes of abnormal changes of intensity and direction of a sound wave. The effect of humidity is well illustrated in the Joss Gap records reproduced on pp. 65 and 66. The value of these chapters on transmission might have been enhanced by the inclusion of data relative to attenuation (other than simple spreading and effects of large amplitudes) over long distances. The attenuation in transmission of sound through the sea is known to be a more important factor than the loss of amplitude due to spreading—it is conceivable that this is so also, and perhaps to a greater degree, in the case of sound transmitted through the atmosphere.

On p. 93 are enumerated twelve important features desirable in a source of sound for signalling purposes, and reasons are afterwards given for considering the centrifugal siren as superior to other forms of source. This information combined with the conclusions reached in the chapters on transmission should prove of considerable value to the acoustic engineer, who is primarily concerned with the production and transmission of sound over great distances. A statement on the lines of the:

summary given on pp. 101-103 would have served as a useful introductory to the book.

The concluding chapter dealing with "Miscellaneous Considerations and Conclusions" might with advantage have been extended. Only five pages of the book are devoted to the choice of pitch, quality, and type of signal, whereas eighteen pages were devoted to a general discussion of the exact meaning of efficiency and the subdivision of the signalling process into many efficiency stages. Data relative to the transmission of sounds of different frequencies would have added greatly to the value of the book—but this section is dealt with in a few brief remarks.

Appendices III. and IV., on the measurement of acoustical energy and on experiments with sources of sound, are very instructive to any one interested in this subject.

Taken as a whole, the book gives a good indication of principles to be considered in the design of sound-signalling apparatus for use in air, and supplies also much information relative to that branch of recent acoustical work carried out by Major Tucker and his staff on behalf of the Royal Engineer Board.

A. B. W.

Birds of Ceylon.

Manual of the Birds of Ceylon. By W. E. Wait. Pp. ii+496+20 plates. (Colombo: Colombo Museum; London: Dulau and Co., Ltd., 1925.) Rs. 10 (15s.).

SINCE Legge published his magnificent volumes on the birds of Ceylon, no attempt has been made to bring out any complete handbook bringing up-to-date and collating what is known about the ornithology of the island. Legge's work appeared in 1880, and though this work is still of the greatest use to any working ornithologist, it is expensive, very bulky and, naturally, in many ways completely behind the times. Mr. Wait now presents us with a single volume containing almost as much information as that contained in Legge's book, and also information that is thoroughly up-to-date and scientific. The classification adopted by Mr. Wait is that of Stuart Baker in the second edition of the "Avifauna of British India," which is now in course of production. No classification in zoology can, of course, be accepted as final, and though Stuart Baker's book is the latest work on the subject, as time goes on, alterations will have to be made in his work, even as he had to make alterations in the work of those preceding him. The author of "The Birds of Ceylon" has, however, done wisely in adopting the classification of a work with which it will undoubtedly be constantly compared by every ornithologist and field naturalist in the course of his work.

Mr. Wait has given us the scientific and trivial name of each species and sub-species dealt with; he then gives the vernacular names and a brief synonymy; a

good description of the bird dealt with in its various phases of plumage and, finally, its distribution and most excellent field notes. The author himself is not only a scientific ornithologist, but is also a keen field naturalist, so that he has been able to add from his own knowledge much of interest and value to the oft-quoted notes of Legge, Holdsworth, and others. A very good outline map accompanies the letterpress, and on this is shown the amount of rainfall in the various districts, a most important matter in an island like Ceylon, where we have an extraordinary variation in the rainfall, affecting the flora generally and therefore the fauna also.

The total number of birds dealt with by Mr. Wait is 372, a very great increase when we compare it with the number about which Legge had to write in 1880. This number in Ceylon is not much affected by the modern method of dividing species into sub-species, for there are but few cases in which species are represented by more than one geographical race in this island, and we notice that in one of the few species which in Ceylon has been divided into two sub-species, that is, *Pellorneum fuscicapillum*, Mr. Wait has suppressed *P. f. babaulti* of Wells, perhaps with sufficient reason.

Some of the most important work which the author of this volume has been able to carry out is the proper identification of many of the older skins contained in the Colombo Museum, where his careful and painstaking work has resulted in many novelties coming to light, as well as the addition of a considerable number of most interesting birds to the Ceylon avifauna. The most important of these are *Puffinus carneipes carneipes*, *Parasula dactylatra persomata*, *Puffinus leucomelas* and *P. pacificus hamiltoni*.

At the end of the volume, Mr. Wait gives us 20 excellent plates containing nearly 100 figures in black and white of the birds of Ceylon. There are few students who will not be able to recognise the birds they come across from these plates alone, and they undoubtedly add considerably to the utility of the volume. The general appearance of the book is quite satisfactory, the printing and paper all that can be desired, whilst printers' errors are conspicuous by their absence. We congratulate Mr. Wait on having produced a book which has long been wanted and fulfils admirably the purpose for which it was written.

Our Bookshelf.

Cloud Studies. By Arthur W. Clayden. Second edition. Pp. xv+200+64 plates. (London: John Murray, 1925.) 15s. net.

WHILE the international classification of cloud forms comprising ten separate types is of the utmost value in world meteorology, it can scarcely be expected that it will satisfy completely the needs of those meteorologists who specialise in cloud study. One is accord-

ingly prepared when opening a book like "Cloud Studies" to find some amplification of the international classification, but it may be doubted whether the separation of clouds into forty named types really serves any useful purpose. Such a system must inevitably be too cumbersome for use in the daily work of meteorological observatories, and stands no chance of obtaining general acceptance. It may also be remarked that although Mr. Clayden pays lip service to the international classification, he makes it plain that in certain important respects he is not in agreement with it.

It is not intended by these criticisms to suggest that the book should be avoided or that it is unworthy of study either by meteorologists or the general public. On the contrary, it may certainly be read with profit and pleasure derived from the numerous cloud photographs with which it is illustrated. The most important change from the first edition published twenty years ago is the inclusion of a chapter on the formation of clouds, in which stress is rightly laid upon the primary importance of dynamic cooling in cloud production. Another useful chapter is devoted to the subject of cloud photography.

For the observation of clouds the use of a mirror of black glass is recommended, the reflected image of the cloud being observed. The same device has been used in obtaining many of the cloud photographs. The printer does not seem to have done full justice to all of these, the delicate texture of the high clouds being in some cases lost. Others are entirely admirable, among which may be mentioned Plate 36 which represents "Alto-cumulus Castellatus Fractus."

J. S. D.

Ergebnisse der exakten Naturwissenschaften. Herausgegeben von der Schriftleitung der *Naturwissenschaften*. Vierter Band. Pp. iii + 242. (Berlin: Julius Springer, 1925.) 15 gold marks.

THE 1925 volume of the "Ergebnisse der exakten Naturwissenschaften" contains eight articles. Dr. J. Stracke deals with the minor planets historically, treating their brightness, diameters, total mass, the statistics of the elements of the orbits, groups the orbits of which show great similarity, planets with unusual orbits, such as Eros, which is often closer to the sun than Mars, and Hidalgo, which at its aphelion is nearly as far from the sun as Saturn. The article gives a short account of the theories of the origin of the minor planets.

Prof. A. Prey's article on the theory of isostasy treats the development and the results of the theory; he does not consider it possible to account for mountain building by means of this theory alone, horizontal thrusts also being necessary. Prof. A. v. Brunn considers that for astronomical purposes the empirical time concept retains its importance, in spite of the Minkowski-Einstein conception. Prof. A. Wehnelt gives an account of oxide cathodes and their practical applications, and Dr. G. Heckmann of the lattice theory of solids, dealing with stability and energy relations, mechanics and electrostatics, acoustics, optics, thermodynamics, ionic lattices, atomic and molecular lattices. Dr. I. R. Katz investigates the swelling of such substances as rubber, nitrocellulose, and acetylcellulose, when soaked in certain organic liquids, the process

being studied by X-ray methods. Dr. W. Hanle's article is on the influence of magnetism on resonance fluorescence, *i.e.* fluorescence occurring when the exciting light has the same wave-length as the natural vibration of the atom; and that of Prof. Strömberg deals with the orbit forms in the problem of three bodies.

A Practical Treatise on Fourier's Theorem and Harmonic Analysis: for Physicists and Engineers. By Albert Eagle. Pp. xiv + 178. (London: Longmans, Green and Co., 1925.) 9s. net.

HARMONIC analysis appeals both to those interested in the mathematical eccentricities exhibited by Fourier expansions and to those concerned merely with the practical question of analysing empirical data into their constituent harmonics. The present volume, by catering in an interesting manner for the latter class, endeavours at the same time to focus the interest of its members on problems of more theoretical importance. In many respects the treatment is novel, and differs materially from that adopted in text-books of this nature. One is accustomed on picking up a "practical" book on harmonic analysis to find the usual medley of special methods unco-ordinated by any guiding principle for determining the coefficients. While certain of these find their place here, the author has centred a great part of his discussion around the expression for the coefficients in terms of the discontinuities of the function to be analysed and its successive differential coefficients, and on this as a basis he develops a number of elegant and at the same time comparatively accurate approximations to the coefficients. In practice these expressions are in a form suitable for numerical computation.

On the theoretical side, however, the book exhibits weakness in parts. There should scarcely be any necessity in such a work for a special section on the meaning of complex numbers, while the derivation of the power expansions for $\sin x$ and $\cos x$ from Demoivre's theorem and the evaluation of $\int \frac{\sin x}{x} dx$ are splendid examples on how *not* to treat limits. Altogether an interesting and valuable book, though slightly marred in places by elementary weaknesses and an irregular style.

Guide to Current Official Statistics of the United Kingdom. Vol. 3 (1924). Pp. 252. (London: H.M. Stationery Office.) 1s. net.

THIS guide consists of three main parts: a numbered list of official publications that contain statistics; a subject-index, giving under each entry the list-number of each publication containing relevant statistics, and some indication of their nature; a key from which the converse may be discovered, namely, the kind of statistics found in each publication. This last is of undoubted value; but we cannot see why the same information should not be more cheaply and conveniently given by adding the page-numbers to which reference is made after each entry in the list of titles, and in saying this we speak from practical experience with a similar publication.

The subject-index, on which the value of such a work depends, has been drawn up with much skill;

any reader who follows the instructions should certainly run down his quarry. If he cannot at once hit on an appropriate reference, he will find it by working down from one of the twenty-five main headings. The heading that will attract most of our readers is "Research." Under this are only two direct entries, but a cross-reference is given to the following, of which those italicised are also main headings: *Agriculture*, *Atmospheric Pollution*, *Fisheries*, *Forestry Commission*, *Fruit and Vegetables*, *Industrial Fatigue*, *Medical Research*, *Mining (General)*, *Radio Research*, *Royal Aircraft Works*, *Statistical Methods*, *Vivisection*. One would have expected references to yet other subjects. None of these, for example, leads one to the entry "Seismological Data" (which is under *Meteorology*); possibly the accumulation of data is not regarded as research.

The Engines of the Human Body: being the Substance of Christmas Lectures given at the Royal Institution of Great Britain, Christmas 1916-1917. By Sir Arthur Keith. Second edition, revised and enlarged. Pp. xvi+343+2 plates. (London: Williams and Norgate, Ltd., 1925.) 12s. 6d. net.

THE second edition of Sir Arthur Keith's book, "Engines of the Human Body," is remarkable mainly for its appendices, of which there are thirteen. They are added for the purpose of expanding and amending the original text of the book, and indicate the directions of advance in anatomical and physiological knowledge, including subjects such as the needs of the muscles of athletes, the control and education of muscles, the effect of altitude, vitamins, and automatic nerve control. The only point which might be queried is the suggestion that beri-beri is due to lack of vitamin C; the accessory substance the absence of which is responsible for this disease is probably vitamin B.

Although the lectures on which this book is based were delivered to a juvenile audience, it may be read with advantage by student, expert, or any individual interested in the working of the human body. As an elementary explanation of the main facts of physiology, for simplicity of language and clarity of description, it has no equal. To the second year medical student it may be particularly recommended, for it gives him in the original lectures a general survey, and in the appendices some illustrations of modern work, than which he could have no better introduction to the subject of physiology.

Man's Life on Earth. By Prof. Samuel Christian Schmucker. Pp. xxx+299+4 plates. (New York: The Macmillan Co., 1925.) 10s. net.

DR. SCHMUCKER is skilled in the art of popular exposition. From this point of view his little book leaves little to be desired. It covers the conditions precedent to man's life on earth as revealed by geology and palæontology, as well as the evolution of man and his cultural history. The author shirks no difficulty and boldly tells his readers when any conclusion which he sets down is doubtful and when the evidence is inadequate, inconclusive, or unsatisfactory. He is a fervent admirer of Dr. H. Fairfield Osborn, and in most controversial questions follows that distinguished author. Consequently, his treatment of the

early stages of man's history up to the beginning of the Neolithic period is both fuller and more satisfactory than it is for the later periods, where he is uncritical and not always exact. He accepts, for example, Pumpelly's very high dating for Anau, and his account of the rise of European culture is sketchy at best. The book is written for the American public; but two features will be helpful to English readers. One is a very clear account of the evidence for the Ice Age in America so far as ascertained; the second is an analysis of the peculiar social conditions in the United States which gave rise to the evolution controversy and culminated in the Dayton trial after this book was written.

Ethnographical Studies in Celebes. Results of the Author's Expedition to Celebes, 1917-1920. By Dr. Walter Kaudern. 1: Structures and Settlements in Central Celebes. Pp. xiii+404+6 maps. (Göteborg: Elanders Boktryckeri A.-B., 1925.) n.p.

IN this volume Dr. Kaudern gives the first instalment of the results of an expedition, in the course of which some three and a half years were spent in the island of Celebes. He expects to complete his work in about ten volumes, each of which will be devoted to some aspect of native culture. Here he deals with the structures and settlements of N.W. Central Celebes, the home of the Mountain Toradjas. Some of the Toradja tribes have been visited by those well-known explorers, the brothers Sarasin, and by Dr. Kruijt. The author, however, so far as possible, confined his investigations to tribes which were practically unknown and untouched by civilisation. In regard to his special theme in this volume, his investigation was to some extent complicated by the slavery resulting from tribal warfare, which has affected the type distribution of houses and temples; but by a skilful analysis, which calls for no little praise, he has distinguished three types in the houses, paddy-sheds, and temples, one of which is of recent introduction, possibly of Chinese origin, and of the remaining two, one appears to be the primitive type of which the form was determined originally by its location on swampy ground.

A School Mechanics. By C. V. Durell. (Cambridge Mathematical Series.) Part 2. Pp. xv+187-322+xi-xvii. Part 3. Pp. xi+323-447+xix-xxvi. (London: G. Bell and Sons, Ltd., 1925.) 3s. each.

IN these two small volumes, Mr. Durell completes his combined course of statics and dynamics, of which Pt. 1 has already been published. The advantage of taking the two subjects together is less obvious in these later stages, when the selection of the topics to be treated in turn is purely arbitrary, but teachers who think such a procedure is desirable will find no book to compete with this, in which Mr. Durell's unequalled skill in the invention of problems has ample scope.

For moments of inertia the reader is referred to the calculus, which is not otherwise required, as the book-work on rotational dynamics is restricted to the discussion of constant forces only, the compound pendulum being treated by assuming the energy equation. More space might with advantage have been allotted to relative velocity, considering the difficulty it presents to young students.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Highly-penetrating Radiation and Cosmical Physics.

If stellar radiation originates in the annihilation of stellar matter, it seems likely to be generated by quanta of wave-length 1.3×10^{-13} cm., each quantum being produced by the simultaneous destruction of one electron and one proton. Such radiation may be either absorbed or scattered when it encounters matter. The absorption of a quantum will eject an atom with a velocity equal to 0.99999985 time that of light. If this strikes an atom, a new quantum is emitted of wave-length equal to that of the original radiation, the hardness of which thus remains unaltered by absorption and re-emission. Scattering, however, produces a softening, precisely as in the Compton effect, and a succession of scatterings will increase the wave-length of the radiation until it degenerates into ordinary temperature-radiation.

Even newly generated energy cannot travel far through the interior of an ordinary star without being changed in this way. On the other hand, there are astronomical bodies which are transparent to ordinary light, and probably also to high-frequency radiation. The most obvious examples are the irregular nebulae, such as the Orion nebula, and the shells of the planetary nebulae, but the most important to cosmical physics are the spiral nebulae. On any reasonable computation the big spirals such as M. 31 (the great nebula in Andromeda) must be almost transparent to ordinary light, as is indeed shown by the circumstance that bright nuclear points, obviously located at the centre, are visible in many. On the best computation I have been able to make (*Monthly Notices R.A.S.*, April 1925, p. 534), the average optical thickness of M. 31 is only about 1 gram per sq. cm. It follows that these nebulae must be almost completely transparent to newly generated radiation, so that practically the whole of the radiation they generate will escape into space without any change of wave-length. Space must be filled with such radiation, and its penetration into our atmosphere would seem to provide a natural explanation of the highly penetrating radiation recently investigated by Millikan.

On the supposition that the spirals are the birth-places of stars, their radiation-generating capacity per unit mass ought to be at least as great as that of the youngest stars, and these have a capacity equal to about 500 times that of the sun. On the other hand, the visible radiation emitted by the Andromeda nebula per unit mass is only about 0.16 time that from the sun. We conclude that only a 300th part of the total radiation of this nebula is visible. One part in 3000 of the total radiation generated inside the nebula is stopped by matter and transformed into light, while the remaining 2999 parts travel through space as high-frequency radiation.

The integrated light from the Andromeda nebula is about equal to that from a sixth-magnitude star, so that the high-frequency radiation received on earth from this nebula alone must be equal in energy to the visual radiation from a star of magnitude -2.7 . This represents an average fall of energy of 15^4 ergs per second on each square centimetre of the outer boundary of the earth's atmosphere.

To produce a single ion in air requires about 2×10^{-11} ergs (corresponding to an ionisation potential

of 14 volts). To produce an average of 10 ions per cubic centimetre through 10 kilometres of atmosphere accordingly requires an inflow of energy at the rate of 2×10^{-4} ergs per second through each square centimetre of the outer boundary of the earth's atmosphere. Thus the high-frequency radiation from the Andromeda nebula alone would contain sufficient energy to produce about one-half of the observed ionisation. No doubt the radiation which strikes the earth is not all expended in ionising molecules, but when we add the radiation from all the other nebulae in the sky, we seem likely to obtain a total effect of about the observed amount.

The essential point is that the hypothesis we have considered gives the effect of the right order. In this respect it would appear to have the advantage over the possibility, to which Millikan alludes (*NATURE*, December 5, p. 823), of the radiation being caused by nuclear changes such as the formation of helium out of hydrogen; an effect of the observed magnitude, which must presumably continue for millions of millions of years, would seem to require a quite incredible amount of hydrogen or similar matter to be scattered through space.

On our supposition that one part in 3000 of the total radiation is stopped by an optical thickness of one gram, the radiation should be reduced to $1/e$ times its original intensity after traversing 3000 grams per square centimetre, or about eight feet of lead. This corresponds roughly to the penetrating power observed by Millikan, but from it he deduces a wave-length of 4×10^{-12} cms. as against the 1.3×10^{-13} suggested by the annihilation hypothesis. If this latter wave-length can be shown to be inconsistent with the observed penetrating power of the rays, it may become necessary to suppose that annihilation takes place by successive stages, in which case our hypothesis would approximate more closely to that discussed by Millikan.

The interaction of this high-frequency radiation with matter, whether by absorption or scattering, must liberate free electrons moving with velocities almost equal to that of light. The majority of these will escape into free space with practically undiminished velocity. Hitherto we have thought of interstellar space as being traversed only by visible radiation, but one must now think of it as being traversed by super- γ -rays and super- β -rays as well. The effect on cosmical physics must be profound. The bombardment by these rays provides an obvious explanation of the luminosity of such objects as the irregular nebulae, as well as of the negative charge of the earth.

J. H. JEANS.

Mendelian Genes and Rates of Development.

THE genetic research of the last quarter of a century, first especially by Bateson and later by the Morgan school, has given us a remarkable insight into the constitution of the hereditary material. We are now enabled to regard it as mainly or wholly composed of separable units (genes or factors), arranged in definite order and quantitative proportions in a series of groups (linkage-groups = chromosomes), and correlated with the appearance of the visible characters of organisms. However, very little is known as to the developmental mechanism by which this correlation is brought about. We thus have accurate pictures of the gene-complex and of the character-complex, but these pictures are, we may say, static, and the dynamic relations between the two are obscure.

Some progress towards filling this great gap in biological knowledge has been made, for example, by Onslow,¹ in his studies on the relations of genes to

¹ Onslow, *Proc. Roy. Soc.*, Series B, vol. 89, pp. 36-58 (1915).

the production of the substrates and enzymes of pigment formation, and notably by Goldschmidt² in his work on sex-determination, and on larval colouration in moths.

We have found in *Gammarus chevreuxi* a form which is in many ways convenient for the study of such relations. It has been known for some time that the red eye-colour (which arose by mutation from the normal black) darkens with age (Allen and Sexton).³ We have studied this process quantitatively by comparing the eyes of our animals with an arbitrary colour-chart. By this means curves giving the rate of darkening can be obtained (Fig. 1).

Before proceeding further, the relations of the different eye-colours (black and red) must be mentioned. We have worked with the "no-white" form, in which the normal white inter-facetary pigment is not present (another mutation). In the facets of the normal "black" eye, both black and red pigments are present. The former appears to be a melanin: it is insoluble in all reagents tried. The latter, however, is soluble in alcohol, ether, chloroform, and a number of other substances. Their embryonic condition can also be studied. The eggs are laid in a

It was further found that both the time of starting and the rate of the darkening process differed very considerably among the red-eyed individuals. The time of starting is also closely correlated with the rate, and we shall here only consider the latter. The effect of its variation is to produce a range of final eye-colour from an apparently pure red to a deep chocolate easily mistaken for black. A curious point is the existence of a "stable phase" as regards the quantity of black pigment. This is usually reached at sexual maturity, or shortly afterwards. Another complication is found in the fact that immediately after each moult a definite lightening of colour is seen. This, however, disappears in a few hours and the normal curve is resumed.

This difference in rate of darkening in the reds was, we suspected, due to the presence of modifying genes. We accordingly mated up a number of pairs, each consisting of a rapid-darkener and a slow-darkener. The results have confirmed our expectations. The F₁ in all cases but one, showed definite but incomplete dominance of rapidity. In the one exceptional case the brood was divisible into "rapids" and "slows" in a 1 : 1 proportion (15 : 17), indicating that the rapid parent had been heterozygous. From the remaining F₁'s the F₂'s were bred. The results indicated definite segregation, the total numbers obtained being rapid 89 : slow 31.⁴ The variations were much greater among the former class than among the latter, indicating, once more, imperfect dominance among the heterozygotes.

The general bearing of these facts may now be considered. *Gammarus* happens to be an organism which (1) has no metamorphosis, and (2) exhibits continuous growth and differentiation long after sexual maturity is reached: a type of development which must be regarded as primitive. It thus has no single size or form which can claim to be typical. The specific characters of any species of *Gammarus* can be arbitrarily defined with regard to a definite instar (such as that at which sexual maturity is attained), but more logically they should take into account the rates of change of the various organs. In a holometabolous insect, on the other hand, the adult characters appear only at the imaginal phase, and no growth or differentiation occurs after this. In ametabolous insects, and warm-blooded vertebrates, there is continuous change before, but no (or negligible) change after, the attainment of a fixed adult phase.

Thus if *Gammarus* were a holometabolous insect and the same factors were operating in it, we should see merely a cross-section of the curves for the rate of pigment production, as indicated by the line S-S in the diagram. Such a cross-section would give a picture similar to that seen in the effects produced, for example, by multiple allelomorphs in *Drosophila*. We may thus, with some reason, conjecture that the difference between the effects of multiple allelomorphs, and possibly between other quantitatively different characters, are usually to be ascribed to a difference in the rate of formation of some definite substance. Such a substance might accumulate gradually, but

FIG. 1.—Diagram showing rates of darkening of eye in different strains of *Gammarus* (the curves given are purely diagrammatic as to shape).

maternal brood-pouch: here they hatch, but the young are kept in it for some further time before extrusion. It has been found possible to remove the embryos from the brood-pouch a day or more before they would normally be hatched in it, and to rear them successfully outside the body. It is then seen that the eye of the future black-eyed animal is first uncoloured: it then becomes pale pink, and later scarlet. This then starts to darken just at the end of embryonic life. The process continues until, at about the time of extrusion, the full black colour is attained; this being about ten days from fertilisation at a constant temperature of 20° C. The darkening of the scarlet to black is entirely due to the deposition of insoluble melanin.

When the red-eyed individuals are examined, it is found that a similar darkening process occurs in them. The darkening is not due to a change in the red itself, but to a deposition of insoluble black pigment. The rate of deposition is, of course, always much slower than in the black-eyed forms; also the process always starts after extrusion.

² R. Goldschmidt, "The Mechanism and Physiology of Sex Determination," London, 1923. Goldschmidt, Seiler und Poppelbaum, 1924, Arch. f. mikr. Anat. u. Entw. Mech., vol. 101, p. 92.

³ Allen and Sexton, J. Mar. Biol. Assoc., vol. 11, p. 273 (1917).

⁴ These figures are from families with a sharp distinction between "rapids" and "slows", in others they are less easily separated. Presumably more multiple factors are here operative, and the results are being further analysed.

only show its effects suddenly, at a certain developmental stage.

One point here deserves mention. In two specimens of *G. chevreuxi* tested, slight darkening occurred, but starting only *after* sexual maturity; in an insect like *Drosophila* it could not have developed at all! Thus many apparent absences of a character may merely be due to extreme slowness in its development. Captain Diver informs us that similar phenomena are to be observed in the banding of *Helix* spp. It is also worth noting that the recessive "red" character is, at least in almost all cases, not due to an *absence* of black, but only to its slower deposition.

We here get a definite relation between Mendelian factors and the rates of a process which is continuous throughout most of the animal's life. We believe the line of thought thus raised to be a fruitful one for very various genetic problems, and hope that others may be induced to test its wider application.

Oceanographical Expeditions to the Black Sea in 1924 and 1925.

THE first study of the Black Sea was undertaken by the General Hydrographic Administration of Russia in the years 1890 and 1891. This expedition discovered the peculiar character of this sea.

After thirty-five years, oceanographical views and methods have developed to such an extent that it was necessary to send a new expedition to study the oceanographical conditions of this sea basin.

The same General Hydrographic Administration of the Navy of U.S.S.R. undertook this work. As a first step, a cruise, repeated four times every year, along the meridian of the south cape of the Crimea, was established. Data were thus collected for the study of the seasonal variations of the oceanographical elements in 1923-25.

For the general study of the oceanographical conditions, two special expeditions, in June-July of 1924-1925, were organised, both under my supervision. In 1924 the eastern part of the sea was studied, 1200 nautical miles being covered with 28 stations. In 1925 both eastern and western parts of the Black Sea were explored. During a 36 days' cruise, 2300 nautical miles were traversed with 72 oceanographical stations, 35 of which were in deep water. A total of 4250 observations were taken, amongst which more than 2000 gas analyses were carried out on board. Deep-sea soundings were made and sections of deep-sea deposits were obtained about 60 cm. long.

The material collected during the last expedition is now being examined, but the four seasonal cruises and others have given data which lead to some conclusions on the oceanographical conditions of the Black Sea. The salinity increases from the surface to the bottom from 18 per mille to 22 or 23 per mille at 2000 metres. The seasonal variations disappear at 100 m. The density has a similar vertical distribution, being about 112 at the surface, and reaching 117.4 at the bottom. Seasonal variations also were not met deeper than 100 m. The surface density in any case cannot exceed that at 200 m.; because of this, convection currents do not descend deeper than 200 m.

The vertical distribution of temperature has a peculiar character. The seasonal variations are observed only in the layer of 100 m. deep. At the depth of about 200 m. a layer of constant temperature

is observed—about 8°-7 C. From this depth to the bottom the temperature increases, and in the bottom layer it reaches 8°-92 to 8°-95 C. Near the shores the vertical distribution of temperature is more complicated.

These oceanographical conditions lead to a special vertical distribution of dissolved gas. Oxygen cannot penetrate deeper than the convection currents. In the open sea it reaches 150-160 m. only, near the shores, 200 m. or a little more. The deep layers below 200 m. contain hydrogen disulphide. In the open sea at the depth of 150 m. this gas is present to the amount of about 0.5 c.c. in a litre, at 0° C. and 260 mm. of atmospheric pressure. The quantity increases with depth and in the bottom layer, at 2000 m., it is 6.8-7.0 c.c. per litre.

Near the shores each of the surfaces, such as isothermobaths, isohalines, isopycnals and those of the vertical distribution of gas, lies deeper than in the middle of the sea. This fact was observed in 1890-1891 also; most probably it is due to the dynamical influence of offshore winds, and of those of the opposite direction, which blow in the coastal parts of the sea, causing the water to descend, or to be raised, thus increasing the vertical convection.

J. SCHOKALSKY.

Leningrad.

The Biological Conditions of the Black Sea observed in 1923-25.

THE observations in coastal waters, and also those made during the seasonal cruise and with the oceanographical expeditions in June-July 1924 and 1925 of the General Hydrographic Administration, lead to the following conclusions.

The Black Sea, from the oceanographical point of view, being formed of two sheets of water, namely, superficial layers of low salinity, and underlying water of great thickness and greater salinity, the conditions of life are determined by these conditions.

In the open sea the limit of life is found at the depth of 150-160 m. and sometimes at 125-110 m. Nearer the coasts this limit is deeper—sometimes about 200 m. The pelagic zooplankton is richer in the layers between the surface and 50 m. of depth; it is very uniform through the whole sea. From the depth of 50 m. to its inferior limit, the zooplankton is less rich. Near the shore it is more abundant, and in the middle of the sea its quantity varies greatly.

The seasonal variations of the zooplankton are very marked in the upper layers, and nearly disappear at the depth of 100 m.

The vertical distribution of the phytoplankton is under the control of some other causes as well as the temperature, such, for example, as the vertical distribution of light and some chemical components in the sea water, as also the hydrogen-ion concentration.

The Line Fluorescence of Cadmium Vapour.

IN a previous communication (NATURE, August 1, p. 170) I gave a preliminary account of the study of the band fluorescence of cadmium vapour. In the further investigations leading to the results presented, special care has been given to the removal of possible impurities in cadmium vapour. In order to remove completely the gases adsorbed by the walls of the quartz bulbs in use, the bulb, joined to the pumps, was heated in an electric furnace to about 900° C. for

several days. The use of gas burners for heating the bulbs is not advisable, as at high temperatures the gases of the flame, first of all hydrogen, pass through the quartz wall and undoubtedly are occluded in it. Then, the bulbs being strongly heated when used, the gases may be liberated from the walls and pollute the vapour in question.

The mercury vapour was removed by the aid of a quartz mercury trap cooled in liquid air.

Pure cadmium previously three times distilled in vacuo was used. A few milligrams of it were distilled into the bulb, which was then placed in an electric furnace. The temperature being kept stationary, a beam of exciting light was projected through the bulb by the aid of a quartz lens. Attention was paid to its chromatic aberration, i.e. the position of the focus for the very short wave-lengths.

By increasing gradually the temperature, first traces of the fluorescence were observed at about 350° C. (pressure of cadmium vapour 0.2 mm.), a condensed spark with the electrodes of cadmium being used as a source of light. The intensity of the fluorescence increases rapidly with the increase of temperature; its colour, at first definitely bluish green, assumes gradually (at about 600° C.) the blue colour formerly described. The spectroscopic examination shows that the green colour is due to the intense emission of the first triplet of the principal series of the cadmium arc spectrum: 5086.06, 4800.09, 4678.37 Å.U. In the ultra-violet part of the spectrum, other lines were found in the fluorescence. In the subjoined table is given a list of these lines as they are observed at different temperatures.

Line Å U.	Series Notation.	Estimated Intensity						Remarks.
		220°	440°	550°	640°	750°	885°	
5086.1	2p ₁ -2s	0	0	2	2	2	2	Resonance line, (Triplet system) Resonance line (Singlet system)
4800.1	2p ₂ -2s	0	3	4	5	5	4	
4678.4	2p ₃ -2s	0	3	4	5	5	4	
3261.2	1S-2p ₂	2	4	6	5	4	3	
2288.8	1S-2P	3	4	0	0	0	0	

Remarks on the above table :

(1) Intensity 1 would denote a very faint line ; 6, a very intense one ; 0 denotes that the line in question was not visible at all.

(2) Intensity 0 of the line 5086 at 440°, and the small intensity at other temperatures, is due to the insensibility of the plates used for the blue-green light. Visually its intensity was not smaller than that of the line 4800.

It is also possible that the lines 2748.7 and 2573.1 Å.U. belonging to the spark spectrum of cadmium are present in the fluorescence at higher temperatures from about 750° C. They fall in a region of the very intense ultra-violet band fluorescence, so that it is very difficult to separate them from the continuous background and from the traces of the scattered exciting light.

It is interesting that the emission of the visible triplet and of the resonance line 3261.2 Å.U. of cadmium may take place also at the excitation over a *certain spectral range* by the emission lines of other elements, for example, of aluminium. Moreover, the intensity of the lines 5086, 4800 and 4678 excited by an aluminium spark is, other conditions remaining unchanged, much greater than when excited by a cadmium spark. Their intensity shows here also the maximum at about 750° C., whereas at higher temperatures (890° C.) it slightly diminishes. In the ultra-violet region only the presence of the resonance line 3261 was observed ;

its intensity reaches the maximum at about 600° ; then it diminishes, and at 890° it appears as a weak and diffuse line. This appearance may be due to the mutual influence of atoms, for example, the Stark effect, intense at these high temperatures because of the considerable density of vapour.

There appears also, with the excitation with the aluminium spark, as well as with the cadmium spark, the resonance line of mercury 2537 Å.U., which originates from the traces of mercury vapour present as impurity in the bulb.

The light of the copper spark excites also in the cadmium vapour the emission of the visible triplet (although much weaker than for the aluminium spark) and the emission of the resonance line 3261. The iron, lead and mercury spark excite the emission of the triplet mentioned as well.

These data would prove that the spectral extent of its excitation must be rather broad, and it lies probably for the most part below 2000 Å.U., where the aluminium spectrum possesses intense lines. On the other hand, lead does not possess any strong lines in the farther ultra-violet region. (below 2170 Å.U.), in spite of which it excites distinctly the emission of the visible triplet of cadmium. Therefore, the absorption must take place over all the wide spectral range.

It remains for the moment an open question, whether the deformations of the cadmium atom leading to the subsequent line emission are the direct result of the absorption of the radiating energy, or whether a number of intra-atomic and intra-molecular processes as well as collisions lead indirectly the atoms to the final excited state.

Impurities and small admixtures of other gases have a considerable, but not yet completely elucidated, influence on the emission of lines. The intensity of emission varies greatly with the bulb used. In a recently prepared bulb, which does not contain any traces of mercury vapour and from which the occluded gases were removed particularly thoroughly, the emission of the visible triplet takes

place at the excitation by the cadmium and aluminium spark only at about 700° C., and it is weaker than in the bulbs previously used. Also the visible band fluorescence is here much weaker, whereas the ultra-violet one is very intense. There may be, therefore, some connexion between the band fluorescence and the emission of lines

Weather Prediction from Observation of Cloudlets.

I FEAR Mr. Cave (NATURE, November 21, p. 749) misunderstands me, or I him. He controverts none of my facts, and his own are indisputable. Thus, though I, with amateurish powers of observation, find it difficult, no matter how long I watch, to perceive the waxing, and waning, of a cloud, I have always thought it probable that a thick or extensive mass, if exposed on opposite sides to unlike weather conditions (e.g. sun-heat), may condense at one extremity while dissolving at another. Also I know that the tendency is, on the whole, one way or the other. Again, I know that in our changeable climate, indeed in any climate, a waxing cloud does not necessarily imply rain ; it may not condense sufficiently. Nor does a waning cloud imply fine weather ; it may cease to wane. Nevertheless, "when clouds are seen wise men put on their cloaks," and exceptions do

not disprove the rule. They should merely direct attention to modifying circumstances—for example, to the variations of the barometer, the season of the year, the time of the day, the direction of the wind, and the colour of the sky. Whatever the modifying circumstances, it remains true that rain cannot come unless rainless clouds condense, or fine weather unless raining clouds dissolve. For most people, even I suppose for the weather expert, observation of this gathering, or breaking, of clouds is the most employed quick method of weather prediction.

It is usually impossible to base judgment on the behaviour of one cloud, or even of a few clouds. The bulk and opacity of these big masses renders observation of their changes difficult. Before we can be sure, each tends to drift out of sight, or be obscured by its fellows. Most of us, therefore, inspect the sky as a whole at intervals to ascertain whether it darkens or brightens. On the other hand, cloudlets—"the smallest and thinnest fragments of cloud that can be clearly isolated"—wax towards rain, or wane towards fine weather, with surprising swiftness. In my letter I wrote that five minutes' observation was usually sufficient. As a fact and as a rule, any one may satisfy himself within fifteen seconds. Cloudlets are small and diaphanous clouds which can be seen at the same time in every part. They do not fade at one extremity while developing at another. They are under the same atmospheric conditions as neighbouring clouds. If they change, their big neighbours are almost certainly changing in the same way. They furnish a quick and easy means of determining the atmospheric conditions not only at the moment, but also usually for hours to come. As compared to clouds, their changes are as easy to watch as the changes in a small smear of moisture compared to those in a cup of water.

That was all I wrote, or implied, in the letter (*NATURE*, November 7, p. 676) that Mr. Cave criticises. He writes, "I do not think that any of the explanations he gives accounts for the phenomenon." But I gave no explanations—unless the inference that changes in cloudlets are indices of changes in clouds be regarded as an explanation. It seems to me a truism. I stated easily verified facts—that and nothing more. "I do not think that the method . . . is at all of universal application." Of course it is not. No weather sign is. I mentioned some exceptions. He mentions another—that early on summer mornings cumuli sometimes wax and then wane without rain. But we have to deal with a rule, not with invariable succession. Moreover, the ordinary man, for whom I wrote, does not usually observe early on summer mornings. "The point is not to account for it, but to decide whether the waxing or waning of the cloudlets is to be taken account of in weather prediction." That certainly is the point. The test is most easy to apply. I think that even the expert will find it useful not only during all times of the day, but for more than the hundred days Mr. Cave mentions.

In this connexion, it is useful to discuss the origins of clouds and cloudlets. Now I really try to explain. How do clouds begin in the first instance? As new cloudlets? Or in a widespread and deepening mistiness? The first supposition seems to me improbable. It implies a sudden change in a minute portion of the drifting and mixing atmosphere. The second seems more likely and may, indeed, be often seen to be true, as when a misty sky gradually becomes grey, or when a ground fog develops. I suppose that the cumuli of which Mr. Cave writes are formed by the condensation of moisture as air rises to colder altitudes and there wane into cirro-cumuli. How do cloudlets originate? If *de novo*, then here again we have a sudden change in a minute portion of the atmosphere.

It seems more probable that they are either the last remains of clouds, or else portions of them which have become detached, not by being torn off by the winds (we rarely, if ever see that), but by the dissolving of connecting links (which we often see). So a puff of steam breaks into vanishing wisps. It follows that the mere presence of cloudlets is an index of clouds that have dissolved. Whether they are still dissolving can be determined by a moment's inspection.

May I direct attention to the fact that I have done no more than indicate an easily observed weather sign. I have not tried to minimise the value of any other sign. G. ARCHDALL REID.

Sulphur Treatment of Soil for Wart Disease.

In the *Annals of Applied Biology*, 12, 2, 1925, a paper was published by Roach, Glynne, Brierley and Crowther entitled "Experiments on the Control of Wart Diseases of Potatoes by Soil Treatment, with particular reference to the use of Sulphur." In 1922, treatment of a light soil at Ormskirk with sulphur had given promising results, whilst in 1924 the amount of disease was reduced from 73 per cent. in untreated soil to 8 per cent. with an incorporation of 10 cwt. of sulphur per acre, and to less than 4 per cent. with 20 cwt. sulphur per acre. On a heavy clay at Hatfield, clean plots were obtained with an application of 40 cwt. per acre.

During the past season a larger experiment has been carried out to test these results and the deductions drawn from them, and to determine whether the effect be a permanent one. As we have learned that experiments are being set up in other countries to test the efficacy of this sulphur treatment, it is desirable that the discrepant results obtained by us this season should be known so soon as possible. In our test at Ormskirk the following arrangement was adopted.

Plot.	Treatment.			
1	None.			
2	15	cwt. sulphur	per acre	in autumn.
3	10	"	"	"
4	{ 7½	"	"	"
	{ 7½	"	"	spring.
5	{ 5	"	"	autumn.
	{ 5	"	"	spring.
6	15	"	"	"
7	10	"	"	"
8	None			

In the untreated plots the plants grew well and were heavily warted. In the treated plots a first set of tubers planted in May and a second set planted in July almost entirely failed to grow. The surviving plants showed in all plots considerable amounts of wart disease although much less than in the control areas. At Hatfield two tons of sulphur per acre was applied: the crop was damaged and a considerable amount of wart disease was present.

Unavoidable differences in the conditions (seasonal, manurial, etc.) under which the work was carried out in 1924 and in 1925 suggest certain explanations of these results, but we are not in a position to say that any one of them is correct. The results already published are not of course invalidated, but it is clear that the sulphur treatment cannot, in the absence of further information on the soil and other factors involved, be regarded as a trustworthy method for freeing soil of the parasite causing wart disease. A more detailed account of our work will be published in the *Annals of Applied Biology*, 13, 2, 1926.

The Occurrence of Dwi-manganese (At. No. 75) in Manganese Salts.

IN a letter to NATURE of November 28 bearing the above title, the authors, Messrs. Dolejšek and Heyrovský, deduce the existence of element 75 from measurements of the potential of a cathode immersed in saturated manganese sulphate solution. Their conclusion is supported by an examination of the X-ray spectrum, with which I have nothing to do. I do not think, however, that their deductions from the potential-current curves are necessarily valid. They find for the deposition potential of manganese -1.34 volt (abs.), a figure in substantial agreement with my own (*Trans. Faraday Soc.* (1924), 19, 559 and 20, 1). Below that potential they find two humps in what should normally be a very flat curve. The first and smaller hump they show to be due to some common impurity removable by hydrogen sulphide. The second, commencing at a voltage of -1.00 volt, they attribute to the discharge of the new element, dwi-manganese. I see no reason why this potential should not represent the potential of incipient hydrogen discharge: the actual deposition of manganese at -1.3 volt is accompanied by violent hydrogen discharge. Assuming their manganese sulphate solution to be neutral, the equilibrium potential of hydrogen should be about -0.13 volt, which requires an overvoltage of 0.87 volt, a readily realisable figure if the cathode were smooth platinum. The oscillatory nature of the potential curve in the neighbourhood of the manganese deposition potential may be due to the simultaneous discharge of hydrogen and manganese.

It would be interesting to know the form of the current-potential curve at the same cathode in an electrolyte containing no manganese, such as sodium sulphate. The effect of superposing an alternating current on the direct might also be tried. In this case, if the inflexion is due to hydrogen discharge it would be greatly displaced by the superposition; if to dwi-manganese, probably but little.

The authors then proceed to isolate a product presumably rich in dwi-manganese, which they dissolve in hydrochloric acid. They give no experimental details, but it is worthy of note that in the electrolysis of manganese chloride solutions, manganese tetrachloride is undoubtedly produced (*Trans. Chem. Soc.*, 1923, 123, 892), which hydrolyses with great readiness in the neighbourhood of the cathode, and might conceivably produce potential relationships of considerable complexity.

It is not my intention to impugn the substantial results of Messrs. Dolejšek and Heyrovský, except in so far as I think their interpretation of the inflexions of their curves is not necessarily correct

Microseisms and the Indian Monsoon.

WITH reference to the note on the above subject in the report of the seismological committee of the British Association, Southampton, 1925, and my letter to NATURE, October 18, 1924, p. 576, it is perhaps worth while to place on record that the observations made during the current year fully confirmed the views regarding the appearance of microseisms of a certain type as a precursor of the monsoon.

This year the microseisms of the monsoon type could be detected in the seismograms on May 13. On May 15 very pronounced microseisms developed, and these lasted for the next two days. They were

apparently associated with a severe storm, which formed in the Bay of Bengal on May 12 and crossed the coast near Masulipatam on May 16. The storm caused strong winds in the south-east Arabian Sea and fairly widespread and locally heavy rain in the south of the Peninsula. With the dissipation of the storm the microseisms weakened, but they did not altogether disappear from the seismograms. During the last week of May, as the monsoon was being gradually established, they became more and more marked, and from the beginning of June onwards, so long as the monsoon conditions continued, their characteristic appearance day after day formed the most noticeable features in the seismograms. One could thus get very important indications regarding the advance of the monsoon in the south-east Arabian Sea long before it arrived on the west coast.

Following the discussion of Darwin on the variations in the vertical due to the elasticity of the earth's surface (Brit. Assoc. Report, 1882), a theory of the microseismic movements of the monsoon type has been worked out. This suggests that they are due to Rayleigh waves set up at the bottom of the sea by the train of water waves maintained by the monsoon currents. The periods of the movements, which vary from 5 to 9 seconds according to the strength of the wind, are correctly indicated by the theory. The complete paper on the subject will be published in due course.

Vitality of an Earwig.

AN earwig was found inside a high vacuum pumping set recently. How it managed to get there is not known, but it was possibly in the glass-blower's rubber tubing and was blown in when the apparatus was being modified a few hours previously.

The earwig was not observed until the pumps had been running a quarter of an hour, when it was seen crawling along the glass tubing. The pressure was about 0.001 mm.

In our efforts to extract the earwig it was rather roughly treated, as it fell into the mercury vapour pump (cold) and was eventually poured into a beaker with the mercury, being entirely submerged for a few seconds. It survived all this and actively crawled about on being released.

It is possibly well known that the skin and legs of this creature can withstand such knocking about, but it seems very remarkable that it could be active in a vacuum!

PHYSICIST

The Course of Instability of Elements.

URANIUM and thorium being the two amongst the old elements which are unstable, and being nearly at the end of the Periodic Table, is there any more reason to regard these as the last to remain unstable, than to regard them as the first to become unstable? If they represent the last to become unstable, we might suppose that all the other elements had passed through an unstable stage and in the course of ages to have become stable, thus throwing the greater part of the earth's history into the past, with less to come in the future. If, however, we suppose that only two elements have reached the unstable stage, all the remainder will have to come to this stage in turn, thus giving to the earth a tremendously long future as compared with that which is past.

The Nature of Man's Structural Imperfections.¹

By Sir ARTHUR KEITH, F.R.S.

II.

DARWIN regarded the appendix as one of man's vestigial structures, and Metchnikoff accepted this verdict without demur, although there were then anatomists, particularly Prof. R. J. Berry,¹⁵ who refused to regard the appendix as a useless structure. Every child is born with a fully and well-developed appendix which varies in length round a mean of 35 mm. Ribbert's investigations¹⁶ showed that amongst the Swiss the appendix has reached its maximum length, 97 mm., by the twentieth year; thereafter the average length falls slowly, so that by the sixtieth year it has become reduced to 85 mm. Prof. Berry¹⁷ found in the population of Edinburgh that the appendix did not attain its full length, 89 mm., until the fortieth year, falling to 83 mm. by the sixtieth year. Drs. Garcia and Salloza¹⁸ measured the length of the appendix amongst Philipinos—a people living chiefly on a vegetarian dietary. By the twentieth year the appendix of this people had attained a length of 81 mm.; its maximum length, 96 mm., was not reached until the fiftieth year, while the average length fell to 82 mm. by the seventieth year. An organ which increases in length until the twentieth year, or even until the fiftieth, does not merit the name vestigial.

The size of the appendix at birth in the various forms of anthropoid apes we do not know, but in adult gorillas, chimpanzees, and orangs the appendix usually attains a length of 150 or 160 mm.—nearly double the length of the human appendix. In the most primitive form of anthropoid known to us, the gibbon, the appendix is most variable in length. In six animals which I dissected fresh from the jungle, all of them adult, the appendix varied in length from 75 mm. to 175 mm. In two of the animals, the cæcal contents were laden with numerous fruit stones as large as those of a cherry; the appendix in these two cases held a row of fruit stones, showing that it shared in the digestive work of the cæcum. There is no evidence to lead us to believe that anthropoid apes suffer from appendicitis in their natural habitat; they become subject to this disease when kept in confinement. Of 61 chimpanzees dying in captivity, 10 of them suffered from appendicitis.¹⁹ The evidence, such as it is, leads us to believe that when the appendix breaks down under the conditions of modern civilisation, it does so not because it is "vestigial," but because of its inability to withstand the conditions to which it is being exposed.

To express the real nature of the structural and functional imperfections seen in the human appendix, it is convenient to use a term coined by the late Sir William Gowers. He noted that in some families certain structures, such as the hair on the crown of the head, was apt to be shed as the result of a premature atrophy of the scalp. To such examples of

premature senility on the part of any organ or structure he applied the term *abiotrophy*.²⁰ In this sense the appendix is an abiotrophic structure, one which is apt to suffer from a disordered life-history; in a large proportions of Europeans it becomes atrophic or senile when other parts of the body are in full vigour. On the evidence collected by anatomists and pathologists, it is permissible to infer that if we could follow the life-histories of 1000 modern Europeans from birth to their seventieth year, the following would be the fate of their appendices. By the end of the tenth year the lumen of this structure would be partially or completely obliterated in 40 of them; by the twentieth year the same fate would have overtaken 70 more; by the thirtieth year 60 others would have been added to the list; by the fortieth year 80 further cases of obliteration would have occurred; by the sixtieth year there would be 110 additional cases. Of the thousand people who reached the age of seventy, only 500 of them would retain their appendix in an unblemished functional state; in the other 500 the appendix would have undergone a premature atrophy at succeeding stages in the journey through life. In this the appendix keeps company with all structures which are of a lymphoidal nature. The tonsils, the thymus, lymphatic glands, and Peyer's patches have similar life-histories, but no one would describe them as vestiges or rudiments. There is much in the name we apply to structures; when we name them "vestigial," "congenital," or "useless," we shut the door on all further inquiry. As Paley declared a century ago, our list of "useless" structures decreases as our stock of knowledge increases.

The eye, which is man's chief organ of sense, has, under the stress of civilisation, become the subject of a wrong growth or abiotrophy. If we take a thousand men or women over the age of twenty-five years, we shall find that about 150 of them suffer from a degree of myopia which prevents them from seeing distant objects clearly; and yet in all of them, just as was the case of the appendix, the eye was normal at birth. The incidence of the disorder is somewhat similar to that of the appendix; it appears during the period in which the eye is undergrowing growth—a process of the most complex kind²¹; in a few, myopic changes appear by the fifth year, the highest rate of incidence taking place as puberty is reached and passed. We cannot believe that among our hunting ancestors, for whom distant sight was so vital, that every seventh man was myopic.

Myopia we must regard as a structural disharmony occasioned by the conditions which civilisation has entailed on us. Short sight, as Dr. John Kirk has stated,²² is certainly a disorder of growth, and the essential problem is to discover not why 15 per cent. of our population suffers from it, but why it does not occur in the remaining 85 per cent. Children may be fed on the same food and undergo the same school

Berry, *Anat. Anz.*, 1895, vol. 10.¹⁸ Garcia and Salloza, *Philippine Journal of Science*, 1921, vol. 18, p. 707. See also Fawcett and Blackford, *Journ. Anat. and Physiol.*, 1900, vol. 34, p. xxi; S. Rutherford Macphail, *ibid.*, 1917, vol. 51, p. 306.¹⁹ Weinberg, *Bull. de la Soc. de Path.*, 1908, vol. 1, p. 556.²⁰ The reader will see later that I use this term in a somewhat wider sense—one which includes irregular as well as reduced growth.²¹ I have dealt with the incidence and nature of myopia in the *British Journal of Physiological Optics*, 1925, vol. 1, p. 369.²² *Brit. Med. Journ.*, 1921, vol. 2, p. 8.

tasks, yet only in certain individuals does the eyeball undergo abnormal elongation. They only are affected by modern conditions, the others are not.

Perhaps no structure in the human body illustrates abiotrophic changes so well as the lens of the eye. By the age of forty-five the elasticity of the lens has become so reduced in most of us that we have to seek the aid of spectacles. Some time ago Dr. Ernest Clarke²³ examined the eyes of 1200 people of all ages, and charted in graphic form the condition of the lens. From that chart we can see that some individuals at the age of forty-five retain the elasticity of lens which is normal at thirty-five years of age, while others have reached a stage usually found in men and women of sixty. It is with the lens of the eye as with the appendix, abiotrophy sets in prematurely in some; in others the change is delayed.

The consideration of the functional failure of the lens of the eye brings us to a problem which fascinated Metchnikoff. What is the term of life which is natural to man? Metchnikoff inclined to place it at a hundred years—that if we escaped accident and disease the inherent vitality of our tissues was sufficient to make a centenarian of every one. At the age of forty-five the lens of the normal man is already old; it has reached the term of its full utility. We have no reason to suppose that civilisation has shortened or is shortening its period of usefulness. The indication it affords supports the belief that Nature has worked out the evolution of the human family on a mean life tenure of forty-five years; she has hitherto run the human army on a short-service system. Unfortunately we have no vital statistics of our nearest allies, the anthropoid apes. Micky, a chimpanzee which died lately in the Zoological Gardens of London, lived there for twenty-six years, and was three or four years of age when he arrived. Thirty years ago I made an intensive study on the age changes of the teeth and skulls of the great anthropoid apes and came to the conclusion that very few of them reached the fifth decade of life. All the elastic tissue and cartilage of the body keep the lens company in their rate of aging; they lose their resiliency by the middle of the fifth decade. The age of forty-five years sees the end of the term of child-bearing which is normal for women. When we consult the rates of mortality which now prevail we find that a sudden rise sets in during the fifth decade, and this rise assumes a steeper and steeper gradient with every subsequent decade. All of these facts seem to show that forty-five years was the span allotted to man when he was the blind slave of Nature. Civilisation now permits many men and women to live the span of two such lives, but whether it would be an advantage for civilisation that all should live to be centenarians, as Metchnikoff believed, is a moot point. We must take civilisation in the round; if it has searched out the weak points in our inherited organisation, it has also added incalculably to the span and comfort of life.

All the structural imperfections of man's body which have been discussed up to this point are of a kind which perish in the grave. We have no means of telling whether or not our remote ancestors suffered from appendicitis or were the victims of myopia. Fortunately, from this point of view, there are certain

of the durable parts of man's body which manifest abiotrophic changes—the teeth and jaws. During the last twenty years I have had an opportunity of examining the facial parts of more than three hundred individuals who lived in England more than a thousand years ago, some of them so much as eight or ten thousand years ago. Seven years ago I made an elaborate comparison between fifty of these ancient skulls—twenty-five of which were adjudged to be those of men and twenty-five of women, with equal numbers of individuals who had lived in England within the last two centuries.²⁴ In only three of the fifty ancient skulls did the upper and lower teeth fail to meet in an edge-to-edge bite; in all of the fifty modern skulls the bite was of the overlapping or scissors type. Our teeth are in an abiotrophic state; the failure of the wisdom teeth or third molars to form, or to erupt if they are formed, is but one symptom of this abiotrophic change; it affects crown, cusp, and root development. In the fifty ancient skulls, instead of 100 upper wisdom teeth, there were only 82, 13 being absent from non-development and 5 from non-eruption. In the fifty modern skulls, instead of 100 upper wisdom teeth, there were only 59; 30 of these were absent from non-development, 11 from non-eruption.

Such evidence shows that although abiotrophic changes had overtaken the dental system of the western European as early as the Neolithic period, yet these changes have been accelerated during the more recent centuries. Dental abscesses were nearly as common in the ancient skulls as in the modern; carious teeth, on the other hand, were three times more frequent in modern skulls than in the ancient. The researches of the Mellanbys²⁵ have proved that the quality of enamel and of dentine, particularly of secondary dentine, has a relation to the vitamin content of a dietary. Equally important for the proper formation of teeth, as McCollum and his colleagues²⁶ have demonstrated, is the presence in food of a due proportion of certain mineral salts. Nevertheless, although a school of children are exposed equally to unfavourable conditions, it is only in a certain number that dental defects will occur; in this respect the dental system behaves as do all structures which are liable to abiotrophic changes.

In not one of the fifty ancient skulls was the palate contracted, whereas of the fifty modern skulls there were thirteen in which this condition was present to a recognisable degree—in more than half of them to a marked extent. No matter which stratum of our population we make observations on, we shall find that every fourth or fifth child or adult we examine possesses a palate which, compared with the older type, may be described as both altered in form and reduced in size. I have never seen this defect and irregularity of palatal growth except in skulls from cemeteries of the eighteenth and nineteenth centuries. It may be thought that this irregular growth with reduction in the size of palate, and the defects in the formation of the jaws and face which usually accompany them, are merely the results of the soft and highly prepared kinds

²⁴ Some of the details of this comparison were published in "Five Lectures," issued by the Dental Board of the United Kingdom, 1924.

²⁵ Dr. E. Mellanby, *Brit. Med. Journ.*, 1912, vol. 1, p. 831; Dr. May Mellanby, *ibid.*, 1924, vol. 2, p. 354.

of food we eat; with such a dietary the teeth, jaws, and chewing muscles are deprived of the work which fell to them in more primitive times. That this is not the true explanation is proved by this fact. When children are fed, clothed, and exercised exactly alike, all are not affected; only some of them develop irregularities of the palate and jaws. There is a special susceptibility to these imperfections in certain races and in certain families.

Amongst modern British people are to be seen various facial characters, particularly in the orbits, in the cheek bones, and in the bony supports of the nose, which are never to be noted in the facial framework of people who lived in Britain during the pre-Norman period. When a Continental cartoonist seeks to represent John Bull he always emphasises these new facial characteristics. Such changes in the form of the facial bones, like contraction of the palate, which they usually accompany, are not the result of a nasal obstruction such as might be caused by enlarged adenoids or tonsils; the cause lies deeper. The incidence of irregularities in the growth of the face follow the same laws as hold for all abiotrophic structures such as the appendix, the sclerotic coat of the eye, the thymus, and the tonsil. Further research will likely prove that the disorders of growth which overtake all these structures are linked to a disturbed action of lymphocytes and of all the constituent elements of the lymphoid tissues. Dr. W. Cramer has become convinced that lymphocytes are actively concerned in assimilation of food and in the nutrition of tissues, and that the nature of the dietary does directly affect their activities. It seems to me very probable that a fuller knowledge of the life-histories of lymphocytes, particularly of the office they perform in growing tissues, will go far to explain the disharmonies which civilisation is producing in the bodies of some of us. But the problem of explaining why some members of our community are highly susceptible to these new conditions, while others are less so, and why the majority remain unaffected, will still remain.

I have touched only the fringe of a great subject; I have left undiscussed the numerous imperfections and disharmonies which civilisation has made manifest in

structures concerned in the maintenance of posture,²⁷ and in those which are concerned with the circulation of blood and with the duties of respiration. I have said enough, I believe, to show that Metchnikoff was right when he declared that civilisation had launched man on a great experiment. From this experiment there is no turning back. We cannot return to the conditions of human life which prevailed in Britain 6000 years ago; there are more people in one of the lesser back streets of London than could find an existence in the whole length and breadth of the Thames valley if we were to resume the manner of living of our distant ancestors. We cannot go back; we must go on. Seeing how differently we are now circumstanced in every relationship of life—in food, in drink, in shelter, in warmth, in occupation, and in amusement—the wonder is, not that structural imperfections and functional disharmonies should develop in a proportion of our numbers, but that so many of us should escape harm altogether and enjoy good health. It says much for the adaptational reaction which is inherent to the human body that it withstands the artificial conditions of modern civilisation so well as it does.

How are our bodies to be protected against these ills with which civilisation threatens them? Metchnikoff, a declared and open rebel against Nature, hoped that science might discover some short-cut for man's escape, some way of speeding up the evolutionary machinery of his body and so making it perfectly fitted for the life which ever-advancing civilisation is forcing on mankind. I also believe that science will find a means of escape, but not by Metchnikoff's way. The solution of our problem is a fuller knowledge of the use and working of those parts of our bodies which are most apt to give way under our modern manner of living—the use of such structures as the great bowel. When we have replaced our ignorance by real knowledge we shall then be in a position, not to adapt our bodily structures to our mode of living, but our mode of living to our bodily structures. This seems to me the best way out.

²⁷ I have discussed the "Imperfections of Man's Postural Structures" in the *Brit. Med. Journ.*, 1923, vol. 1. pp. 451, 493, 545, 587, 642, 669.

Hypothesis about Push or Contact Force.¹

By Sir OLIVER LODGE, F.R.S.

ONE of the remarkable discoveries of our times has been the pressure of radiation. Though this pressure is ordinarily so extremely minute that it was difficult to discover—and perhaps would not have been discovered had it not been predicted mathematically beforehand by Clerk Maxwell—yet in certain circumstances the pressure of light can be very large and of cosmic importance. Whether it has an influence and ought to be taken into account in the intimate structure of atoms, I am not prepared to say, but I suggest it. The Boscovich contemplation of regions where force changes sign, and our whole knowledge of the stability of Bohr's atomic orbits, represent facts which have not yet been accounted for.

¹ From the first Norman Lockyer Lecture, "On the Link between Matter and Matter," delivered to the British Science Guild in the Goldsmiths' Hall, E.C., on November 16.

Moreover, I am going to suggest that the pressure of light may have to be taken into account before the most ordinary operations of daily life, even the propulsion of a wheelbarrow, are properly explained. The force of ether-waves may encroach on the region of mechanism, and be needed for a fuller interpretation of the familiar mechanical force exerted by one body in contact with another. When denying action at a distance we must not slur over a difficulty by pleading that the distance is small.

It may seem absurd to demand a theory of the manner in which one piece of matter pushes another. Even if one denies actual contact between atoms, it is reasonable to think of each atom as so surrounded by planetary electrons as to oppose similar electrifications to each other, and thus account statically for the repulsive

force. But the electrons are in motion, and that suggests further non-static possibilities. Moreover, one effect of close approach is attraction followed by cohesion, if the approach is close enough—the atoms themselves, being charged, naturally arrange themselves for some collateral mutual attraction—a sort of residual affinity between the molecules. Why should there be repulsion instead of attraction at a certain distance?

The one thing that always gives repulsion without reference to sign of charge is radiation. Can any of this repulsion be due to radiation pressure? The idea is not to be turned down off-hand without consideration, unlikely as it may appear at first. The alternations of attraction and repulsion, at different distances apart, have to be accounted for somehow.

The pressure of radiation is proportional to the energy in unit volume, and in the case of heat radiation depends on the fourth power of the temperature, which again is proportional to the square of the atomic speed. The speed associated with any given temperature is not great; for example, the speed of helium atoms at ordinary temperature is reckoned by Eddington at 1 mile a second, and at 4 million degrees is still only 100 miles a second. The speed of electrons at the same temperature would be 40 times greater, but even that is not quick for an electron. They may be moving at anything up to 100,000 miles a second in an atom. But they are moving regularly; and regular motion is not temperature: temperature requires irregular motion. Well, my point is that the mutual perturbation of approaching atoms may cause the necessary irregularity, and that the radiation thus caused, at really close quarters, may be very intense.

We know that radiation is emitted or absorbed whenever an electron jumps from orbit to orbit. I picture the electrons of closely juxtaposed atoms as jumping up and down, like caged birds, from perch to perch. Each bird jumping up consumes energy, each bird jumping down restores it. No matter whether radiation is emitted or absorbed, the result is still repulsion. At each jump a quantum is emitted, and at very high frequencies the quantum is by no means negligible. The temperature comparable to a thirtieth of the speed of light is some thousands of millions of degrees, and the energy and pressure of radiation corresponding to that temperature are enormous; quite enough to account for any mechanical force.

Between the contiguous surfaces I picture radiation going and coming, emitted and absorbed, continually. There is no loss of energy, the radiation does not escape, but it can be very intense and can produce an enormous pressure, as it does in the interior of stars.

I spoke of the orbital electrons being perturbed by proximity, but they cannot be perturbed infinitesimally. Nothing short of a quantum of disturbance is effective. An orbital electron will not yield to any inferior disturbance; it cannot respond slightly, it responds by a jump or not at all. It is apparently under some constraint to remain in a stable orbit, until it can jump out; and if it jumps, it either emits or absorbs radiation. The quantised orbits are not susceptible to continuous perturbation: every occurrence in an atom is discontinuous. The frequency of the radiation, and

therefore the energy of the quantum, will be determined by the speed-energy-difference between the orbits.

What reason is there to suppose that proximity would introduce perturbation of any kind? Well, in inverse square orbits, equilibrium is only preserved by a certain tangential velocity. Any sluggishness or retarding force causes a projectile to drop in; any tendency to increase the speed makes it move farther away. The law of conservation of areas will no longer be obeyed when a repulsive force is applied in the plane of the orbit. On one side the particle will be accelerated, on the other retarded. Ordinarily, revolution of the apses would occur. But this may become too violent to be thus conveniently described, and it is doubtful how much ordinary perturbations are permissible in the very peculiar stable orbits of Bohr. In a quantised orbit the above sort of influence must at some stage of violence lead to a jump. A jump cannot leave the particle's energy as it was: it gains too much by a fall, some must be emitted.

That is my present idea of the force which keeps bodies apart and enables one to push another.

Parenthetically we may observe that in massive atoms the inner electronic speed is very great, and so, from these, extremely high radiation may perhaps escape, and may stimulate spontaneous radioactivity in other atoms, by getting down to and ejecting some of the deep-seated nuclear electrons. If two of those go away, an alpha particle is likely to be driven out violently by electrical repulsion.

The state of matter in or near a nucleus may be comparable to the state inside a star like the companion of Sirius, except that gravitation is inoperative. The close-packed density is prodigious.

These ideas are crude, granted; but a working hypothesis is a thing to be worked, its consequences to be traced, and then either improved or discarded. Anyhow our aim ought to be to explain those facts on dynamical principles, perhaps not the ordinary dynamics, but etherial dynamics, and that is far from having been worked out; perhaps it cannot be said to have been begun.

Already some attempt has been made to assimilate radiation with matter by the unlikely path of thermodynamics. Radiation has been used as the working substance in a theoretical heat engine. Its pressure has thus been mechanically employed. It has been dealt with almost like a gas. The laws of gases—the statistical behaviour of discontinuous random particles—have been applied to electricity, and even to radiation. By this means not only can the known law of Stefan, connecting *total* radiation with temperature, be deduced, but also a law regulating the distribution of energy among different wave-lengths has been formulated by the genius of Wien: which formulation, though it is not yet fully explained, is nevertheless true. The average energy associated with any particular wave-length must be equal to some function of the product of wave-length and absolute temperature, divided by the fifth power of the wave-length. That is Wien's law. This law involves an unknown function, as well as the curious idea of the temperature of space or of radiation; for it deals with the waves statistically, after the manner of the kinetic theory of gases. The flying about of the radiation inside a completely

reflecting enclosure has a complete irregularity, which justifies the application of the term "temperature" to the energy therein contained.

As for the unknown function—the discovery of that was elucidated by Rayleigh, and completed by Planck; and it is there that the "quantum" made its appearance. For if the energy could be absorbed or emitted continuously, all the energy of matter would go into the ether, and the universe would fade away and die, or at least would cease to be active. The effect of dis-

continuous emission and absorption saves the universe from destruction, and makes this lively planet possible. If radiation could go on from atoms continuously, all the energy would get into the ether: matter would have none, and none of us would exist.

These discoveries have no human significance, people think. They are chock-full of significance. We are down among the foundation-stones of reality, the laws which make activity possible, the laws which perpetuate the atoms of which our own bodies are composed.

Scientific and Industrial Research in 1924-25.¹

THE latest report issued by the Department of Scientific and Industrial Research consists, as usual, of a short summary report by the Committee of the Privy Council, a long report by the Advisory Council, a summary of the work done by research institutions directly under the Department, numerous appendices, and a good index. In the first report the view is expressed that the embarrassments and losses which British staple industries are suffering do not arise primarily from the neglect of science, although in many cases delay in recovery is caused by lack of scientific leadership. The successful application of scientific discoveries to industry is a slow and expensive business, as witness the delay of two generations in applying Faraday's work on electro-magnetism, and the interval of twenty years which elapsed between the discovery of artificial indigo and its successful exploitation at a cost of 1,000,000*l.* The Fuel Research Station is apparently following these precedents, for in spite of an expenditure of more than 400,000*l.* in seven years, it has found no solution of the problem of producing smokeless fuel at an economic cost. It is, however, stated that the work has produced profits and economies in other directions which exceed in monetary value the total expenditure on fuel research. Attempts to manufacture power alcohol from beets, mangolds, and Jerusalem artichokes have also proved abortive, although the last-named are still being cultivated in various localities for use in future tests.

The Food Investigation Board has devoted most of its attention to the handling and preservation of food in order to reduce loss and to increase supplies. The problem of the freezing of beef has been attacked from the point of view of the freezing of colloids, and it has been found that if a mass of colloid, *e.g.* a disc of jelly, be frozen slowly, ice forms on the external surface, whereas if the rate of freezing be high, congelation takes place within the mass. When eggs are preserved by cold, protein is thrown out of solution and is not redissolved on thawing. In the living organism highly insoluble substances are often held in solution by other substances, and freezing apparently renders them permanently insoluble. Changes undergone by fruit and vegetables during storage and transport are still under investigation, but the work on fish preservation has been held up owing to the impossibility of conducting experiments at an inland station. Many problems connected with cold storage are being studied at the National Physical Laboratory, such as the inflammability of heat-insulating materials, the physical

properties of refrigerants, hygrometry, rate of flow of fluid in the circuit of a refrigeration plant; and on the chemical side, work is being continued on the higher unsaturated fatty acids, glycogen, and the formation of fat by yeast.

The Geological Survey has surveyed the coalfields and adjacent areas, investigated mineral deposits, water-supplies, and examined rocks and soils exposed during the construction of new roads. The Museum of Practical Geology and the Geological Survey are to be permanently housed in buildings to be erected adjoining the Natural History and Science Museums at South Kensington. A site has been acquired at Princes Risborough for the Forest Products Laboratory, but for the next two years work will be continued at the Royal Aircraft Establishment in Hampshire. Investigations in progress include the cause of brittleness in timbers, preservatives for wood other than creosote, and the improvement of kiln-drying practice.

Building research is assuming greater importance owing to the serious housing situation, and so a new and larger research station is about to be opened at Watford. The fundamental problems that are being attacked, under the advice of four expert committees, include: (1) architectural acoustics, moisture-condensation on internal wall-coverings, and the rate of transmission of moisture through building materials; (2) setting and hardening of cements, including non-corrosive oxychloride flooring materials, and changes in volume of building materials due to moisture changes; (3) preservation of stonework, and attempts to express "weathering" in terms of temperature and moisture variations; (4) wind-pressure on roofs, bridges, etc., vibration due to machinery, or road and rail traffic, permeability of concrete and its movements due to moisture and temperature changes, standardisation of tests for compression, abrasion, and hardness. Some of these investigations are already yielding results of immediate practical importance.

The work of the National Physical Laboratory (N.P.L.) is so vast and diverse that reference can only be made here to some of the investigations in pure science which it has undertaken recently, namely, calorimetry at high temperatures, the magnetic properties of iron and other alloys, properties of dielectrics, the vertical-force magnetometer, the efficiency of power transmission by gears, ferrous alloys free from carbon, and methods of spectrographic analysis of metals and alloys.

Important duties are also carried out by the various co-ordinating research boards. In chemistry, the commercial production of formaldehyde as a cheap

¹ Report of the Committee of the Privy Council for Scientific and Industrial Research for the Year 1924-25. Pp. 155. Cmd. 2491. London: H.M. Stationery Office. Price 3*s.* net.

disinfectant for wool has been investigated, but owing to the cost of concentrating the dilute solutions obtained, success appears improbable. The production of carbon tetrachloride on a large scale, the corrosion of metals, accumulators, and containers for liquid oxygen, have been studied experimentally, but work generally has been impeded by the lack of adequate laboratory accommodation. More rapid progress can now be anticipated in view of the completion of the new chemical laboratory at Teddington, where special attention will be given to the study of chemical reactions under high pressures. The Engineering Co-ordinating Board has dealt with researches recommended by the Aeronautical Research Committee, such as light alloys, fatigue of materials, elasticity of steel strip, strength and properties of materials at high temperatures, prevention of rust, and tests for motor tyres. Among the researches undertaken in physics are: the silencing of aeroplanes, a high-power source of sound, acoustical properties of building materials, elasticity of aircraft materials, yellow glass for railway and aircraft lights, standardisation methods for the specification of colour, and the general nature of phosphorescence.

The gross expenditure on the various programmes of research was 303,070*l.*, of which 50,471*l.* was incurred for fuel research, 22,927*l.* for engineering, 17,571*l.* for food investigation, 14,529*l.* for chemistry, 13,948*l.* for radio, 11,940*l.* for building research, and 140,138*l.* for research and standardisation at the National Physical Laboratory. In all, 173,455*l.* was expended on the N.P.L., but nearly one-half of this sum was recovered in fees for tests and special investigations made for outside bodies.

The number of research associations in being during 1924-25 was twenty-five, of which twenty-one were in active operation. The Glass Research Association and the British Portland Cement Research Association have been liquidated, and the future of the Scottish Shale Oil Research Association appears doubtful. Research on glass will for the present be continued at the N.P.L., by the British Scientific Instruments Research Association, and in the Department of Glass Technology of the University of Sheffield. It is anticipated that a research association for food manufacturers will be launched shortly. Several associations appear to be in financial low water, and have needed the assistance of increased or extended grants; on the other hand, no payment was made to the British Iron Manufacturers' Association (which is temporarily suspended), or to the newly formed British Colliery Owners' Research Association.

The total disbursement on grants was 100,118*l.*, and the unexpended balance of the Million Fund was 518,200*l.* Average grants made to some of these associations during their existence—ranging from two to seven years—have been as follows: glass, 11,720*l.*; electrical and allied industries, 9552*l.*; cotton industry, 9819*l.*; scientific instruments, 9212*l.*; linen industry, 7510*l.*; portland cement, 4418*l.*; Scottish shale oil, 1500*l.*; rubber and tyre manufacturers, 5061*l.*; non-ferrous metals, 4070*l.*; boot, shoe, and allied trades, 797*l.* The total expenditure on the 258 grants made to individual research workers and students in training was 35,000*l.*; and the cost of administration at headquarters was 35,920*l.*, or about 6.5 per cent. of the total expenditure of the Department (539,199*l.*).

Obituary.

PROF. J. N. LANGLEY, F.R.S.

"YOU will always find it easy to generalise so long as you are content not to inquire too closely into detail." In these words, or words rather like them, Langley once expressed something which was very near to being the pivot of his intellectual outlook. The occasion was somewhere about the summer of 1900, when he was working at the properties of adrenalin, and discussing whether it could or could not be regarded as a general stimulant of the nerve-endings of the sympathetic system.

He came into the old physiological library at Cambridge, Foster's old room, from his operating room next door, to snatch a couple of rolls and a glass of milk. These formed the standard laboratory lunch of those days, and Langley would fall to talking about his work. Having finished his lunch he would return and perhaps operate until four or five in the afternoon, having started at about half-past ten. When he was conducting a research he would work in this way at high pressure for days on end, carrying through a long and exacting experiment each day, his marvellous skill as an operator making it possible for the animal which he was studying to remain in good condition for a very long time. When his experiments on a particular point were finished, he would absent himself from the laboratory until the paper was written—I am now speaking of the days before he was professor; when it had gone to press he would take up the next point. He was essentially a

worker who did one thing at a time and developed his thesis, or allowed his thesis to develop itself point by point.

Langley was never content not to look too closely into detail. "The exception which proved the rule" had no meaning for him. It just upset the rule, and Langley was always more content to remain ignorant of "the rule" than to compromise in the slightest degree with the detailed statement of facts. His attitude was possibly born of his experience in making his survey of the autonomic system. That was his great work, and alone it would have formed a sufficient basis for his equally great reputation. Whether or not it was a feat of anatomy rather than of physiology is a matter which might provoke discussion. I have thought at times that had Langley labelled himself as an anatomist he would have been accorded an outstanding position in that subject. It would have been difficult for him to adopt that label, for he was not a qualified medical man, and indeed I suppose he was one of the first men who were pre-eminent in physiology without being medical practitioners. As time has passed, Langley's example has been followed by many another, and I imagine that as chemistry plays an increasing rôle in physiology, an increasing number of physiologists will be "unqualified."

To return, however, to the autonomic system; the methods by which Langley explored it were partly physiological and partly anatomical. On the physio-

logical—or perhaps even the pharmacological side—he discovered that nicotine abolished the conductivity of a synapse. This discovery provided a method for the charting of all stations throughout the autonomic system. One such still bears his name—Langley's ganglion in the submaxillary gland. Also, of course, much of his routine consisted in the stimulation of nerve-trunks with the object of ascertaining what response was produced in the peripheral endings attached to them. But a great deal of the method was frankly anatomical. It consisted in cutting a nerve-trunk and seeking out through the innumerable ramifications of the sympathetic system the destination of all the cut fibres. These might amount to hundreds or even thousands. The cut fibres were allowed to degenerate and so could be recognised from their sound fellows by their histological appearance. When the fibres had degenerated the animal was killed, all the peripheral nerves involved were examined, and the sound fibres were separated from the degenerate ones and the latter were teased out into rows under the microscope and counted.

It is not very easy to appraise the value of Langley as a lecturer; in my student days he did not give elementary lectures; therefore I can only speak of his advanced lectures at first hand. My memory of these is that they were mines of information, and the notes which I took from them were of the utmost use to me in subsequent teaching. But I remember also that to get a clear idea of the lectures required very close attention on the part of the student. Langley's method was to pass from one subject to another by a very gentle gradation rather than by an abrupt change; so gradual indeed was the passage that unless the student was attending pretty closely he ran the chance of missing it altogether. If that happened—if, for example, you thought he was still lecturing about the spleen when he had really passed to the thymus—it was not very easy to pick up the threads. This habit, which provided an occasional stumbling-block to advanced men, presented, I imagine, much more difficulty to a class more ignorant and less able to concentrate. At all events it is certain that different persons derived very different amounts of benefit from his elementary course. No one, however, regarded the lectures as in any way trivial, or Langley as anything but the great physiologist which he was. It was a matter of conscience with him to demonstrate in person throughout the whole of every practical class in histology, and also many of those in the "machine room," his object being to get to know each man individually in so far as that object could be attained.

Langley was seventy-three years of age at the time of his death on November 5. He and Sir Edward Sharpey-Schafer formed the remaining two of a generation of experimenters which really placed British physiology in the position which it now occupies. That position has been amply sustained by a brilliant group of men ten years or so their juniors. Langley's whole life as a physiologist was spent in Cambridge, excepting a short time after the taking of his degree when he worked in Heidenhain's laboratory. It was there, I think, that his interest in the salivary and other secreting glands commenced. That interest, by a gradual transition, led to an investigation of the nerves

which operated them. Those were days of antagonistic nerves; the salivary glands provided an outstanding example of their action, and it was not unnatural to hope that if the action of the chorda tympani and the sympathetic respectively on the protoplasm of the submaxillary gland was understood, a great stride would have been achieved towards the comprehension of living processes in general. It was not to be. Nearly fifty years have passed; much work has been done (the most recent being that of Anrep and Harris), and the submaxillary gland now appears rather the example of an anomalous meeting-place of the cutaneous and internal innervations than the *venue* of a typical process of life. Langley, I think, saw this. At any rate, he forsook the study of its cells and was led by that of its nervous supply to the investigation of the autonomic system as a whole.

In Cambridge, Langley took an active part in the organisation of the scientific side of things. He was chairman, at the time of his death, of the Special Board of Biology and Geology, and at an earlier period he served a term in the Council of the Senate. Langley's "distinctions" were so numerous as to make their mere recital tedious; they occupy about a dozen lines of small print in the year book of the Royal Society. Probably there was none that he valued more than the Royal Medal of the Royal Society itself.

The above account of Langley has of necessity dealt chiefly with his scientific work. It would be incomplete without emphasising the fact that, scientist as he was, he was singularly many-sided and the very antithesis of the stage professor. Excellent company, whether as a host or as a guest, and fond of outdoor exercise of many kinds, he excelled as a skater. At one time it was his custom to go to Switzerland for the winter, and in the early 'nineties possibly there were not a dozen such good skaters as he in England.

Langley has left two material monuments, the *Journal of Physiology* and the Cambridge Physiological Laboratory. Of the former he became owner and editor. By universal consent there is no better journal; it was rigorously edited, papers were ruthlessly pruned of anything which was redundant or confusing—"woolly," as Langley used to say. Yet as an editor Langley had a wonderful sense for the important, and, severe as was his critical faculty, he had a generous appreciation of any grains of real merit in a man's work. The Physiological Laboratory at Cambridge is no less the product of his power of minute organisation. He, aided by Dr. (now Sir Walter) Fletcher, set himself the task of producing a laboratory which should be adapted, down to the minutest details, for the very various kinds of work which went on in Cambridge at that time, the work of Gaskell, of Anderson, of Hardy, of Mines, of Fletcher, of Keith Lucas, of Rivers, of Hopkins,¹ of Hill, and of quite a number of others. Greater than any material monument, however, is that of the school of workers over which he presided.

J. BARCROFT.

PROF. A. V. HILL writes: "Attention has been directed recently in the Press to the faculty of prophecy which—within limits—mankind possesses. The

¹ The physiological laboratory as originally designed included a wing for biochemistry.

following letter sent to me just sixteen years ago (Nov. 11, 1909) by my late friend and master, Prof. J. N. Langley, is an example of those qualities of scientific judgment which, on occasion, enable men of rare intellect and knowledge to predict the future. In view of what has happened since he wrote, in the scientific study of muscle, physiologists will appreciate the accuracy and insight of Prof. Langley's forecast and advice; and they may be glad to read, as a tribute to his scientific memory, the words which he himself wrote in 1909."

HEDGERLEY LODGE,
CAMBRIDGE,
Nov. 11, 1909.

MY DEAR HILL—I have been thinking over the question of what piece of work it would be best for you to undertake. I am inclined to think that you might settle down to investigate the variation in the efficiency of the cut-out frog's muscle as a thermodynamic machine. A good many years ago Heidenhain and Fick worked at this, but there is an especial problem suggested by Fletcher and Hopkins' work, as to the efficiency of the muscle working with and without oxygen, which I don't think has been touched. Once started there are plenty of further experiments to do, and the question is a very important one for muscle physiology. . . . I have, I think, Blix' apparatus in the Laboratory [he had bought it some time before as a speculation for some future pupil] which he stated to be delicate enough to show the heat developed in frog's muscle by a single muscle contraction, and we can get any other apparatus you want.

So think it over. I enclose a couple of pages showing some of the bearings of the problem.—Yours sincerely,
J. N. LANGLEY.

MR. THOMAS CASE.

MORE than one branch of learning is the poorer for the death of Thomas Case, late president of Corpus Christi College, and sometime professor of moral and metaphysical philosophy at Oxford. He was an accomplished musician, a learned student of architecture, and in his day a most successful lecturer on ancient history. Philosophy was with him only one among many interests which claimed his attention almost equally. In philosophy he was as one born out of due time. A man of singularly individual mind and temperament, he took his own line in philosophy, and vigorously resisted the semi-Kantian, semi-Hegelian idealism which in his earlier days became the prevailing philosophy at Oxford. But though he resisted it, the influence of Green and Wallace, of Bradley and Bosanquet, was too strong for him, and he remained to a large extent a solitary figure among Oxford philosophers—less fortunate in this respect than Cook Wilson, whose reaction against idealism carried with it the support of many of his younger colleagues. Wilson's realism was, it must be admitted, the better based and the more philosophical of the two.

Case was always somewhat too dogmatic in his mode of thinking and of presentment. His own insight was often keen and penetrating, and he was too apt to assume a readier assent to what to himself seemed clear, than he was actually likely to receive from the average reader. It must be confessed, also, that he was capable of strange blunders. In his first

book, "Physical Realism" (1888), while he says much that is acute and well worth reading, he puts forward a theory of the object of perception which is one of the least plausible of all theories on the subject—that what we see or hear is our optic or auditory nerves coloured or resonant.

Apart from this book, Case's chief philosophical writings are the articles on logic, on metaphysics, and on Aristotle in the 11th edition of the "Encyclopædia Britannica." The article on metaphysics is a learned and able study of the main trends of metaphysical thought in modern times. That on logic, while devoted in part to expounding the views of Case's two heroes in philosophy, Aristotle and Bacon, shows considerable appreciation of the advances made by the subject in the nineteenth century. The article on Aristotle is notable for the attempt, in which Case to a large extent anticipated the brilliant German scholar Werner Jaeger, to trace a development in Aristotle's thought as between different writings and to use this as a reason for the determination of their dates. Two of his main contentions, that the "De Interpretatione" and the "Eudemian Ethics" stand on the direct line of development from Plato's thought to that most typical of Aristotle, and are therefore genuine and early works, are likely to stand the test of time.

To the younger generation at Oxford, Case's attitude on political and academic questions seemed to be that of extreme Toryism. But he himself insisted that he was not a Tory but a Palmerstonian Liberal. He was, first and last, above everything else an individualist. What could not be doubted by any one was that he was an able, public-spirited, and extremely formidable fighter in whatever cause he espoused. Oxford had no more genial, clever, and amusing resident than "Tommy Case," as he was universally called, *amoris causa*.

SIR JOHN MACALISTER.

SIR JOHN YOUNG WALKER MACALISTER, who died in his seventieth year on December 1, had been for many years secretary and consulting librarian to the Royal Society of Medicine, a post in which his imagination, energy, and personal charm enabled him to do great things. The second son of Donald MacAlister of Tarbert, Cantyre, he was educated at Liverpool High School, studied medicine for three years at Edinburgh, and was then driven by ill-health into the quiet waters of librarianship, only to spend the rest of his life in overflowing his banks, much to the benefit of the surrounding country. He passed rapidly from a sub-librarianship at Liverpool to librarianships at Leeds, at the National Liberal Club, and finally, in 1887, at the Medical and Chirurgical Society, then uncomfortably housed in Berners Street. Under its new librarian's inspiration, the Society soon moved to a fine house at 20 Hanover Square, where it became the benevolent landlord of many other associations.

While the Medical and Chirurgical Society was developing in its new quarters, MacAlister put in eleven years of fine work as the honorary secretary of the Library Association, which he piloted until it obtained a royal charter in 1898. He also founded *The Library*, which for ten years was the organ of the Association, for twenty more an independent quarterly,

and six years ago was handed over by him to the Bibliographical Society, which itself had been founded, in 1892, at a meeting at 20 Hanover Square, brought together by MacAlister. By 1905 his ideals for the Medical and Chirurgical Society had taken definite shape, which led to the building of its present fine quarters at the corner of Wimpole Street, where it now thrives as the Royal Society of Medicine, with some four-and-twenty associated societies under the same roof. At the dinner which was given to MacAlister in 1920, after he had been knighted, Sir William Osler, who was in the chair, hailed him as the layman who had done more for the profession of medicine than any doctor, a fine achievement for a man who had been prevented himself by ill-health from adopting it as a career.

Current Topics and Events.

OUR readers will accord hearty congratulations to Prof. W. C. Unwin, F.R.S., a veteran of the engineering world, who celebrates his eighty-seventh birthday this week, namely, on December 12. An Essex man, he was educated at the City of London School, and afterwards became a pupil in the firm of William Fairbairn, Manchester. Following the managership of engineering works, he was engaged as instructor at the Royal School of Naval Architecture and Marine Engineering, South Kensington, 1868-72; afterwards as professor of hydraulic engineering at the Royal Indian Engineering College, Coopers Hill, 1872-85. Prof. Unwin then took up a professorial post at the Central Technical College of the City and Guilds of London, occupying this for twenty years. One might have thought that this long period of strenuous work would have dulled endeavour, but it was otherwise. In 1911 he was president of the Institution of Civil Engineers. At a conference there in that year on the training and education of engineers, Prof. Unwin said: "I believe the idea that a college course unfits a man for practical work is a wholly mistaken one . . . the view of the employer who looks only to the immediate usefulness of the student is a short-sighted one." On retirement from office the late Sir William White emphasised that "Unwin was looked upon as a master and teacher of the science of engineering." In 1915 the professor was elected president of the Institution of Mechanical Engineers. His portrait, painted by Harold Speed, may be seen there—testimony to service. Prof. Unwin's views on the organisation of research work on British timber may be quoted as of current interest. Speaking at the Royal Society of Arts, in 1913, he remarked that if a forest laboratory were established on any considerable scale in Great Britain, the discovery of information about our colonial timbers would be of even greater importance than that dealing with home forest products. So recently as April last, Prof. Unwin took part in the discussion of a paper by Mr. G. A. Hankins on "Hardness Research Tests," at the Institution of Mechanical Engineers.

PROF. JOHN T. CASH, F.R.S., formerly Dean of the Faculty of Medicine in the University of Aberdeen, will be eighty-one years of age on December 16,

WE regret to announce the following deaths:

Mr. R. G. Backall, a pioneer in X-ray work at the London Hospital and the recipient in 1923 of the honorary certificate of the Carnegie Hero Fund, on November 29, aged forty-four years.

Prof. E. D. Campbell, chief of the chemical and metallurgical laboratory in the University of Michigan, member of the Iron and Steel Institute, known for his work on the constitution and magnetism of iron-carbon alloys, who was blind for the past thirty-three years, on September 18, aged sixty-two years.

Dr. W. R. Dykes, secretary of the Royal Horticultural Society and an authority on the genus *Iris*, on December 1, aged forty-eight years.

Mr. W. P. Hiern, F.R.S., author of "*Dicotyledons*" (1896-1900) and of a monograph on the *Ebenaceæ* (1873), aged eighty-five years.

and to him also our cordial congratulations are extended. After graduating at the University of Edinburgh, he engaged in scientific research at Berlin, Leipzig, and in London. He collaborated with the late Sir Lauder Brunton, F.R.S., in a series of medico-chemical studies, detailed in papers, notably "Contributions to our knowledge of the connexion between chemical constitution and physiological action"; "On the effect of electrical stimulation of the frog's heart and its modifications by heat, cold, and the action of drugs"; "Action of caffeine and theine upon voluntary muscle."

IMMEDIATELY after the tragic death of Prof. Maxwell Lefroy on October 14, an appeal was made to the public to subscribe twenty thousand pounds to establish a memorial to him. The institution which made this appeal is called the College of Pestology (Incorporated), with a registered office in Bedford Square, London. The "College" is not included, however, in any standard book of reference of educational institutions, and apparently it exists as such an institution only in name, for there seem to be no laboratories or staff, except the honorary director, Mr. A. Moore Hogarth. It formerly existed as the Incorporated Vermin Repression Society, and the present name was assumed only two or three years ago. The "College" has, of course, no connexion with the University of London, and its title is therefore a little misleading to those who do not know the difference between a propagandist body and an educational institution. We have complete sympathy with what the organisation has done in directing attention to the danger and destruction due to rats, mosquitoes, and other pests, but it is another matter to ask the public to subscribe twenty thousand pounds for "a chair and centre of applied biology at the College of Pestology, Bedford Square." If a memorial is contemplated, surely the right place for it would be the Imperial College of Science, South Kensington, where Prof. Lefroy had his laboratory, and where he met with the accident which led to his death. In any event, a matter of this kind ought not to be in the hands of a small committee connected with such an unofficial organisation as the College of Pestology, but of a representative group

which would include Prof. Lefroy's scientific colleagues. We hope, therefore, that further consideration will be given to the proposal and the constitution of the appeal committee before subscriptions are sent in response to the circular letter recently distributed.

THE Streatfeild Memorial Lecture was delivered on December 3 at the Finsbury Technical College, London, by Mr. F. H. Carr, who spoke on "The Scientific Basis of Industry," and dealt chiefly with the training of chemical engineers, and with the possibility of prolonging the existence of the College in a new form. Like many others, Mr. Carr regrets the impending dissolution of "Finsbury," which was a pioneer in teaching the elements of engineering to chemical students, and in educating them for industrial careers. The view is often expressed, and Mr. Carr seems to share it, that the successful application of science to industry is the main pivot upon which civilisation hangs, and that the future belongs to those nations which can attain a higher standard of living and shorter hours of work by substituting machines for human labour. This material view of progress may be sound economically, and we know that there is a constant interaction between the material and the non-material, but surely such factors as character, courage, adaptability, and eugenics are at least of equal importance. Herein, we believe, lay the weakness of those who favoured specialised training for the immature in the isolated technical college, as against training in the much wider culture offered by the university proper. Man cannot live by bread alone, and even the highest technical efficiency cannot save a nation if it is wanting in the more spiritual virtues. It is therefore with interest that we note Mr. Carr's suggestion that the future of "Finsbury" should be in a close association with the University of London. In the past, he says, chemists have been trained on lines that were too stereotyped; the student with little aptitude for abstract studies, but with great potential capacity for technology, has failed to profit from the ordinary degree-course in science; and the fault lies with the course of study, not with the student.

IN 1914, Great Britain was crying out for men who could apply science to industry, and particularly for chemical engineers. The need is still urgent. The Ramsay Memorial Laboratory of Chemical Engineering at University College, London, lacks endowment and the necessary means to develop. The Finsbury Technical College is about to be closed down. Why not, says Mr. Carr in effect, solve the three problems simultaneously by accommodating the Ramsay Laboratory in the Finsbury buildings, and asking the City and Guilds of London—or a private benefactor—for a generous endowment? The idea is ingenious and well worth examination; but whether it be accepted or not, there is no doubt of the need in Great Britain of a great school of chemical engineering comparable in magnitude and efficiency with those possessed by Germany, Switzerland, and the United States, which, as the lecturer pointed out, have been

responsible for some of the greatest recent advances in applied chemistry. Such a school would require not only a different equipment, but also a different curriculum from those now in use in our universities. To obtain admittance, the student should have reached the standard of the London Intermediate Science Examination; training in engineering should not wait upon an advanced knowledge of organic and physical chemistry, but should precede or accompany it. Adequate provision should be made for research in applied chemistry, which demands a more mechanical type of technique than that upon which chemical technologists have been reared in the past; and special attention should be given to bridging the gap between laboratory and works. It is a fallacy to think that any one type of chemical education is suitable for all. The student who is to control plant or manage a works requires more than a good foundation of general science; he needs an insight into works' problems, and special knowledge that will help him to solve them.

At the opening of the National Radio Conference, held at Washington in November, Secretary Hoover said that the interests of the listening public must come before all other interests. He first pointed out that the leading position in the international field is taken by American radio-telegraphic companies. Direct service with Sweden has been commenced, and in another year telegraphic communication will be established with practically every country in the world. During last year there was a great increase in the number and the power of the broadcasting stations in the States. Last year there were 115 stations using 500 watts or more and generating a total power of 67,500 watts. There are now 197 stations and the total power has increased to 236,500 watts. The desire for publicity is the basic motive, and furnishes the financial support for almost all the broadcasting that is taking place. Listeners may well object to their sets being monopolised at stated times by advertising matter. In the future it will be necessary to distinguish between unobtrusive publicity accompanied by an engaging entertainment and unobtrusive advertising. The problem of interference has become a serious one. In the States there is a total of 578 stations, no more than four of them being under the same management, and there are now pending 175 applications for new broadcasting stations. Something therefore has to be done. A few high power stations operating full time give a far better service than many smaller stations operating for part time only. Mr. Hoover considers that the allotment of wave-lengths, the control of power, and the policing of interference should be in the hands of the Federal Government. Although radio is not circumscribed by State lines and still less by city boundaries, it is possible to establish zones which roughly correspond to service areas. Each zone might be entrusted with the settlement of its own local problems.

EVERY year brings forward new evidence that insects are important factors with reference to

public health, and the list of diseases that are partially or entirely spread through the agency of these organisms is steadily increasing. The first human disease to be traced directly to an insect carrier was malaria, and this discovery gave the impetus which has led to the recognition of the extensive rôle played by insects in disease-transmission, either from man to man or from one animal to another. The efforts of the entomologist, coupled with those of sanitarians and doctors, have resulted in truly remarkable progress being made in the reduction and restriction of such diseases as yellow fever, malaria, typhus fever, and plague. The subject of "Insects in Relation to Public Health" was selected by Sir Wilfred Beveridge for a Chadwick Public Lecture delivered by him in the Barnes Hall of the Royal Society of Medicine on November 18. Apart from its value in economics and the prevention of disease, the study of insect life, Sir Wilfred maintained, generates the quality of accurate discrimination and develops the capacity for observation. A knowledge of entomology, he added, is essential to every medical man, but training in that subject is generally restricted to those who embark on public health work or practise medicine in the tropics. A knowledge of entomology likely to be of real value must not be confined merely to the study of insects which are at present known to be injurious, but should be sufficiently comprehensive to enable the student to be prepared for any new problem that may arise. The measures in vogue for combating flies and other insects carrying disease germs were referred to, and Sir Wilfred showed the importance of regulating our sanitary efforts so as to reduce the breeding places of such insects. In dealing with the planning of preventive measures, the importance of studying natural methods of control was pointed out, and how they should be emulated so far as may be possible in the campaign against noxious insects.

PROF. F. G. PARSONS delivered at St. Thomas's Hospital on December 4 an interesting lecture on the early inhabitants of London, illustrated by specimen skulls of the Long Barrow type—surviving among the miners of the Forest of Dean—the Beaker folk and the Celts or prehistoric Nordics. Evidence pointed to Cymbeline as a possible founder of London. His capital was at St. Albans, and the position of London may have been selected for purposes of trade at a point lower down the river than the earliest ford at Westminster. Cymbeline's name is recorded in the name of the Buckingham villages, Great and Little Kimble, in the Chiltern country, which was the limit of his kingdom. That the earliest site of London was in the south of Cornhill is indicated by two lines of evidence: first, the absence of Roman interments in that area, and secondly, the recently discovered relics of Boadicea's burning of London. The converging Roman roads are evidence of the importance of London. Melitus, the first Bishop of London, ruled in the early part of the fourth century. The lecturer also dealt with the second Nordic incursion and the relations of the Saxons, Franks, Angles, Frisians and so-called Jutes to London.

SIR RONALD ROSS is leaving for Ceylon on the s.s. *Yorkshire* on Friday, December 11. His journey is being undertaken at the invitation of the Ceylon Association and he will investigate conditions in the island from the point of view of malaria control. Plantations in various areas will be visited, and Sir Ronald hopes to be able to advise as to methods which should be adopted in combating the disease.

THE sixteenth annual exhibition of the Physical Society of London and the Optical Society, which is to be held on Tuesday, Wednesday and Thursday, January 5, 6 and 7, at the Imperial College of Science and Technology, Imperial Institute Road, South Kensington, will be open in the afternoon (from 3 to 6 P.M.) and in the evening (from 7 to 10 P.M.). The following lectures have been arranged:—Mr. J. E. Barnard, on "The Search for Ultra-Microscopic Organisms," at 8 P.M. on January 5; Prof. A. F. C. Pollard, on "The Mechanical Design of Instruments," at 8 P.M. on January 6; and Major W. S. Tucker, on "Electrical Listening," at 8 P.M. on January 7. Some seventy firms are exhibiting scientific apparatus, and in addition there will be a group of non-commercial exhibits by fellows of the Societies and others, including demonstrations of famous historical experiments in physics, recent physical research and effective lecture experiments. The exhibition will be open to the general public without tickets on the third day, January 7. On January 5 and 6 tickets of admission, obtainable from the secretaries of scientific societies or from Prof. A. O. Rankine of the Imperial College of Science and Technology, will be required.

THE scientific society known as the Priestley Club, founded in 1875 for the purpose of promoting the discussion of scientific topics and of facilitating the social intercourse of scientific men in Leeds and the West Riding of Yorkshire, is to celebrate the attainment of its jubilee by a dinner in the University, Leeds, on Tuesday, December 15. The members of the Club include chemists, physicists, biologists, mathematicians, medical men and technologists who, for the most part, are engaged in scientific work at the University of Leeds or other institutions, in the industries of the neighbourhood, or in the practice of the learned professions. The speakers will include Sir J. C. Irvine, Principal of the University of St. Andrews; Dr. J. B. Baillie, Vice-Chancellor of the University of Leeds; and Prof. Arthur Smithells.

THE weather in Canada during October, as shown on the weather map of the Canadian Meteorological Service, was abnormal in several respects. In arctic Canada the weather was warmer than usual in that month, in some places by so much as 6° F., while elsewhere it was a cold October, and in some parts, as Saskatchewan, the coldest October for fifty years. In British Columbia there was a remarkable deficiency of rainfall; in Saskatchewan the deficiency was less marked, and in Alberta all districts except the extreme south-east had an excess. In eastern Canada there was much more snow than is usual in October and precipitation generally was in excess of the normal. Threshing and ploughing in the prairies were carried

on with great difficulty, and in some districts considerable work was unfinished at the end of the month. Nowhere, in fact, was October a favourable month for agricultural work.

THE majority of modern scientific appliances are the results of team work, and the cinematograph is no exception to this. So long ago as 1870, Henry Heyl exhibited on a screen in Philadelphia a series of posed pictures showing the movements of a couple dancing, but it was C. F. Jenkins, of Washington, who invented the first practical projector for throwing on the screen life-sized pictures from films taken of living moving objects. His first public exhibition took place in 1894 in Richmond, Indiana. The following year the brothers Lumière gave a public exhibition of cinematograph pictures in a café in Paris. The site of this, the first cinema hall in the world, is No. 14 Boulevard des Capucines, and we note with interest that the municipality of Paris is to commemorate the event by placing a tablet on the building which now stands on the site.

THE lecture arrangements at the Royal Institution before Easter next year have recently been announced. The Juvenile Lectures will be delivered by Sir William Bragg on "Old Trades and New Knowledge," commencing on December 29 at 3 o'clock. On Tuesdays, at 5.15 P.M., beginning on January 19, there will be two lectures by Dr. J. A. Crowther on "X-rays and Living Matter"; two by Dr. E. K. Rideal on "Surface Action"; four by Prof. J. Barcroft on "The Egg"; and two by Dr. C. H. Desch on "The Growth of Crystals." On Thursday, January 21, at the same hour, Dr. C. J. Patten will give the first of two lectures on (1) "The Language of Birds," (2) "The Breeding Factor in Birds." These will be followed by three lectures by Dr. J. L. Myres on "Who were the Greeks?"; three by Dr. C. D. Ellis on "The Atom of Light and the Atom of Electricity"; two by Dr. J. Holland Rose on "The Indecisiveness of Modern Warfare." On Saturday afternoons at 3 P.M. Mr. Henry Balfour will give two lectures, commencing on January 23, on (1) "The Evolution of Currency and Coinage," (2) "The British Coracle, or the Skin-covered Boat and its Affinities." On succeeding Saturday afternoons there will be two lectures on "The Nature and History of the Triad and the Perfect Fourth," by Sir Walford Davies, with musical illustration; two by Dr. George Macdonald on "Roman Britain"; and four by Sir Ernest Rutherford on "The Rare Gases of the Atmosphere and their Importance in Atomic Theory." The Friday evening meetings will begin on January 22, when Sir William Bragg will deliver a discourse on the work of the Davy Faraday Research Laboratory. Succeeding discourses will probably be given by Sir William Hardy, Prof. George Gordon, Prof. Robert Robinson, the Hon. J. W. Fortescue, Dr. C. Hagberg Wright, Sir J. J. Thomson, Mr. John Tweed, Sir Ernest Rutherford, and others.

THE Pathological and Bacteriological Laboratory Assistants' Association continues its successful career under the presidency of Prof. H. R. Dean, of Cam-

bridge. There are now 102 registered members who have obtained certificates of proficiency in various branches of pathological laboratory work, 158 ordinary members and 97 junior members. Regular courses of lectures and practical instruction are organised by the branches, of which the one in London is the largest and most active, and the educational policy which has throughout been pursued is proving very satisfactory. The founders of the Association from the first had in mind the ultimate inclusion of all laboratory assistants in one federation, and the Association admits as associate members laboratory assistants in any recognised scientific laboratory. It is hoped that from this may spring sections following for other branches of scientific work the lines of the educational programme of the parent Association, which is prepared to offer financial and any other assistance which it can. The secretary is Mr. H. P. Hudson, Panama Villa, Trumpington, Cambridge.

THE opening meeting of the Illuminating Engineering Society on November 26 was, as usual, devoted to reports of progress and exhibits of novelties. The customary report of progress, presented by Mr. L. Gaster, referred to the course in illuminating engineering recently established at the Polytechnic, Regent Street, and to the varied work now being done by the committee working under the Department of Scientific and Industrial Research. The latter is dealing, amongst other matters, with methods of lighting necessary for difficult factory processes, and for authority and impartiality it cannot be readily paralleled elsewhere. Equally important is the work of the various British Engineering Standards Association committees concerned with standardisation. It is hoped that these activities will be described more fully at a forthcoming meeting. Another outstanding feature is the development of interest in illumination abroad. There have been frequent references made to this subject at international congresses, and the necessity for Great Britain to be strongly represented at such gatherings was urged. The exhibits included a new form of long-burning enclosed flame arc, from which much is expected; the mutochrome projector, by the aid of which any desired coloured pattern can be built up and projected on the screen; and a new form of integrating photometer exhibited by Col. Kenelm Edgcumbe. Another item was the demonstration of the use of partially colour-sprayed lamps with motor-car headlights; by this means, it is claimed, the greater part of the beam can be limited below a given horizontal plane, with the advantage that the "cut-off" is gradual, a mild diffused light being emitted above this level.

THE Department of Scientific and Industrial Research has published a *Bulletin* (No. 1) of *Building Research*, describing the preparation and use of magnesium oxychloride in flooring compositions. Details are given of the constituent materials, method of mixing and laying, surface treated, the advantages and disadvantages of the material, together with tables of analyses showing the effect of varying the composition on the tensile strength.

AN address delivered in the United States by Prof. Alex. Findlay, of the University of Aberdeen, entitled "The Appeal of Science to the Community," appears in *Science* of October 23. In spite of its immense utilitarian value to mankind, Prof. Findlay considers that the real claim of science to a fuller appreciation is for its idealistic aim, the seeking out of the truth. Prof. Findlay expresses disagreement with those who claim that, on account of the great benefits to be derived from the diffusion of scientific knowledge, men of science should have special power in the general government of the country.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Works chemist and organic chemist—Research Department, The Walpamur Co., Ltd., Darwen, Lancs. (December 15). Assistant at the Commonwealth of Australia Solar Observatory at Mount Stromlo—High Commissioner for Australia, Australia House, Strand, W.C.2 (December 18). Assistant engineer for the Timber Mechanics Section of the Forest Products

Research Laboratory, South Farnborough—Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (January 1). Senior agricultural officer for the Department of Agriculture, Nairobi—Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1 (January 31). Several men with training in experimental psychology—Secretary, National Institute of Industrial Psychology, 329 High Holborn, W.C.1.

ERRATA.—The writer of the article "Does the Solar Heat Stream Vary?" (*NATURE*, November 21) directs attention to two corrigenda. The quotation from Mr. Clayton on p. 755, col. 2, should read "These were supplemented by telegrams of the maximum temperature observed at Seattle, Williston, and Chicago, in order to ascertain to what extent the temperatures at those stations were responding to solar changes." It should have been stated at the top of col. 1, p. 756, that, with uncorrelated variables, the standard value of a correlation coefficient, computed from 84 samples, was about 0.11.

Our Astronomical Column.

COMETS.—Further observations of Van Biesbroeck's Comet on November 27 indicated that the R.A. of the Möller-Stromgren ephemeris was too small by 1 sec., and its declination too large by 0.7'; these discordances are small, and are in the direction of making the perihelion passage a day or two earlier than September 29, and the perihelion distance slightly greater than 1.447 units. The proximity of the moon has probably prevented later observations.

Comet Wilk-Peltier was observed at Greenwich on December 5 and 6; the approximate position on December 5^d 17^h 16^m U.T. was R.A. (1925.0) 19^h 29^m 59.78, N. Decl. 1° 21' 27". The comet was bright with decided central condensation, and was visible before twilight ended.

The following elements and ephemeris for 0^h are by Dr. A. C. D. Crommelin from observations extending to November 24:

T 1925 Dec 7.2828 U.T.
 ω 126° 22' 35"
 Ω 141 0.16
 i 144 34.17
 $\log q$ 9.88281.

	R.A.	S Decl.	log A.
Dec. 10.	19 ^h 43 ^m 38 ^s	3° 26'	0.0373
14.	19 52 58	7 0	0.0851
18.	20 0 11	9 58	0.1271
22.	20 5 55	12 29	0.1640
26.	20 10 38	14 39	0.1961

The comet will be lost in the sun's rays after January 10 (about), but may still be within reach when it emerges.

TOTAL SOLAR ECLIPSE OF JANUARY 14, 1926.—The Einstein problem has practically monopolised the attention of British eclipse expeditions since the War. It is now considered that sufficient evidence has been obtained to verify the prediction of light-bending, and the observers are free to resume the spectroscopic study of the corona. An article in the *Observer* of December 6 refers to Prof. E. A. Milne's predictions as to the relative intensities of the lines in the coronal spectrum, made on the basis of Bohr's theory. Special endeavour will be made in Sumatra

to test these predictions. In addition to Mr. F. J. M. Stratton and Mr. C. R. Davidson, the party there will include Dr. F. W. Aston.

An article in *Science* for November 20 describes the programme of one of the American expeditions to Sumatra, consisting of Prof. H. T. Stetson of Harvard, Dr. W. W. Coblentz, Mr. W. Arnold and Mr. W. A. Spurr. They are taking a reflecting telescope of 20-inch aperture with radiometric and photometric accessories, and will make measurements of the coronal radiation by vacuum thermo-couples, and photometric studies of the colour and brightness of the corona by photographic methods; these will be in continuation of those made last January in Connecticut. This expedition, and that from Swarthmore College, will be located at Benkulen.

RECENT LARGE SUNSPOTS.—The last sunspot minimum occurred about the middle of 1923. Since that date, solar activity has been rising consistently, and for some months past the increase has been very marked. More recently, there have been three very large spot disturbances visible to the naked eye. Particulars of these are given briefly as follows:

Date on Disc (1925).	Central Meridian Passage (G.M.T.).	Latitude.	Area.
Oct. 14-26	Oct. 20.4	19° S.	1/900
Nov. 8-20	Nov. 13.6	15° S.	1/800
Nov. 18-30	Nov. 24.5	17° N.	1/650

(Areas are corrected for foreshortening and express the proportion of the sun's hemisphere.)

The first of these groups contained a large principal spot with smaller companions. The second consisted of a pair of large spots of remarkably rapid growth and decay, in the place occupied by a moderate spot disturbance in the previous rotation. The third group was a very large stream, some 17° of longitude in length. It was a conspicuous object through the mist and fog prevailing in London on several days towards the end of November, and it was picked up by several people previously unaware of its existence.

It is remarkable that no magnetic disturbances were recorded at Greenwich associated with the transit of these three large spot groups across the sun's disc.

Research Items.

THE FINNISH HOUSE.—Some interesting details of the plan and methods of construction of the traditional type of habitation in Finland are given by Mr. Donald Smith in Part 4 of *Observation*. These houses were constructed to contain several generations, and the communities were self-contained, the men being hunters, fishers, graziers, farmers, and artificers, lacking only a forge; while the women performed the operations of grinding, baking, brewing, spinning, etc. They grew their own tobacco. The first portion of the house to be erected was always the bathroom of round unshaped logs—of the "steam-bath" type, with a stove of rough blocks of granite. Then followed a vestibule used as a store-room and dairy connecting the bath-house with the living-room or house proper. This was roughly square with a seat fixed to the wall running round two sides, and an oven of clay and granite blocks in the right-hand corner. Smoke was emitted by the door or slits in the wall, but sometimes a hollow tree-trunk served as a chimney, its lower end being closed by a slide which was opened at intervals. A trough was provided to give the horses warm meals in winter, for which purpose they were brought in from the stables. The upper end of the room was divided into the man's corner and woman's corner, each pursuing their occupations on their respective side of the line, the woman alone crossing the line rarely as her duties required.

THE EARLIEST MAYAN DATES.—Among the contributions to the Göteborg session of the twenty-first International Congress of Americanists, of which the proceedings have just been published, is an examination of the earliest evidences for Maya dates and the inferences which can be drawn from them, by Dr. Sylvanus G. Morley. The earliest dates known at present are on the Leyden jadeite plaque and the Tuxtla statuette, which show Baktun 8 dates equated, that on the latter with 97 B.C. and that on the former with A.D. 61. It is probable, though by no means certain, that in both cases the dating is contemporaneous. Dr. Morley gives a table showing 29 early dates, of which 24 are certainly or probably contemporaneous and five non-contemporaneous, ranging from 97 B.C. to A.D. 275. Of the dates covering Baktun 8 and part of Baktun 9, the former come from two sites only, Uaxactun and Uolantun. It is established by Steele at Tikal, the latest of the Old Empire monuments, that the Baktuns—the name given to the Maya cycle of 144,000 days—numbered 8, 9, and 10 fitted into a system which could not complete itself in more than sixty-four millions of years. Taking the evidence bearing upon dating as a whole, it would appear that Uaxactun was the first Maya city at which stone monuments came into use. Before that time, it is generally agreed, the stelæ were carved out of wood; and these have now disappeared. Exhaustive search in the region of the oldest cities has failed to reveal any simpler beginnings of the elaborate time count. Uaxactun is at the heart of the Yucatan peninsula and of the Old Empire. Its geographical and topographical position concur with the archaeological and chronological evidence in pointing to it as the central point of distribution of Mayan culture to other regions.

TRYPARSAMIDE IN SLEEPING SICKNESS.—The efficacy of trypanamide in the treatment of sleeping sickness in the Belgian Congo is the subject of a communication by Dr. Clement C. Chesterman in the *Lancet* for November 7, p. 965. He notes that though spontaneous recovery may sometimes occur without

any treatment, he himself has observed no case in a series of 650 which has remained in good health. On the other hand, there is evidence that after single doses of atoxyl, soamin, arsacetin or tartar emetic, early cases may remain in perfect health, while with repeated dosage the number of cases which appear to be cured is greater. Bayer 205 likewise gives good results in cases in the first stage of the disease, which means that there is no involvement of the central nervous system as evidenced by changes in the albumin and cell content of the cerebro-spinal fluid. In the second stage of the disease, none of these drugs gives satisfactory results. In trypanamide, first used in sleeping sickness by Pearce of the Rockefeller Institute of Medical Research, there is hope of permanent cure even in cases in very advanced stages of the disease. Of the first stage cases originally treated by Pearce in 1920, so many as 100 per cent. are still in good health and may reasonably be regarded as cured. Of cases in the second stage, Van den Branden and Van Hoof have carefully followed 35 which were treated with trypanamide. Of these 45.7 per cent. have remained in good health for an average period of three years. Dr. Chesterman himself has obtained cures in 37.5 per cent. of 40 cases observed for two and a half to three and a half years. A number of cases, however, do not react to the drug, and the reason of this is obscure. The drug *in vitro* is only feebly trypanolytic, so that its curative action appears to depend on some factor in the human body. There is evidence that this may be found in the liver, and that when this organ does not function properly, the drug has less chance of acting favourably in sleeping sickness. Dr. Chesterman concludes that trypanamide should be the mainstay of our attack on sleeping sickness. The principle has been adopted by the Belgian Government, which is responsible for the treatment of 50,000 cases annually.

GOLD COAST SURVEYS.—The report of the Survey Department of the Government of the Gold Coast for the year ending March 1925 shows a record of steady progress not only in the production of topographical and cadastral surveys, but also in the attainment of a high standard in local production of maps. In addition to a great deal of cadastral work including several town plans, the topographical survey is proceeding satisfactorily. Of the total area of the Gold Coast and mandated territories, some 92,000 square miles, 41,000 have been surveyed, including 2500 during the year under review. The scale is 1 to 62,500 from the coast to lat. 7° 30' N., and half that scale to the northward. The reproduction of the smaller scale maps is now undertaken at Accra instead of sending them home. To judge from the sheet attached to the report, there is little scope for improvement. Experiments with the use of wireless in longitude determinations are leading to useful results.

AGRICULTURAL POPULATION IN EUROPE.—At the International Geographical Congress at Cairo last April, Prof. A. Demangeon opened a discussion on agricultural systems and schemes of distribution of population in western Europe. The subject evoked so much interest that an international commission was appointed to investigate the matter and prepare reports for a later Congress. In the autumn issue of the *Geographical Teacher*, Prof. Demangeon's paper is printed in full. His conclusions are as follows: The nature of the rural habitat is closely related to the system of exploitation of the land. The isolated farm and small hamlet, characteristic of western

France, Flanders, the Campine, and many parts of England, is very ancient in regions of predominant stock-raising, in contrast to the compact village which may be held to imply the existence, at least in origin, of some form of communal cultivation. The latter is found chiefly on fertile lands which lent themselves to early settlement by reason of lack of forest. Prof Demangeon does not believe that the origin of the compact village can be ascribed to any one people. In France it appears to be a very ancient feature evolved before the Frankish conquest. The article concludes with some contributions by other geographers to the discussion at Cairo.

MIOCENE MOLLUSCA FROM JAMAICA.—A fine volume on the Miocene Pelecypoda and Scaphopoda from Bowden, Jamaica, by W. P. Woodring, part of a series of reports dealing with the geology and palæontology of the West Indies, has been issued as one of the invaluable Publications (No. 366) of the Carnegie Institution of Washington. The work, save for some brief but adequate introductory remarks, is devoted to a systematic description of the species met with. These are estimated to amount to 185 species and subspecies of bivalves and 20 of scaphopods, of which some 85 are claimed to be new, while new sections and genera have also been founded. The accompanying illustrations are included in 28 plates, and are some of the finest we have had the pleasure to meet with. In the treatment of his subject the author has taken a most important step for a palæontologist, since he acknowledges the importance of following the International Rules of Zoological Nomenclature and points out that the "time-consuming task of attempting to discover what generic names should be used has no direct bearing on the history of the earth and therefore may seem like wasted time for a palæontologist. But if the significance of the genera composing a fauna is considered, and their rise, spread, and restriction are analysed, the uniform use of generic names is essential."

MYCORHIZA OF PINE AND SPRUCE.—The relations of the fungus hyphae of various species of Hymenomycete, including species of *Boletus*, *Cortinarius*, etc., to the roots of these forest trees have been very fully investigated by Elias Melin of Stockholm ("Untersuchung über die Bedeutung der Baummykorrhiza." Jena: Gustav Fischer, 1925, 7.50 marks). The fungi have been grown alone in pure culture, and seedlings of the conifers also raised in sterile culture, and their relation to the nutrient medium studied separately and when growing together. Melin concludes that whilst the trees can manage to assimilate inorganic or diffusible organic nitrogen (e.g. asparagin) readily, when the fungus is present they are able to utilise more freely complex organic nitrogen compounds. In this connexion he examines the fruit bodies of the fungi to obtain some light upon the digestive enzymes present in the fungi which may influence the utilisation of such nitrogen compounds. Melin has an interesting note on the effect of water-soluble "phosphatides," extracted from the conifer seeds by the methods of Hansteen Cranner, upon the growth of these fungi in culture. In quantities too small to permit of the result being due to their nutritive value, they excite a markedly catalytic action upon the rate of growth of fungi, which usually grow very slowly in the absence of the root system of the higher plant. Melin suggests these experiments may throw light on the relations of the fungi to the roots. In no case did he find evidence of fixation of atmospheric nitrogen, either by fungus or by fungus and host together.

ATMOSPHERIC ELECTRICITY.—The search for the cause of the potential gradient in the atmosphere has been stimulated by the theory of von Schweidler and Swann, and the September issue of *Terrestrial Magnetism and Atmospheric Electricity* contains a paper by Mr. C. H. Dwight on a search for rapid variations in the earth's electrostatic field. An insulated plate was suspended 8 metres above the roof of the laboratory and connected to one of the deflecting plates of a cathode ray oscillograph tube, the other plate of which was earthed. The two plates were shunted by a resistance of 12 megohms, which prevented secular accumulation of charge on the upper plate. The cathode rays were deflected by the field between the plates, and the light from the fluorescent spot they produced on the screen at the end of the tube was focussed on a revolving photographic film. The records show that there are no rapid variations of the electric field in the atmosphere except during actual lightning discharges.

THE "HOLWAY" DIATHERMY APPARATUS.—Messrs. Newton and Wright, Ltd., 471/3 Hornsey Road London, N.19, describe in a leaflet just issued the Holway diathermy apparatus, in which special attention has been paid to the spark gap. The spark gap consists of an aluminium chamber extensively ribbed on the outside, so that even with a large current it does not become unduly hot. This chamber is provided with an inlet and an outlet tap for gas dielectric, and can also be arranged for use with ether in cases where no gas supply is available. The actual gap comprises a large copper disc heavily silvered, bridging over the space between a pair of heavy copper electrodes, likewise silvered, so that the gap is in duplicate, an arrangement which conduces to a steady current, while affording means of convenient and delicate adjustment. The electrodes, which are mounted on thick mica diaphragms, are provided with radiation fins for cooling. There is no doubt that the surgical efficiency of some diathermy apparatus leaves much to be desired, and it is to be hoped that the design described will effect an improvement.

HYDROGEN PEROXIDE.—A solid hydrogen peroxide, sold under the registered name of "Hyperol," is described in *Chemistry and Industry* for November 20. Hyperol is a stable white crystalline compound of hydrogen peroxide and urea having the formula $\text{CO}(\text{NH}_2)_2 \cdot \text{H}_2\text{O}_2$, and it contains 35 per cent. of hydrogen peroxide. The only impurity is a trace of citric acid which is not sufficient to affect methyl orange. It dissociates completely when dissolved in water or ether, and 1 gm. of "Hyperol" dissolved in 10 c.c. of water produces a 10-volumes strength solution of hydrogen peroxide.

STRUCTURE OF MALEIC AND FUMARIC ACIDS.—A description of an X-ray examination of maleic and fumaric acids carried out by K. Yardley appears in the September issue of the *Journal of the Chemical Society*. Preliminary investigation indicated that maleic acid has four molecules per unit cell, and from this it is shown that the planosymmetry given to the acid from chemical evidence does not exist in the crystalline state. A structure is suggested, and several projections of this on the planes of symmetry are given. On account of the poor nature of the crystals, the measurements with fumaric acid were more difficult; the minimum cell contains six molecules of fumaric acid. Further evidence shows that neither maleic nor fumaric acid has symmetry in the crystalline state.

The International Council for the Exploration of the Sea.

THE report of the British delegates just received shows that the last meeting of the International Council for the Exploration of the Sea, held in Copenhagen on September 1-4, was, though short, an important one in the Council's history, for at this meeting the machinery of the Council, which had grown rather cumbrous, was thoroughly overhauled and in a considerable measure replaced and renewed, in accordance with a plan prepared by the president, Mr. H. G. Maurice, with the help of Prof. Johan Hjort. To take the less important changes first: the main Committees of the Council are now formed on a regional basis, instead of being based partly upon geographical areas and partly upon the species of fish studied. The regional committees which came into being after the War proved to be a very convenient and practical means of getting co-ordinated researches carried out, and the logical step has now been taken of arranging all the main researches of the Council on this regional basis. The "Area Committees" now formed are seven in number—for the North-Eastern Area (the Norwegian Sea east of the 1000-metre line), the North-Western (Rockall, Faeroe and Iceland), the Atlantic Slope (Rockall to Morocco), the Northern North Sea, the Southern North Sea, and two committees for the Skagerrak, Cattegat and Baltic area. In addition, the Statistical, Hydrographical, Plankton and Limnological Committees remain in being.

For each of the area committees there has been appointed a chairman with very definite duties and responsibilities, who will see that the work done in his area is properly co-ordinated in accordance with the programmes agreed upon, and will report on the progress made. Now comes the most important point in the new organisation. The chairmen of these committees, together with the chairman of the Hydrographical Committee, will form a Consultative Committee which will advise the executive of the Council, the "Bureau," on the proper conduct of the scientific work, and must be consulted by the Bureau. (The two Baltic committees will be represented by one of their chairmen only.)

The criticism has sometimes been made of the International Council that its affairs are too much in the hands of administrative delegates, while too little power is allowed to the scientific experts. What truth there may be in this opinion it is difficult to say, but the voting power is limited to the official delegates, who are usually, but by no means always, scientifically qualified, and conditions are conceivable in which the opinion of the experts might not carry its due weight. The new arrangement gives the scientific members of the Council a more definite status and responsibility, for the members of the Consultative Committee are men of scientific standing and voice the opinions of the experts composing the area committees. We regard this new move on the part of the Council as a healthy and fruitful one.

Another new departure resolved upon at the last meeting is the founding of a scientific journal, which will deal with the many aspects of the Council's work, taking cognisance also of similar work done in other parts of the world. The useful short papers hitherto issued by the Council in the series of *Publications de Circonstance* will in future be published in the journal. We understand that the journal will contain also general articles of a comprehensive nature, reviews, and a bibliography, and will be published quarterly, commencing early in 1926. The new journal should serve a very useful purpose in knitting the work of the Council together, and disseminating its results. The editor will be *ex officio* a member of the Consultative and the Editorial Committees. The publication of short reports of a popular nature is also contemplated by the Council.

Apart from these matters of organisation, the delegates' report gives much interesting information regarding the Council's work. Since the War the number of participating countries has increased, particularly among the southern nations, and the area covered by the Council's organisation now extends over the whole seaboard and adjacent waters from the Barentz Sea right down to the coast of Morocco. Only one important country still stands out—Germany, which has not yet resumed membership. It is understood that Germany will shortly rejoin the Council.

Great Britain continues to do the lion's share of the work, particularly at sea, and we are glad to note that she is well represented in the new organisation, Dr. Alex. Bowman being chairman of the Northern North Sea Committee, Mr. J. O. Borley chairman of the Southern, while Dr. E. S. Russell is editor of the journal. Mr. Maurice continues his energetic work as president, and the other British delegate, Mr. David T. Jones (who has succeeded Prof. D'Arcy W. Thompson in this office), presides over the two North Sea Committees when they meet in consultation over problems common to both. Prof. Thompson remains chairman of the Statistical Committee and editor of the *Bulletin statistique*.

Other points of interest in the British delegates' report we can touch upon only briefly. At their request a special committee was appointed to study the very vexed question of the closure of the Moray Firth to trawling, consisting of Norwegian, Danish, Dutch, Belgian and British experts. Reference is also made in the report to investigations commenced by the English Department during the present year on the effect of the size of trawl mesh on the size of fish caught, which are yielding promising results. Finally, we are glad to learn from the report that His Majesty's Government has agreed to support the Council's work for a further period of five years. Results in fishery and oceanographical research cannot be obtained quickly, and the long view will prove in this case to be the wise view.

Relation between Physical and Mental Defects.

A PAPER on the testing of physically defective and of mentally defective children, by Dr. C. R. McRae, who was obliged to return to Australia some days before the recent meeting of the British Association at Southampton, was read before the Section of Psychology. The paper was divided into two parts.

(1) THE BINET-SIMON TESTS AND SPEARMAN'S PRINCIPLES OF COGNITION.—These principles, as enunciated in Prof. Spearman's book, "The Nature of

'Intelligence' and the Principles of Cognition," offer an explanation of the remarkable success of the Binet-Simon tests of intelligence. Of particular importance are the noegenetic principles concerning the eduction of relations and the eduction of correlates. On the basis of these principles an *a priori* analysis and criticism of each component test of the Binet scale was made. To test the validity of this analysis in practice, both physically defective and mentally

defective children were tested. The most satisfactory tests of innate ability should be those in which superior natural endowment enabled the physically defective children furthest to outstrip the mentally defective despite inferior educational opportunity, while the least satisfactory tests would be those in which superior educational opportunity enabled the mentally defective to approach nearest to the physically defective.

A close agreement between the theoretical judgment made on the basis of the noegenetic principles and the practical decision obtained by testing these children was found to exist. Thus it seems likely that Ebbinghaus's completion test is a satisfactory mental test, not because "intelligence" consists in "combination activity," but because the performance of the test is mainly a matter of educing novel correlates, or that the "opposites" test succeeds, not because "intelligence" consists in seeing differences, but because the performance of the test is essentially a matter of educing relations.

(2) PHYSICAL DEFECT AND MENTAL EFFICIENCY.—Children in metropolitan schools for the physically defective, and patients in the Lord Mayor Treloar Hospital at Alton, were tested. The London children show a retardation of 1.95 years, the Alton children of 1.14 years. This difference of almost a year in favour of the Alton children was found on analysis to be inexplicable in terms of social environment and heredity, of the nature of the physical defect or of educational opportunities. One explanation alone

seemed feasible, that the alleviation brought to the physical defect by the medicinal measures and environmental conditions of the Hospital stimulates the mind as well as the body.

	Metropolitan Schools.	Alton Hospital
No. of cases . . .	117	62
Average age . . .	11.13 years	11.85 years
Average mental age .	9.18 years	10.71 years
Average mental ratio	82.5	99.4

Sir Henry Gauvain, Medical Superintendent at the Hospital, is inclined to invoke as explanation of the mental superiority of the Alton children the setting free from the skin by ultra-violet rays of certain organic compounds which are essential brain foods. Whatever the true explanation may be, it would appear tolerably certain that physical defect, if widespread and of long duration, simulates the symptoms of some degree of amentia, and that these symptoms may be removed by such treatment as is afforded at the Treloar Hospital. In the ensuing discussion, Dr. Shrubsall questioned the validity of pooling the London children together, as they represented several specified categories of diseases. It was stated, however, on behalf of Dr. McRae, that this point had been considered in his full report, of which the present paper was a partial summary.

New Laboratories at St. Andrews.

NEW chemical and physical laboratories were opened by Sir William Bragg at the United College of St. Salvator and St. Leonard, University of St. Andrews, on the afternoon of Friday, December 4. Before proceeding to the new building, Sir William Bragg, who received a cordial welcome in the city of the scarlet gown, was promoted to the honorary degree of LL.D. at the hands of Sir James Irvine, Vice-Chancellor. Mr. William Whitelaw, chairman of the London and North-Eastern Railway Company, was the recipient of the same honour. In a memorable address, Sir William Bragg described the modern developments of atomic and molecular theory, pointing out the extreme delicacy of the method of X-ray analysis, not only in determining the structure of crystals, but also in measuring the length of one of the curious chain-like molecules which are based on carbon links. He emphasised the importance of inquiry into details in pure and also in applied science. It is that intimate examination of details which results in the advance of knowledge, and affords so fascinating a prospect to the inquirer.

The new building opened by Sir William adjoins the Chemistry Research Laboratory and runs southwards with a frontage of 170 feet. It is in the Renaissance style, two stories high, and faced with local sandstone from Nydie. Above the entrance doors are mullioned windows and a moulded gable, in keeping with the seventeenth-century type of work of the old quadrangle. The architect was Mr. J. Donald Mills, and the internal benches and fittings were designed in collaboration with Prof. J. Read, of the Chemistry Department, and Prof. H. S. Allen, of the Department of Natural Philosophy.

The chemistry accommodation, which is located in the northern part of the block, forms an extension of the institute for chemistry research, which was presented to the University and endowed by the late Prof. Furdie. This institute, which has been re-

organised during the alterations, contains accommodation for twenty research workers, in addition to rooms for special purposes. For the past twenty years the research institute has been widely known as a centre of research work on sugars and carbohydrates, problems of optical activity, and general synthetic organic chemistry; during the War much important work was carried out within its walls under the supervision of the present Principal and Vice-Chancellor, Sir James Irvine.

The new accommodation for chemistry tuition comprises on the ground floor an elementary laboratory, containing bench space for forty students at once, together with a balance room and other service rooms. A fully equipped laboratory for advanced students occupies a position on the first floor; this has accommodation of the most modern type for eighteen students, and is provided with fume-chambers, apparatus for organic combustion work, steam-ovens, and other necessary accessories. Adjoining it are a small balance room and two physical chemistry rooms, to which low voltage current is supplied from an accumulator room. The addition also includes private rooms for members of the staff, a chemistry museum, a lecture room for advanced classes, and store accommodation. A telephonette system has been installed throughout the building.

The Physical Laboratories are contained in the southern block, and have been fitted up to provide for advanced teaching and research, as well as for the usual elementary courses. On the ground floor is a large laboratory for elementary students, together with dark rooms for photographic and optical work, and two rooms which are available for research work. On the same floor is a mechanic's shop provided with machine tools, each driven by its own electric motor. Above is a long room which is arranged as a photometer room. On the first floor is the advanced laboratory, which adjoins the reading room and reference library, so that students can write

a record of their experimental work and immediately refer to the standard authorities on the subject of their experiment. On the same floor are the professor's room, three research rooms, and an optical room. The laboratories are well equipped with gas, water, and electric light and power, provision being made for an electric supply from accumulators in a separate building. At the top of the main staircase is a large room which is being arranged as a laboratory for experimental mechanics. Research work is already in progress, and is at present directed to the study of band spectra, for which purpose two large spectrographs have been installed.

University and Educational Intelligence.

BIRMINGHAM.—The University has received a magnificent gift from Sir Charles Hyde, Bart, who writes to the vice-chancellor: "It will give me the very greatest pleasure to put at your disposal the sum of 100,000*l.* unconditionally for the immediate needs of the University." The donor mentions in his letter some of the more pressing needs of the University which are known to him, namely, a Union building for the students; an extension of Chancellor's Hall (the hall of residence for men); the extension of the Harding Library; the purchase of certain land (if it can be bought at a reasonable price); and "the endowment fund of the research committee, which I consider of the most supreme importance." The vice-chancellor (Sir Gilbert Barling, Bart.) states that the gift will be applied to all these objects. Sir Charles Hyde has long been a generous benefactor to the University, and during his tenure of the office of warden of the Guild of Undergraduates, he showed himself particularly interested in the welfare of the students and keenly alive to the advantage of providing residential facilities. Sir Charles Hyde's wisdom in making the gift "unconditionally" is much appreciated and indeed greatly enhances its value. It is understood that no part of the money will be used for the building of the new biology block which is in course of erection.

In addition to the generous gift of Sir Charles Hyde, referred to above, a donation of 2400*l.* from the Miner's Welfare Committee has been given towards the further equipment of the coal-mining department.

Dr. Ratcliffe has presented to the anatomical department casts of fossil remains of Rhodesian man. The Council has decided to establish an honours school in geography.

CAMBRIDGE.—The University Commissioners have issued regulations for initial appointments to lectureships and demonstratorships under the new statutes. Roughly these regulations provide that, within certain age limits, all persons who have held college lectureships for three years or were University lecturers or demonstrators on October 1, 1924, are to be offered lectureships or demonstratorships under the new regime. An appointments committee is to be nominated by the Council of the Senate to fix the financial terms of each offer. It will be a matter of interest to note whether this committee merely contents itself with making such offers that each person concerned receives the same salary as heretofore, or if it makes a definite effort to interpret the spirit as well as the letter of the Statutory Commissioners' recommendations by regulating salaries according to services performed.

SIR THOMAS KIRKE ROSE, past-president of the Institution of Mining and Metallurgy, will deliver an address on "Metallurgy and Minting" at the Sir John Cass Technical Institute, Jewry Street,

Aldgate, London, E.C.3, on December 15, on the occasion of the annual distribution of prizes and certificates.

From the Battersea Polytechnic we have received a copy of the Principal's report on the work of the session 1924-25. A summary of student hours per week shows that the decrease which has been going on since 1921 continued last year. The evening class work, however, showed an increase, and the number of students taking courses in preparation for university degrees increased from 190 to 210. Technological courses for flour millers and lectures on hygiene and sanitary science were attended by twice as many students as in the previous year. Forty-two students obtained degrees of the University of London, including 19 B.Sc. honours degrees in chemistry. The Polytechnic was attended by 68 university graduates for advanced technological instruction.

THE fourteenth annual Conference of Educational Associations will be held at University College, Gower Street, London, W.C.1, on December 31-January 8, under the presidency of Prof. A. C. Seward, vice-chancellor of the University of Cambridge. Prof. Seward will deliver his presidential address, entitled "The Relation of a University to Secondary Education," on the first day of the Conference. Other noteworthy features of the provisional programme are: a joint discussion on the relation of technical education to other forms of education and to industry (Dr. Schofield, Miss Fox, and others); a lecture by Dr. Harold Wager to the School Nature Study Union on "Some Aspects of Nature Study"; and a lecture by Sir Robert Blair to the London Head Teachers' Association on "Education and Industry." Exhibitions are being arranged of books and school apparatus.

THE annual report of the Royal Technical College, Glasgow, for the session 1924-25 records a decrease in the number of day students from 1006 to 936, and an increase in evening students from 3810 to 3817. Considering the depression in the Clyde industries, the decrease is surprisingly small. The Clyde engineering apprentices form the principal reservoir from which the College students are drawn, and the report points, with justifiable pride, to the fact that although only half as many apprentices have been engaged in the local shipbuilding and engineering works as before the War, the number of College engineering students taking a degree or diploma course is almost double the corresponding pre-War figure. There is evidence of revival in the demand for trained chemists and metallurgists. the College has not been able to respond to all the requests for qualified metallurgists and the list of unemployed chemists is small. Some indication of the range and standard of the evening classes is given by the number (148) of graduates of universities (English, Welsh, and Irish, as well as Scottish) enrolled in them and the number (2648) of students more than twenty years of age. Six students received the Ph.D. degree of the University of Glasgow, 95 the B.Sc. of Glasgow, and 4 the B.Sc. of London. The College received during the year substantial recognition of esteem in the form of a gift of 50,000*l.* from an anonymous donor and an undertaking by the Carnegie University Trust to continue for five years an annual grant of 1000*l.* and increase it by 120*l.*, provided that sufficient money from other sources is forthcoming to form, with 5000*l.* of the Trust's grants, an endowment for a chair of metallurgy. The first number of a new official College journal appeared during the winter and contained the results of research work in the departments of chemistry, mechanical engineering, metallurgy and bacteriology.

Early Science at Oxford.

December 14, 1683. The peice of Iron which had been cast into an Ingot, lying North and South, was produced. We did not observe that it did in ye least draw ye needle. A letter from Mr. Aston gave an account that *Gerbertus* brought ye use of numeral figures into these parts of the world; it was ordered that enquiry should be made whence this appears. A letter from Dr. Tyson related to ye observations, lately made by Dr. Bagly on ye *Lumbricus latus*, with an account, and draught, of a little Insect, which he found in ye *Trachæa* of ye *rana Piscatrix*. Dr. Smith was pleased to oblige us, with an account of some observations, made by ye learned Mr. Greaves, in Ægypt, and transcribed from his MS, by ye Doctor, to whom it was communicated by Mr. Stubbs, formerly of Wadham Colledge.

1686. The Minutes of ye Royal Society were read, which gave an account of some cubical *Stones* of a substance resembling a *Marchasite*. Dr. Plot tells us they are ye *Ludus* of Van Helmont, and that he has great variety of them by him, which have been found in Staffordshire, Pembroke-shire, Merionidh-shire, and Carnarvonshire; and that in his History of Staffordshire he has mentioned them.

An account communicated by Mr. Caswell, how and in what proportion the Quicksilver may stand at different heights, reckoned on ye plates of different *Baroscopes*, though filled in ye same place, and with quicksilver equally free from air.

Some Observations of ye *weather* in ye hottest week of ye last summer 1686 made joynly with ye Baroscope and Thermoscope at several hours of the day, in order to find how much heat affects ye Baroscope. By Mr. Caswell.

A peice of *Tin-ore* usually called Shoad, found above-ground, and native copper as found in the West of Cornwall, were communicated by Dr. Plot.

December 15, 1685. A Letter from Mr. Molyneux concerning ye circulation of the blood as seen in the *Lacerta Aquatica* was communicated and read.

A Letter of Mr. Flamsteed's concerning ye eclipses of Jupiter's satellits in ye year 1686 was read.

Mr. LLOYD communicated some stones like ye *Lapides judiaci*, and others like Shell-fish, which were gathered in this County.

A Paper of Mr. Bayly's containing an account of the application of a needle to a piece of iron held perpendicular, made by one in a voyage crossing ye line was read.

December 16, 1684. Our President, and Director, being now returned home, we had a full meeting, in which was read Sir William Petty's Catalogue of Experiments. Dr. Plott was pleased to shew us a piece of cloth, which he brought from London, woven and made with ye flax of ye Amianthus, or Asbestos-stone; which before Mr. Vice-chancellor, and some other Doctors of the University (who were then pleased to honour us with their presence) was heat for some considerable time red-hot, with no other alteration, after it was cold again, save only it appeared somewhat whiter, and cleaner, than before; and was, whilst hot, more brittle; but being cold; of ye same strength, and toughness, as before calcination; which it had now undergone 5 or 6 times; contrary to our Paper made of ye Anglessey-Asbestos, which, being of a shorter thread, was at ye first of a contexture not so tough and strong, as ye cloth, and after ye fire is so friable and brittle, as not to endure any bending, nor ye very handling, if any thing roughly: this paper, it was thought, might be made much finer, and whiter, if it could be made also tough, and tenacious for any use.

Societies and Academies.

LONDON.

Royal Society, December 3.—W. A. Bone and G. W. Andrew: Studies in catalytic combustion. Pt. ii. The union of carbon monoxide and oxygen in contact with nickel, copper, and other oxides. With nickel gauze at 365° C., the formation of a highly reactive Ni-CO (or possibly O-Ni-CO) complex in the surface layer may become a prime factor in the catalytic combustion. The action of the metal may really be of a dual character, involving (a) the "activation" by the metal of the two gases marked by a comparatively low rate of carbon dioxide formation, and (b) the intermediate formation of still more reactive CO-Ni-O complexes. With copper gauze at 135° and 250° C., for the real "catalytic" reaction, no prior formation of either copper oxide or any Cu-CO complex was required, but only the "occlusion" of the respective gases. With granular nickel oxide at 150° C., and granular copper oxide at 165° to 175° C., respectively, the catalytic action depends upon the formation at the surface of an "activated" oxygen film probably of more than monomolecular thickness. The real catalytic combination of carbon monoxide and oxygen over all these surfaces is independent of either the oxidation of a primarily formed "carbonyl" film or the reduction of a metallic oxide.—F. H. Constable: Immobile groups of atoms with strong, specific external fields as the cause of catalytic activity. Copper surfaces made by electrolytic deposition, reduction of alkaline copper solutions, and by hammering and polishing, have an activity probably less than 1/9000th that of the reduced metal. When the surface was produced by sudden cooling of the vapour, or by thermal decomposition of copper salts of organic acids, or by reduction of copper oxides, a markedly active product was obtained. The passage of ammonia gas over the metal at 820° C. produced some activation. The physical appearance of the surfaces varied from a metallic colour, through dull yellow to red-brown. Generally the surface activity and the temperature coefficient of activity were nearly the same. A new method of comparing surface activities of preparations has been devised, depending on the behaviour of copper on alternate oxidation and reduction. The catalytic action is considered to be due to fixing groups of atoms in such a state of strain that strong specific external fields are maintained.—S. C. Roy: On the law and mechanism of monomolecular reaction.—F. A. Williams: The effect of temperature on the viscosity of air. The coefficient of viscosity of dry air free from carbon dioxide has been studied by a comparative transpiration method, with a silica spiral, from 15° C. to 1002° C. The results show that Sutherland's formula for the temperature coefficient of viscosity holds with great accuracy between 250° and 1000°, the value of *C*, the Sutherland constant, in this range being 172.6. Below 250°, Sutherland's law is no longer true, and the value of *C* falls off as the temperature decreases.—R. W. Fenning: Gaseous combustion at medium pressures. Pts. i. and ii. Pressure-time records of the explosion of a complete combustion, carbon monoxide-air mixture with additions of (a) hydrogen-air and (b) water vapour, give records identical with those produced by (1) carbon monoxide-air plus 1.2 per cent. of water vapour, (2) carbon monoxide-air plus 2.1 per cent. of hydrogen-air (nearly dry). Closed-vessel explosions of methane-air mixtures were also investigated, the initial temperatures ranging from 24° C. to 400° C., and the initial pressures from 30 lb. to 171 lb. per square inch. For a mixture

containing 9.9 per cent. of methane, the explosion-time was increased by (1) increasing the charge density, (2) reducing the initial temperature, and (3) adding a diluent such as combustion products or water vapour.—R. K. Schofield and E. K. Rideal: The kinetic theory of surface films. Pt. ii. In Pt. i. it was shown in the case of dilute aqueous solutions of the fatty acids C_4 – C_8 , that the ratio FA/RT (where $A = 1/T$ is the area occupied by a gram molecule of fatty acid in the film) is not unity, but varies with F in a manner completely analogous to the variation of pV/RT with p for real gases. FA/RT , F curves for surface films of the sparingly soluble fatty acids C_8 , C_{10} , and C_{12} on dilute hydrochloric acid have been constructed from the surface tension-concentration data of Frumkin. At high-surface pressures the curves are straight, and thus (like those for the lower acids) conform to the two-dimensional Amagat equation $F(A-B) = \pi RT$. At low-surface pressures the curves, though essentially similar, do not correspond exactly with those of fluids. This is attributed partly to the molecules in the film having two distinct parts with different cohesions, and partly to the elongated shape of the molecules, which become inclined to the plane of the interface when in the act of separating from one another, thus causing the critical area to increase with the length of the hydrocarbon chain.—H. B. Dixon and G. Greenwood: On the velocity of sound in mixtures of gases. The method adopted was by comparing the dust-figures produced in a standard gas and those in the mixture by the resonance set up in two similar tubes. The results obtained (i.) in mixtures of gases of different density, (ii.) in mixtures of gases of the same density, are in close accord with the theoretical values calculated from the density of the mixtures and the specific heats of their constituents.—A. Fage and L. F. G. Simmons: An investigation of the air-flow pattern in the wake of an aerofoil of finite span. The vorticity is distributed over an area forming a band roughly parallel to the plane and ending in regions approximately opposite the tips, where the intensity is high. Farther behind the aerofoil, the band disappears from the central part, and at about 13 chords away the vortex system resolves itself into two localised areas. In front of the aerofoil, and beyond each wing tip, the flow is irrotational. Over each of the planes of exploration behind the aerofoil, the velocity is sensibly uniform.—W. L. Webster: Magnetostriction in iron crystals. For the (1, 0, 0) axis there is an increase in length for all values of the magnetisation; for the (1, 1, 0) axis there is an initial increase in length, followed by a contraction as magnetic saturation is approached; for the (1, 1, 1) axis there is a continual contraction. A combination of these effects seems to explain the results for soft iron, which are similar to those for the (1, 1, 0) axis. The effect of stress on magnetisation in the same rods is measured, and the results applied to a thermodynamically obtained, reciprocal relation between magnetostriction and the effect of stress on magnetisation. The agreement is satisfactory.—R. W. James and W. A. Wood: The crystal structure of barytes, celestine and anglesite. The structures of the isomorphous sulphates of barium, strontium and lead are all very similar. The structure is based on a simple orthorhombic lattice having four molecules to the unit cell, and the space group is V_h^{16} . The positions of the atoms have been determined by a study of intensities. In calculating the structure factors, the figures for the diffracting power of ions at different angles calculated by Hartree have been employed with slight modifications. The absolute intensity of reflection observed is lower than, although

of the same order of magnitude as, that calculated on the classical theory.—O. Maass and J. H. Mennie: Aberrations from the ideal gas laws in systems of one and two components.—R. G. Lunn: Fluid resistance to moving spheres. A large number of measurements of the times of fall of spheres, differing in size and density, through distances varying from 3 to 538 metres, in coal-mine shafts and other places, have been made. The resistance of air is calculated, and the way in which resistance depends upon velocity and acceleration for any sphere in linear motion is deduced. The range of velocity is such that the values of the Reynolds number are in the critical region ($10^4 < R < 10^6$), in which the resistance to uniform motion is proportional first to a power higher than the second, and later to a lower power. The effect of acceleration is to accentuate the rapid change in the resistant coefficient ($F/\rho V^2 d^2$). An application of the theory of dimensions suggests that the fluid resistance may depend not only upon velocity and acceleration, but also upon the rate of change of the acceleration.—W. G. Palmer: The adsorptive equilibria of binary gaseous mixtures. The method of the "coherer" is now applied to the determination of the composition of films containing two gases in adsorptive equilibrium with mixtures of the gases. The present application leads to a purely empirical method. The hypothesis that gaseous films are commonly only one molecule thick is corroborated. Examples of the following cases are given: (1) each gas competes equally for all the spaces on the surface; (2) a complex containing both gaseous molecules is formed, and acts as a single unit on the surface; (3) one gas is adsorbed only on specific areas of the surface. The method is rapid and should form a useful adjunct to investigations of catalytic actions upon solid surfaces.—I. Sandeman: The secondary spectrum of hydrogen at higher pressures. (ii.) A P and an R series have been selected, fitting along with Richardson and Tanaka's 83Q into a P, Q, and R combination, and closely conforming with the combination principle. This band is one of four bands the null lines of which are given by the Rydberg formula:

$$18567.47 - \frac{109678.3}{(n + 0.159883)^2}$$

where n takes the values 6, 7, 8, and 9. Indications have also been obtained of a band corresponding to the integer 10.—P. A. M. Dirac: The fundamental equations of quantum mechanics. The paper is a development of Heisenberg's work on a new quantum significance of kinematic and mechanical relations. It is assumed that the equations of motion of a multiply periodic dynamical system can be taken over as they stand into the quantum theory, but that special mathematical operations must be used for interpreting them, which are such that the different solutions of the equations of motion are all interlocked and cannot be considered separately. Any variable x is taken to be represented by harmonic components of the form $x(nm) \exp. i\omega(nm)t$, where n and m refer to two stationary states or two sets of quantum numbers, and the frequencies $\omega(nm)$ satisfy the relation $\omega(nm) + \omega(mk) = \omega(nk)$. The product of two variables x and y has the amplitudes of its components determined by the equation $xy(nm) = \sum_k x(nk) y(km)$. Multiplication is thus not commutative, but except for this the algebraic laws are the usual ones. Certain quantum conditions are necessary to complete the solution of the mechanical problem. It is shown that the energy is the same function of the action variables as on Bohr's theory, and Bohr's relation between the frequencies and energy levels is deduced.

Royal Meteorological Society, November 11.—C. G. Abbot: Measuring sun rays. Solar radiation measurements are made by the Smithsonian Institution on two desert mountains in Chile and Arizona, and by estimating the losses due to the earth's atmosphere, the "solar constant" or radiation in free space at the earth's mean distance is determined. The average value of the solar constant is now known to within much less than 1 per cent. The determinations show two sorts of variation, one with a range of 2 per cent. associated with the sunspot cycle, and the other of short and irregular interval ranging up to an extreme magnitude of at least 5 per cent. The latter variations also are associated with the passage of sunspots across the sun's disc, the radiation decreasing when the spot reaches a central position. About ten years ago, Mr. H. H. Clayton began to investigate the weather changes associated with these apparent solar changes. Since December 1918 official weekly forecasts of temperature and rainfall have been issued by the Argentine Government, but the accuracy is not yet great. The solar radiation observations are responsible for some of the errors, and the Argentine Government has recently equipped its own observatory at La Quiaca. Mr. Clayton is now making experimental forecasts for New York, three, four, five days ahead, for the day, week, and month, and the forecasts are steadily improving. The National Geographical Society of the United States has made a grant to establish a third solar radiation station in the eastern hemisphere, with the view of improving the solar radiation observations. The requirements are a stable government, ready means of communication, cloudless skies, and a high altitude, and Dr. Abbot is to examine possible localities in south-west Algeria, north-east Baluchistan, and south-west Africa.

PARIS.

Academy of Sciences, November 3.—H. Deslandres: The progress made in the study of the sun at Meudon Observatory.—A. Béhal: The sixth International Conference of Pure and Applied Chemistry.—V. Grignard and J. Savard: The constitution of pulegone, the tertiary alkylpulegols and the alkylpulegenes.—Romanovsky: A method of interpolation of Tcheycheff.—G. Foëx and J. Kampé de Fériet: The application of photography on a moving plate to the study of the movement of projectiles, especially to the measurement of their velocity.—E. Esclangon: Measurements relating to the values of g at Paris and at Strasbourg. These experiments were carried out during the years 1922–1925 with the view of making the University of Strasbourg a new comparison centre. Use was made of a Deffonges pendulum oscillating in a vacuum, and incidentally it was noted that the effect of temperature on the period of oscillation could not be entirely accounted for by the resulting changes in the length of the pendulum. Variation in the elasticity of the knife-edges and suspension planes and in the coefficients of friction with temperature also produce effects to be considered.—A. Dauvillier: New researches on the Crookes' tube. Experimental studies on the disappearance of gas in the Crookes' tube and on the dark space.—C. Chilowsky and F. Perrin: A new method of distinguishing between natural pearls and cultivated pearls. In the natural pearl the layers are spherical and concentric, but in the cultivated pearl they are approximately plane. The method proposed consists in drilling a fine hole through the pearl and strongly illuminating the interior by means of a minute mirror: the natural pearl appears uniformly

illuminated whilst the cultivated pearl shows striae.—C. Féry and C. Chéneveau: The secondary reaction in the discharge of the lead accumulator. A new theory of the action of the secondary battery has been suggested by one of the authors based on the reversible reaction

In the present note an attempt has been made to measure experimentally the variations in the weights of the plates during charge and discharge. The results are in marked disagreement with the usually accepted theory and are nearer those predicted by the above equation, but the differences are such as to suggest that there is a secondary reaction taking place. A possible secondary reaction is indicated.—Pierre Jolibois: Methods permitting the study of the chemical effects of the electric spark on gases at low pressure. The apparatus described and figured permits the measurement of the energy of the spark and the change of pressure produced in the gas under examination.—A. Girard and E. Fourneau: A new method of great sensibility for the detection, separation and estimation of bismuth. If a benzene solution of tetracetylammmonium hydrate is shaken up with an aqueous solution containing potassium iodide and a trace of bismuth, a complex red compound is formed which is soluble in the benzene layer. A quarter of a microgram can be detected. The preparation of the reagent and mode of working will be described in a future communication.—Emile André and Henri Canal: Contribution to the study of the oils of marine animals. Squalene and spinacene. The oil from *Cetorhinus maximus* gave a well-crystallised chlorhydrate which proved on fractional crystallisation from acetone to contain two different products. The oil from *Scymnus hcha* behaved in a similar manner. The conclusion is drawn that squalene and spinacene are not definite chemical compounds.—Louis Longchambon: Cristobalite.—Fromaget: The extension and affinities of the fossil fauna of Indo-China.—Jean Motte: The cytology of the mosses.—F. Henrijean: The genesis of the rhythmic contraction of the heart.—L. Fage: Forms of the polychetal annelids.—René Fabre: Contribution to the study of hæmatoporphyrin. The application of the spectrophotometer to the determination of the distribution of the intensity in the fluorescence spectrum. Curves are given which may be utilised for the direct determination of hæmatoporphyrin.—L. M. Bétancès and J. de Luna: The rôle of the lymphocytes and granulocytes in the reparation of wounded tissues in the crayfish.—H. Guillemard: Azotemia in the course of mountain sickness. The experiments described indicate that there is a notable accumulation of non-proteid nitrogenous substances in human blood during the crisis of mountain sickness.—J. Duclaux and P. Jeantet: The transparency of natural waters to the ultra-violet rays.

INSTITUTE OF METALS (Scottish Local Section) (at 39 Elmbank Crescent, Glasgow), at 7.30.—Dr. H. Hyman: Aluminium and its Alloys as used for Engineering Purposes. ARISTOTELIAN SOCIETY (at University of London Club), at 8.—Prof. J. L. Stocks: The Unity of Thought. MEDICAL SOCIETY OF LONDON, at 8.30.—C. A. R. Nitch and others: Discussion on The Treatment of Genito-urinary Tuberculosis.

TUESDAY, DECEMBER 15.

ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15.—Sir R. H. Rew: The International Statistical Institute and its 16th Session. INSTITUTION OF CIVIL ENGINEERS, at 6.—A. Honeysett: Pressure-Boosting Station for the Waterworks of the City of Monte Video. INSTITUTE OF MARINE ENGINEERS (at 85-88 The Minories), at 6.—J. A. Sim: Economic Application of the Scott-Still Engine. INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at Engineers' Club, Manchester), at 7.—Prof. S. P. Smith: An All-Electric House. ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—H. H. Featherstone: Home Kinesmatography with the Baby Ciné-Camera and Projector. INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.—Otto Kahrs: The Economic Value of Bunker Coal. ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Capt. Pitt-Rivers: The Inhabitants of Ana Island. BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES (at Royal Society of Arts), at 8.15.—Sir Frederick Pollock, Bart.: Do we need a Philosophy of Law in England?

WEDNESDAY, DECEMBER 16.

SOCIETY OF GLASS TECHNOLOGY (London Meeting) (in the Chemistry Lecture Theatre, University College), at 2.30.—Prof. W. E. S. Turner: The Composition of Glass suitable for Use in Automatic Machines.—Violet Dimbleby and Prof. W. E. S. Turner: The Relationship between Chemical Composition and the Durability of Glass.

ROYAL METEOROLOGICAL SOCIETY, at 5.—I. D. Margary: The Marsham Phenological Record in Norfolk, 1736-1923, and some others.—C. D. Stewart: Experiments on the Shielding of Raingauges.—Dr. H. Jeffreys: On the Dynamics of Geostrophic Winds.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. W. D. Lang and Dr. L. F. Spath: The Black Marl of Black Ven and Stonebarrow in the Lias of the Dorset Coast.

RADIO SOCIETY OF GREAT BRITAIN (at Institution of Electrical Engineers) (Annual General Meeting), at 6.—D. Sinclair: Some Facts and Notions about Short Waves.

INSTITUTION OF CIVIL ENGINEERS (Students' Meeting), at 6.—Sir C. R. S. Kirkpatrick: The Development of Harbour and Dock Engineering (Lecture).

ILLUMINATING ENGINEERING SOCIETY (at the Lighting Service Bureau, 15 Savoy Street, Strand), at 7.—A Report on Progress in Electric Lamps and Lighting Appliances.

INSTITUTION OF AUTOMOBILE ENGINEERS (Birmingham Graduates' Meeting) (at Chamber of Commerce), at 7.30.—F. G. E. Clarke: Press Tools.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Watgate House, Adelphi) (Graduates' Meeting), at 7.30.—C. A. Edwards: Sales and Service.

GLASGOW UNIVERSITY ALCHEMISTS' CLUB (at Glasgow University), at 7.30.—Prof. E. P. Cathcart: Problems of Metabolism.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Dr. W. Cramer and Dr. R. J. Ludford: Bile Canaliculi and the Golgi Apparatus in Hepatic Cells.—Dr. C. De Fano: Recent Methods for the Study of the Neuroglia.—Miss A. Lorrain Smith: Some Lichen Dyes.—F. I. G. Rawlins: The Theory of Dimensions in Microscopy.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (at the Royal Society of Medicine, 1 Wimpole Street), at 8.30.—Dr. J. Glover: Divergent Tendencies in Psychotherapy.

EUGENICS EDUCATION SOCIETY (at Royal Society), at 8.30.—Prof. J. S. Huxley: The Courtship of Animals and the Present Position of the Sexual Selection Theory.

SOCIETY OF CHEMICAL INDUSTRY (Chemical Engineering Group, jointly with Nottingham Section) (at Nottingham).—R. G. Parker and D. N. Jackman: Some Effects of Humidity on the Properties of Fabrics, with Special Reference to the Control of Humidity during Strength Tests.—Dr. E. B. R. Prideaux and E. C. Roper: The Analysis of Commercial Bifluorides.

INSTITUTION OF STRUCTURAL ENGINEERS (Lancashire and Cheshire Branch) (Students' Evening).—J. L. Manson: Factors in the Development of Structural Practice.

THURSDAY, DECEMBER 17.

LINNEAN SOCIETY OF LONDON, at 5.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.—Dr. H. S. Hele-Shaw and T. E. Beacham: A New Form of Air-Compressor.—A. Livingstone Oke: Notes on Diamond Prospecting, Gold Coast Colony.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—C. E. Webb: The Power Losses in Magnetic Sheet Material at High Flux Densities.

ROYAL AERONAUTICAL SOCIETY, at 6.—Informal Discussion on Aero-engine Starting Gear.

CHEMICAL SOCIETY (Informal Meeting), at 8.

INSTITUTE OF CHEMISTRY STUDENTS' ASSOCIATION (London), at 8.—Discussion on Regulations of the Institute.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, Cavendish Square), at 8.15.—Sir T. C. Evans: The Surgical Aspects of Amoebiasis.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children and Dermatology Sections), at 8.30.—Discussion on The Aetiology and Treatment of Infantile Eczema.

INSTITUTION OF MECHANICAL ENGINEERS (Birmingham Branch) (at Birmingham).—H. F. L. Orcutt: Characteristics and Uses of Ground & Gears.

FRIDAY, DECEMBER 18.

SOCIETY OF CHEMICAL INDUSTRY (Liverpool Section) (at Liverpool University), at 6.—Dr. W. Clayton: Coagulation and Flocculation in Colloid Systems, with Special Reference to Industrial Problems.

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), 7.—Discussion on The Work of the Mechanical Engineer in Non-Engineering Industries, introduced by W. P. F. Fanghanel.

JUNIOR INSTITUTION OF ENGINEERS, at 7.—Lecture and Demonstration of Industrial and Domestic Electric Lighting at the Demonstration Rooms of the Lighting Service Bureau.

PHOTOMICROGRAPHIC SOCIETY (at 4 Fetter Lane), at 7.—Members' Meeting.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—F. L. Emanuel: An Artist's Remarks on some Old Photographs.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at Literary and Philosophical Society, Newcastle-upon-Tyne), at 7.30.—Prof. T. H. Havelock: Some Aspects of the Theory of Ship Waves and Wave Resistance.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

WEST OF SCOTLAND IRON AND STEEL INSTITUTE (in the Royal Technical College, Glasgow).—L. Rothera: Speed Control in Relation to Modern Rolling Mill Drives.

SATURDAY, DECEMBER 19.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (at Newcastle-upon-Tyne), at 2.30.

PUBLIC LECTURES.

SATURDAY, DECEMBER 12.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. H. G. Cannon: Floating Life in the Sea.

MONDAY, DECEMBER 14.

DYERS' HALL (Dowgate Hill, E.C.), at 6.—Prof. G. T. Morgan: Recent Researches on Mordant Dyes.

SATURDAY, DECEMBER 19, 1925.

The Highway to the University.¹

THE report on the accessibility of university education to poor students prepared by Mr. G. S. M. Ellis for the Stapley Trust, for which Lord Haldane has written an appreciative foreword, reopens an ancient controversy on a basis of modern needs. The author's case, reduced to its bare bones, is that the percentage of the population of England educated at a university is far behind that of Scotland or Wales; that the wider opportunities in Wales and Scotland are reflected in the larger numbers of pupils from elementary schools who reach the university; and that the scholarships offered by local education authorities in aid of university education in England are inadequate in number and, on the average, insufficient in amount.

The remedy proposed is that a uniform minimum provision of university scholarships should be made a statutory obligation on all local education authorities. Incidentally, the author criticises severely the Board of Education for neglecting to bring up-to-date statistics of scholarships such as were supplied for 1911-12 to the Royal Commission on the Civil Service, and published in 1914. The author apparently had not seen, before his booklet went through the press, the recently published Statement of Expenditure on Maintenance Allowance Awards incurred by local education authorities in 1923-24 (Cmd. 2415). It would have warned him of the unreliability of any conclusions drawn from the figures of 1911-12 being applicable to the conditions of 1924-25. The limitation also of the report to one—though no doubt the largest—source of supply of scholarships, namely, those offered by local education authorities, makes impossible any kind of estimate of the adequacy or inadequacy of the supply as a whole. A general review, however, is a task for the Board of Education, and not for an individual worker. The most valuable part of the author's case is that he has shown the pressing need for such a survey.

Mr. Ellis calculates that 21 per 10,000 of the Scottish population were full-time university students in 1922-1923, the figures for Wales and England being 12 and 8 respectively. The actual numbers were 27,994 (England), 2650 (Wales), and 10,294 (Scotland). It is long since Scotland acquired the university-going habit. It was the outcome in the past of the excellence of her parish schools, of inexpensive university education, of the inducement of hundreds of small university bursaries, of parental sacrifice, and, above all, of the fact that to poor and able Scottish youths the university became the gateway to the world. In more recent days, the extended provision of secondary school education

¹ "The Poor Student and the University." By G. S. M. Ellis. Pp. xi + 60. (London: The Labour Publishing Co., Ltd., 1925.) 2s. 6d. net.

and assistance from the Carnegie Fund, have strengthened the traditions of earlier generations. A telling example comes from the Hebrides. The island of Lewis has a population of 28,000 persons, 4000 of them in the town of Stornoway. In 1894 the Nicolson Institute in that town was a small elementary school of 256 pupils with a handful of ex-standard children included. The newly appointed headmaster organised a secondary course, and a few school bursaries were made available from county funds to bring in the landward children. Four years later the school sent its first two students direct to the university.

The same headmaster, about to retire, reports a roll of 400 secondary school pupils (half from country districts), and that in the interval the school has sent 250 boys to the university and 240 girls to training colleges for teachers. These students were the sons and daughters of townsmen, crofters, and fishermen, with here and there one from the schoolhouse or the manse. The maintenance bursaries at the school vary from 5*l.* to 24*l.* About 180 country pupils are living in lodgings. That number includes 50 girls in the hostel provided three years ago by the Carnegie United Kingdom Trust (charge, 12*s.* per week). The county (university) bursaries, in any individual case, do not exceed 30*l.*, to which may be added the Carnegie fees grant of 9*l.* A few of these scholars hold in addition a small bursary from the Highland Trust or other granting body. The balance of the cost is made up in many cases with much effort and self-denial on the part of parents, brothers, and sisters. It is often a family concern, with uncles and aunts and cousins also helping. The old students of that school are so much scattered over the globe that a much-travelled Scot who has an intimate knowledge of it said recently that the island of Lewis was the most cosmopolitan rural area in Great Britain.

Until two generations ago, higher education in England was the privilege of the middle and upper classes. But the progress made in the present century has been remarkable. By the end of last century the School Boards had done their work of providing elementary schools and getting the children into them. The Education Acts of 1902-3 empowered the new authorities to supply or aid higher education and to organise a system by means of which pupils might pass from the elementary schools to the secondary, and from these to the university. In 1904-5 there were 95,000 pupils in secondary schools in England and Wales: twenty years later the number in schools on the grant list had risen to 359,000. Since 1914 the figures have been doubled. The Board of Education estimates (Report, 1923-24) that in 1900, 5500 children were being assisted to proceed from elementary to secondary schools;

to-day the free places in secondary schools on the grant list number 110,000, 36 per cent. of the total. Moreover, the school life is lengthening; the proportion of pupils above eighteen years of age is steadily growing, and the candidates for the higher school certificate examinations are increasing annually at a great pace. In the present year the number reached 5000: six years ago it was only 2000. The number of university scholarships awarded in 1911-12 was 464, the total maintained at universities in that year being 1327, the average value 43*l.*, and the total 57,000*l.* Mr. Trevelyan stated in the House of Commons in April 1924 that in the year 1922-23 the local education authorities had expended 220,000*l.* in scholarships to universities and other institutions of university rank. We now learn from the Statement of Expenditure (Cmd. 2415) incurred by local education authorities in maintenance allowances under Grant Regulations No. 14, that allowances of 127,000*l.* were made to undergraduates in 1923-24, the number of awards being 2756, while other awards to technical colleges and other institutions of university rank amounted to 81,594*l.* Lastly, whereas in 1908-9 695 boys and 361 girls proceeded to a university from grant-earning schools in England and Wales, by 1920-21 the numbers had risen to 1674 boys and 1214 girls, nearly three times as many. In the former year one-third of the schools contributed; in the latter, two-thirds.

This array of figures does not prove that the number and value of scholarships in 1924-25 are greater than they were in 1911-12. But it does suggest with certainty that a profound change has been effected, and that it would be unwise to frame any policy on figures so completely out-of-date as those of 1911-12. The splendid record of the progressive authorities must not, however, be allowed to hide the parsimonious attitude of a good many others whose contributions to university education are nil or negligible. In this connexion, one of Mr. Ellis's subsidiary points deserves greater attention than it usually gets: the possibility of higher education has come to depend overmuch on accidents of birthplace and residence, and the exact position of the county or borough boundary has assumed a fortuitous and unreasonable importance.

Space forbids much further consideration of this very interesting pamphlet. "Obviously," says the author, "the provision of scholarships does not meet the national need for trained men and women." Again, "it would be difficult to maintain that only this small percentage (0.73) of elementary school boys and girls who reach the university has outstanding ability." The crux of the problem is the bringing together of ability and opportunity. The concern in the homes of poor students is with the opportunities that follow a

university course. Here is a task for the Appointments Boards, which have already done much to facilitate the process of getting graduates placed. When conditions become such that a high percentage of honours graduates has little difficulty in obtaining posts with reasonable prospects, the story of such successes will soon reach the schools, and there will be no lack of graduates of "outstanding ability." The desire to reach the university will then react on the scholarship system and help to expand it.

The road to the university is not, however, the only outlet to the poor student. Among others, some attention might have been given to the technical colleges which provide full-time three-year courses for 4500 students.

Radioactivity and Geology.

The Surface-History of the Earth. By Dr. John Joly.

Pp. 192 + 9 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1925.) 8s. 6d. net.

IN this brilliant and stimulating book, Prof. Joly has conveniently brought together the results of many years' work and thought on the radioactivity of the rocks. Its central theme is an illuminating hypothesis, according to which the radioactivity of the rocks has been the dominant influence in controlling geological history. The search for adequate causes and convincing explanations is beginning to be rewarded, and theoretical geology need no longer grope in a maze, albeit a fascinating one, of unco-ordinated observations. Prof. Joly's inspired originality should henceforward lead geology into a new phase, the more mature phase that lies beyond the initial observations and their classification.

The present Lord Rayleigh's pioneer work on the distribution of radium in rocks showed nearly twenty years ago that the earth must gain from radiothermal energy at least as much heat as it is losing by radiation into space. It was difficult, indeed, to believe that the earth was not actually growing hotter. In 1921 Lord Rayleigh again expressed the guarded opinion that the internal temperatures should be rising, but he added, "we are puzzled to explain the existing state of things" (NATURE, October 27, 1921, p. 280). In 1915 the present writer elaborated a cooling hypothesis that has since been widely adopted, involving a distribution of the radioactive elements that permitted the earth to have cooled from a molten state since the beginning of geological time, and allowed for internal temperatures that were thought to be adequate to explain vulcanism. Further consideration of the implications of this hypothesis have led to its abandonment for the sufficient reason that they were found to be in contradiction with

the known facts of geological history. It should be said, however, that Dr. Harold Jeffreys still considers that any departure from this hypothesis in the direction of admitting more radioactivity leads to consequences that flatly disagree with observations. Apparently it is as impossible to believe that the earth is cooling as it is to believe that the earth is not cooling.

A way out of the impasse has been found by Prof. Joly. He persuades us to believe that both heating and cooling have taken place. There would be a touch of Irish humour here, were it not that the two processes do not occur at the same time. They alternate; and in the alternation lies a clue to the cause of the mysterious heavings and crumplings that have periodically affected the outer shell of the earth.

From the known data of seismology, and the well-established theory of isostasy, Prof. Joly concludes that the continents are essentially composed of granitic rocks having a thickness of about 32 km., and a density of about 2.67; and further, that they are submerged in a deep substratum of basaltic composition which rises around them to form the ocean floor, and has a density when solid of about 3.0. The materials of the continents and the substratum respectively are supposed to contain substantially the same proportions of the radio-elements as actual specimens of them, represented by granites and basalts from various parts of the globe. From the data adopted, and there seems here to be no possible flaw, the temperature at the base of the continents is easily calculated to be approximately that of the fusion-point of basalt, while the heat emitted is equivalent to that lost from the surface of the lands by radiation. It follows from this that the heat generated in the underlying basaltic layer by the radio-elements must accumulate; and since the substratum is solid at the present day, it evidently lacks only latent heat to become fluid. In about forty million years it must become so throughout. Similarly, at and below a certain depth beneath the ocean floor, the substratum must also pass sooner or later into a fluid condition.

Geological time is to be measured in at least hundreds of millions of years, and consequently this accumulation of latent heat in basalt must have occurred in the past; and as the substratum is now solid, the excess of heat must in some way have been dissipated. Tidal action is ingeniously invoked to provide a mechanism whereby the accumulated heat can be for the most part harmlessly discharged into the oceans. When widespread fusion supervenes, a slow westerly drift of the still solid crust begins, and the deep, possibly superheated magma formed beneath a continent thus comes to underlie the ocean floor to the east. The ocean floor is then stopped and melted away from below, until the upward loss of heat by conduction becomes sufficiently rapid to bring

the process to an end. Widespread consolidation is promoted by convection currents, and owing to the sinking of stoped-down blocks and newly formed crystals, solidification develops from below upwards. Finally, the lateral movement is brought to a standstill by the grounding of the continental roots on a solid foundation. Each level of the substratum is thus left at the end of the cycle at a temperature that must be that of its solidifying point, or a little lower, at the pressure there obtaining.

Tectonic and igneous processes are obviously facilitated by the changing volume and changing state of the substratum. The overlying crust becomes heaved up as fusion progresses, but the continents sink a little relatively to the oceans, and transgressional seas advance over the lands. Continents and ocean floor are now under tension, and basaltic magma squeezes through the cracks, healing the ocean floor and preventing its wholesale subsidence into the depths, and giving rise to vulcanism on a large scale such as broke out in early Tertiary times in the Deccan and Brito-Arctic provinces. Present-day vulcanism is of a different nature altogether, being a consequence of the ascent of hot gases from magmas now in the later stages of crystallisation.

When the expansion due to the growth of the magma is at its maximum, the area of the surface is greatly increased, and when consolidation sets in, the increased area has to settle down on the contracting substratum. Where the margins of the continents have been weakened by the filling of bordering geosynclines with sediment, they become deformed by folding and overthrusting due to the resulting compression. The seas withdraw as the lands begin to rise again, and finally isostatic adjustments complete the orogenic processes, and the newly folded mountains rise in proportion to the depths of their roots.

In broad outline, the ideal cycle of events thus briefly sketched can be matched several times over by the actual sequence of events in geological history. In detail, a simple repetition of the cycle is quantitatively insufficient. Prof. Joly acknowledges only three complete cycles since the Charnian orogenesis of the late pre-Cambrian, terminating in turn in the Caledonian, Hercynian, and Alpine movements. The Laramide of America is thought perhaps to imply a fourth. The writer has found that the evidence suggests a list of five times as many cycles since the pre-Cambrian; some involving merely subsidence and emergence; others being accompanied by moderate folding; and a few, the great "revolutions" of Prof. Joly, being marked by overthrusting to a degree that would be mechanically incredible had it not indubitably occurred. Such a striking variation in intensity seems to imply not only

the expansion and contraction of the basaltic layer alone, but also the superimposed effects of underlying layers which may reasonably be expected to be less radioactive.

The different interpretation to which attention is here directed may be tested with reference to geological time. It is well known that Prof. Joly favours the smaller estimates of time, such as that based upon the supply of sodium to the oceans. He also believes from the evidence of pleochroic haloes that uranium may have disintegrated very much more rapidly in the past, and for this reason that certain thorium minerals may give more reliable lead-ratios than uraninites. The chapter in which these matters are dealt with is distinctly provocative and certainly unsatisfactory. The sodium method has really no bearing on the question at all, for the data that have been employed are both faulty in themselves and contradictory in their implications. Some thorium minerals (such as the thorianites of Ceylon) give the same lead-ratios as the associated uranium minerals, and it seems unfair to pick out the smaller results as being better than the larger. The atomic weight of lead from radioactive minerals definitely suggests that uranium has decayed at the same or nearly the same rate throughout geological time. The anomalies of pleochroic haloes can be explained in at least two other ways besides the one favoured by Prof. Joly, and all three must remain speculative until we know more of the complexity of "uranium" and the origin of actinium. The reviewer can find no reason to believe that the lead-ratios of uranium minerals may be "four times too high." At the worst it is improbable that they should be in error by more than 10 per cent.

Prof. Joly's application of his hypothesis to earth movements implies three or four cycles of about 40 million years each, giving only 120 or 160 million years since the beginning of the Cambrian. But if the actual length of time is of the order 600 million years, as indicated by radioactive minerals, then there should have been many more cycles, as indeed there have. The more prominent mountain-building periods would then be due to the superimposed effects of the consolidation of a deeper-seated magma, such as that of peridotite. This presumably has gone through only a few cycles, each being of much longer period than those of the comparatively shallow basaltic substratum.

It must not be supposed that this difference of opinion in a matter of interpretation is intended to detract in any way from the value of Prof. Joly's far-reaching hypothesis. On the contrary, it illustrates in a remarkable way the fertility and all-embracing character of that hypothesis. Logically extended, and applied on a more detailed scale to the geological history it is

intended to elucidate, a still stronger case can be made out in its favour. Moreover, it renews interest in the principles of Wegener's displacement theory, for this can no longer be resisted on the grounds of permanent rigidity. It raises a substantial hope that in the lateral movements of the crust a solution may be found of the tantalising problems of the climates of the past. In the domain of igneous petrology it will prove invaluable by providing for the first time the possibility of a real genealogy of rocks. Already it has so much to its credit that it must be regarded as a contribution to geology of the highest rank.

The thorough assimilation of the contents of this book by all geologists is indispensable, and indeed every one who is at all interested in the behaviour of the earth should read it. The lucid style reveals the author at his best, and the book is easily readable, for technical matters of detail are relegated to the appendices that close many of the chapters. Finally, a word of praise is due to the publishers. They have made a book that is worthy of its subject and its author, beautifully printed and illustrated, and issued at a price which can only mean that they wished to encourage every geologist in the world to buy it.

ARTHUR HOLMES.

Electrical Precipitation: Natural and Artificial.

Electrical Precipitation: a Lecture delivered before the Institute of Physics. By Sir Oliver Lodge. (Physics in Industry, Vol. 3.) Pp. 40+5 plates. (London: Oxford University Press, 1925.) 2s. 6d. net.

CHEMISTRY has been defined as "the dirty past of physics." The electrical precipitation of dust from industrial gases, for example from producer gas, blast furnace gas and various gaseous products of chemical industry, is a dirty business. This may in part account for the fact that the subject is, so far as current English scientific literature is concerned, treated only in works on chemistry. The literature of physics is practically silent about the subject. No reference to it is found even in Glazebrook's "Dictionary of Applied Physics," and this even though the process is decidedly both applied and physical in character. This deficiency is now rectified by the appearance in book form of Sir Oliver Lodge's lecture on electrical precipitation delivered before the Institute of Physics, in which the subjects of natural and artificial precipitation of moisture, dust, etc., are discussed in a manner of which Sir Oliver almost alone would appear to possess the secret. His recent plea for a simplification of the language in which science seeks to deliver its message is here followed up by a glowing example of the manner in which this may be achieved.

The story of natural electrical precipitation as evidenced in thunderstorms is first told. In fine weather the average atmospheric positive potential gradient at the earth's surface is of the order of 100 volts per metre. The gradient diminishes with height, the potential assuming a practically constant value of about 1 million volts at a height of 10 kilometres. During a thunderstorm the vertical force at the ground frequently exceeds 10,000 volts per metre. An average flash of lightning has a length of 10 kilometres, and the energy liberated in the flash is equivalent to that acquired by a mass of 100 tons falling 650 yards.

The maintenance of the fine weather potential gradient in the atmosphere is one of the outstanding difficulties of meteorological physics. At least four theories, against each of which some objection can be sustained, have been proposed. As regards the origin of the potential gradients associated with thunderstorms, Simpson's theory proposed in 1909 is that most generally, though by no means universally, accepted. Simpson discovered the remarkable fact that the mere breaking-up of a drop by a current of air results in electrification. A large drop falling through air and breaking-up becomes positively charged, the air receiving a negative charge. Sooner or later the small ascending globules of water produced coalesce into larger drops and the cycle of operation is repeated, until the drops become so highly charged that they no longer combine and fall. They are then carried to a higher stratum and form part of an electrified cloud. This, very briefly, is Simpson's theory of the origin of a thundercloud. Prof. Armstrong, in explanation, brings in hydrone, forsooth! (NATURE, 1923, 112, 537, 827; 1924, 113, 124.) Is the hydrone theory helpful in explaining even the simplest experimental facts of electrolysis, for example, the phenomenon of visibly moving boundaries met with in the determination of "ionic velocities"?

Sir Oliver suggests that natural precipitation in the form of rain should be artificially assisted, whereby the "rain-makers" may be dispossessed of this field. We foresee trouble arising from matters relating to the degree of control to be exercised, and to the selection of one or more in whom the right to exercise this control is to be vested. Have we not heard of a Scotch divine who, on his prayer for rain being "answered" by an immediate and boisterous thunderstorm, exclaimed, "Oh, Lord, this is too ridiculous"?

A section on the precipitation of dust from gases on an industrial scale is contributed to the volume by Lionel Lodge. The idea of removing suspended particles from gas streams by means of electrical discharge would appear to have been originated by Hohlfield in Leipzig in 1824. Guitard revived the

subject in London about twenty-five years later. Sir Oliver Lodge and Mr. J. W. Clark in 1884 investigated the dust-free space in the neighbourhood of hot bodies—a phenomenon to which is attributed the blackening of walls, ceilings, etc., in the neighbourhood of gas flames and electric light bulbs (p. 24)—and suggested the use of an electrical discharge as a means of dissipating fog and smoke. In 1885, Messrs. Walker and Hutchings, in association with Lodge, attempted the commercial exploitation of the electrical cleansing of gases. In those days the methods of producing high-tension discharges were primitive, and the difficulties of securing efficient insulation were insufficiently appreciated. The attempt was ultimately abandoned.

The subject was revived by Cottrell in 1906 and the practicability of the system definitely established. The first successful commercial plant was erected by the Selby Smelting and Lead Company at San Francisco Bay. The Lodge and Cottrell financial interests were amalgamated by the formation of Lodge-Cottrell Limited, now working in friendly co-operation with the Metallbank u. Metallurgische Ges. A.-G. The scale of the operations may be gauged by reference to the first successful plant erected at Queen's Ferry by the Ministry of Munitions in connexion with a Gaillard sulphuric acid tower. Here about 64,000 cubic feet of gas at 80° C. flow per minute past the discharge and collecting electrodes and carry about 4 grains of SO₂ per cubic foot. The operating voltage is about 100,000 volts, and about 30 tons of sulphuric acid are recovered a day.

The practical difficulties have not as yet, in all cases, been overcome. There are troubles connected with the dislodgment of the deposited dust from the electrodes. The hygroscopic character of the dust introduces difficulties in some cases; the shape of the electrodes is of paramount importance in others. The plant is necessarily on a large scale. Thus a plant erected to operate in conjunction with a number of blast furnaces was, on account of its size, popularly known as "the cathedral." Even with plant on such a scale, difficulty was experienced in purifying the gases, originally containing 5 grams of dust per cubic metre, to such a degree as to render them fit for use in gas engines. However, progress is being made, and the process is nowadays applied in a variety of directions, there being about 200 plants operating in conjunction with plants for the recovery of products from acid fumes, waste gases from metallurgical processes, combustible gases and miscellaneous dusts. The average efficiency of the plants is such that about 95 per cent. of the dust content is deposited. Cleaning costs amount on the average to about 1s. per 100,000 cubic feet of gas treated.

J. S. G. THOMAS.

The Art and Life of Early Man.

Prehistory: a Study of Early Cultures in Europe and the Mediterranean Basin. By M. C. Burkitt. Second edition. Pp. xxvi+438+48 plates. (Cambridge: At the University Press, 1925.) 35s. net.

It is not surprising that Mr. Burkitt's treatise on prehistory should so soon have reached a second edition. It is a unique summary of the handicraft and art of the successive races of Palæolithic man in Europe, with some references to Neolithic and Bronze Age man. It is based on personal observation, guided by one of the foremost pioneers in such research, the Abbé Breuil. It is not only a clear statement of the facts in convenient order, but also a discussion of all the important inferences which may be drawn from these facts as to the life and ideas of primeval man. It is, indeed, both a work of reference and one which will satisfy the general reader who desires only a broad view of the subject.

The new edition is not much changed, only one chapter, that on "The Neolithic and Bronze Ages," having been largely rewritten. The author, however, mentions that he has taken note of various press criticisms, and he has made the book more useful by adding to the text references to the figures in the plates. He has also included a map of western Europe showing the position of the more important localities cited. The new frontispiece, representing the "sorcerer" in the cave of Trois Frères in southern France, is a striking addition. It is the figure of a man disguised by placing a stag's antlers on his head, drawn on the wall "dominating the situation beside the natural pulpit where no doubt the actual artist-medicine-man-priest performed." This and some other recent discoveries are specially mentioned in the preface prepared for this second edition.

The chief additions to the text are in short notes where space admits them at the end of each chapter. It is perhaps the simplest, but not altogether a satisfactory arrangement. The text itself still needs revision. The statement that "bone was first utilised in Upper Mousterian times" (p. 76) is contradicted by the reference to the bone implement from Piltdown (p. 89). A footnote on p. 94 has escaped notice. Some of the English construction could also be improved. The author does not mean what he says, for example, when he refers to heads which have been decapitated (p. 188); and there are other expressions which need some modification. These, however, are minor blemishes in a work which will continue to be indispensable to every student of prehistoric archaeology who would keep abreast of his subject.

- (4) *La relativité dégagée d'hypothèses métaphysiques: exposé des théories d'Einstein, discussion de ces théories, essai d'une théorie nouvelle construite dans l'espace et le temps classiques*. Par H. Varcollier. Pp. xx+542 (Paris: Gauthier-Villars et Cie., 1925.) 50 francs.

(1) THIS short account of the theory of relativity was given as a lecture to the Literary and Philosophical Society of Liverpool in 1921. The book is—as the title states—a very elementary exposition. It is certainly hopeless to give a popular account which bears even the slightest resemblance to the theory of relativity without drawing on the concepts of ordinary life; and this essay is interesting to read because it shares with the other writings of Sir Oliver Lodge the agreeable characteristic of being filled with vivid illustrations from the everyday experience of the man in the street.

(2) Mr. Henderson's small book is designed for a popular audience, and it is unfortunately not unlike a large number of other books meant for the consumption of the general reader, in that the language and the treatment are frequently obscure. It is indeed difficult to know what useful purpose can be served by introducing the ideas of the theory of relativity into the discussion, on general non-technical lines, of questions such as "the nature of truth," "meaning," "the mind," and so on. The argument from analogy used with no regard for the niceties of problematical inference is a poor instrument.

(3) Prof. Heyl's essay on relativity breaks new ground in popular exposition. The plan is to give first a brief historical account of the development of the data relevant to the law of gravitation, and many interesting pieces of information are to be found in the opening chapters. The author gradually builds up, in the simplest language, the position of affairs before Einstein, and shows how the outstanding discrepancies were accounted for by the theory. This side of the book is good; but there is another side.

The author makes remarks, which may or may not be cryptic to the popular reader, about the "repelling appearance" of Einstein's theory and its "artificial nature," and he quotes the jejune observation that it is "repugnant to common sense."

Now it is undesirable to leave the erroneous impression in the mind of any reader that the theory of relativity is fundamentally artificial, however poor his knowledge of mathematics may be. For the nature of the postulates and the new and subtle appeal which they make to the scientifically developed common sense is the outstanding characteristic of the theory of relativity from the point of view of scientific method.

The notion of an "Invariance Postulate" is perfectly simple and can be explained to any intelligent person. This is the really important idea, and is what should be emphasised if an appeal to intuition and plausibility is to be made. There should therefore be an attempt to introduce it in a book which deals with the common sense of the theory of relativity.

(4) Prof. Varcollier's interesting volume should be very stimulating to the student of modern theories of world geometry and mechanics. The work is concerned with the exposition of the mathematical structure of relativity theory and with special interpretations of the results. Whatever may be the verdict on the interpretations, the very detailed account of the mathematical groundwork of modern mechanics should prove useful.

Tabulae Anatomico-Comparativae Cerebri: a Series of Nine coloured Maps with Description. Edited by Dr. C. U. Ariëns Kappers. Descriptive Text. Pp. 30. Plates 44 in. $\times$ 31½ in. (Amsterdam: The "Kosmos" Publishing Co., 1925.) 20 U.S. dollars.

THE "Tabulae Anatomico-Comparativae Cerebri," edited by Dr. Ariëns Kappers, director of the Central Institute for Brain Research in Amsterdam, consist of a set of nine large coloured plates illustrating the comparative anatomy of the brain and spinal cord. Two of these charts are before us.

The central nervous systems of Acrania, cyclostomes, selachians, teleosts, amphibia, reptiles, birds, marsupials, and primates (man) are to be exemplified by those of certain carefully selected types. The different nuclei and the chief fibre systems are all so represented in different colours that the comparative arrangement of any part of the central nervous system can be recognised at a glance. As the various parts of the central system are represented in sagittal projection, the nuclei and the tracts are all reduced to one plane, and for the sake of clarity some freedom in drawing has been necessary.

The chief interest in the series centres in the evolutionary changes whereby the human brain is the outcome. It is to be made apparent that in the human brain the thalamus proper, and more especially the dorsal thalamus, have undergone striking increase, whereas the tonic and autonomic striatum has increased but slightly. The pallial centres of sensory, visual, acoustic, and olfactory projections, regarding them as a whole, have not increased so much as the centres of correlative functions, which depend not only on inter-cortical systems but also on connexions with sub-cortical nuclei. For example, the increase of the frontal is chiefly associated with the increase of rubro-frontal projections and the appearance of fronto-pontine fibres which have stereopractic functions; the increase of the parieto-occipital is associated with the stereognostic projections of the pulvinar, and is thus correlated with the recognition of external objects by means of the skin, joint, and muscle sensibility. Dr. Kappers wisely refrains from giving any anatomical explanation of the increase of the temporo-occipital region of the cortex, but hints that owing to the connexion of the occipito-temporal lobe with the red nucleus it may, in addition to its acoustio-visual correlations, be some sort of stereognostic centre.

Dr. Kappers has brought his extensive knowledge and consummate skill as a draughtsman to bear on the preparation of the plates. The results are at first sight somewhat bewildering in their complexity, but they will prove invaluable to the student and investigator of comparative neurology.

Air Ministry: Meteorological Office. British Meteorological and Magnetic Year Book, 1918. Part 5: Réseau Mondial, 1918. Monthly and Annual Summaries of Pressure, Temperature, and Precipitation at Land Stations, generally Two for each Ten-degree Square of Latitude and Longitude. (M.O. No. 2318.) Pp. xiii+116. (London: H.M. Stationery Office, 1925.) 21s. net.

THE present volume is the ninth of the series, the work now being completed for each year from 1910 to 1918. All the information refers to land stations; it has not yet been practicable to give data over the sea. The total number of stations utilised is 449, which is 9 fewer than in 1917. Stations are easily identified by a systematic numbering, maintained year after year. The majority of the stations for which information is given are under the control of government meteorological services. Wherever possible, the departures from normal of the monthly and annual values of mean pressure, mean temperature, and precipitation are given. Wind data are given for selected stations in the tropics; and there are notes on the state of the ice in the Arctic Seas and in the North Atlantic Ocean.

When data are received for another year, making a consecutive period of ten years, there will be sufficient information for many tentative inquiries, such as stable or varying barometric pressure from year to year over the whole globe, the effect and influence of normal and abnormal changes in one part of the globe on the conditions experienced elsewhere, the controlling factors being of much value for long period forecasting.

The highest mean shade temperature for 1918 was 86° F. at Berbera, Somaliland: the lowest mean 4° F. at Verkhoiansk. The absolutely highest temperature was 115° F. at Bourke, in New South Wales, on December 9: the second highest was 114° F. at Berbera on July 12, 16, and 25: the absolutely lowest was -76° F. at Verkhoiansk on February 2. The heaviest total rainfall for the year was 511 inches at Cherrapunji, which is 87 inches more than the average; 170 inches fell in June. The latter is more than seven times as heavy as the annual average fall at Greenwich. No rain fell during the year at Insalah or Iquique.

Tabulae Biologicae. Herausgegeben von C. Oppenheimer und L. Pincussen. Band 1: Reine und physiologische Physik, physikalische Chemie und biologische Anwendungen. Pp. vi+522. (Berlin: W. Junk, 1925.) Subscriptionspreis für alle vier Bände (einzelne Bände werden nicht abgegeben) 100 marks.

THESE are, we believe, the first biological tables of their kind, and in one respect they indicate very clearly the degree to which the biological sciences have advanced quantitatively. The old barriers dividing the so-called exact and the descriptive sciences are down, and many are exploring long-neglected territory. Science has to wait for its problems to be tackled, but there are now biologists who can themselves go a long way in problems

demanding some exact science. To these and to others following in their wake, we think that these tables will be of great service.

The authors are very frank in acknowledging the prototype of their work, and they assure us that what they have prepared is nothing but a Landolt-Börnstein of the entire field of biology; this includes physiology, anatomy, medicine, hygiene, zoology, botany, technics, pharmacology and bacteriology.

The range of information is extraordinarily wide, but there remains the all-important question of accessibility of the data. How easy is it to find the required information? The volume under review contains 522 pages, literally packed with data. The table of contents occupies one page and indicates thirty-four different sections. While, of course, some sections are longer than others, it will be seen that considerable time must be taken in getting what these tables have to give; vastly less time, however, than by any other method. Readers have the opportunity of consulting the original papers, for references to these are given at the ends of the sections. The authors have been at great pains to secure trustworthy data, and we have little doubt that advantage will be taken by scientific workers and readers of this mass of information.

Plant Life on East Anglian Heaths: being Observational and Experimental Studies of the Vegetation of Breckland.

By Dr. E. Pickworth Farrow. Pp. x+108+23 plates. (Cambridge: At the University Press, 1925.) 7s. 6d. net.

THE interesting studies of vegetation at Breckland, East Anglia, which Dr. E. Pickworth Farrow has been publishing in the *Journal of Ecology*, have now been gathered together and published, with additional matter, in book form. This work provides the most definite and striking data as to the effects produced by rabbits in determining the nature of the vegetation. Thus their influence is traced in the degeneration of Calluna heath to grassland and in the prevention of natural regeneration of woodland. Interesting notes are provided on wind effects upon Calluna in sandy soils and upon the water supply in the soil as a determining factor in the type of vegetation of the soils at higher levels at Breckland, but in the main this work is characterised by the manner in which it underlines the significance of biotic factors. Cases that may be cited, in addition to the rabbits, are the effect of the shade thrown by Pteris, notably by the dead fronds, upon the spread of Calluna, and the influence of the litter of needles below the pines upon the spread of *Carex arenaria*.

Analytical Geometry of Conic Sections and Elementary Solid Figures. By Dr. A. Barrie Grieve. Pp. xv+314+xiv. (London: G. Bell and Sons, Ltd., 1925.) 9s. net.

A TEXT-BOOK for students who have already finished the straight line and circle: its contents are about equally divided between the conic sections and the geometry of three dimensions, finishing with confocal quadrics and a chapter on curvature. The author wisely uses the calculus for finding gradients, but also gives the alternative treatment. The book can be confidently recommended for boys reading for scholarships and for first-year students at universities.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Boskop Skull.

TWELVE years ago there was discovered in the Transvaal a remarkable human skull of apparently great antiquity. Fitzsimons, of Port Elizabeth Museum, first described it as perhaps allied to the Neanderthal but without the large supra-orbital ridges. The skull was next sent to Capetown on loan, where it was described at some length by Haughton as allied to the Cromagnon man. Shortly afterwards I examined it in Port Elizabeth, and, impressed by the huge size of the brain, the great thickness of the bone—in places 15 mm.—and certain remarkable features in the jaw, I thought it worthy of specific rank and named it *Homo capensis*. Now the specimen has been sent to the British Museum for further examination, and there has just appeared a paper by Pycraft which will be regarded as the official British Museum report.

Prejudice has played a considerable part in anthropology. Since the belief in evolution became accepted, all old human skulls are expected to be ape-like, and if not ape-like are regarded with suspicion. Doubts have been thrown on the Galley Hill skull because it is not sufficiently anthropoid. When in 1855 a human jaw was found in the Red Crag it was submitted to Owen, Huxley, Lyell, and all the leaders of the day, but as it was not like an ape's jaw they all shook their heads and said it was an interesting curiosity, and as no one recognised its value the jaw got lost. The Boskop skull has been threatened with a similar fate. It has an enormous brain and is not at all ape-like. Therefore, according to some, it cannot be old, and in any case cannot be very interesting.

Pycraft, in concluding that it is a Proto-Bushman type, agrees with the view I expressed some years ago, and in his phylogenetic tree he places it low down on the branch that leads to the Bushman and Negro. Unfortunately elsewhere in the paper he states "very certainly that he was a derivative of Cromagnon man," and Cromagnon man he places well up the branch that gives rise to the European types of to-day.

By means of certain formulæ Pycraft estimates the cranial capacity at 1717 c.c. Haughton estimated it at 1832 c.c., Elliot Smith puts it at 1900, and I made it 1950 c.c. Sollas has just shown that those beautiful formulæ, while fairly trustworthy for normal-sized skulls, are quite untrustworthy for large skulls, giving at times an error of more than 200 c.c. If instead of estimating the capacity by formulæ suitable for normal skulls of *Homo sapiens*, which do not take into consideration the abnormal thickness in places; and the unusual thinness in others of a skull like the Boskop, we make a cast of the brain in plaster and restore it into at least approximately its original condition and then measure its size, as I have done, I still feel quite confident the capacity will be found to be more than 1900 c.c.

In Pycraft's paper there is one serious omission which I deeply regret. He admits that there is preserved "a fragment of a mandible" and it is not at all an inconsiderable fragment. It was on this jaw largely that I (not Hewitt, as Pycraft states) founded the species *Homo capensis*, believing that the jaw differs in certain characters from all other known human types. I may be entirely wrong in my view

of the jaw, but it was with considerable disappointment that I found Pycraft had a good deal to say on the easy problem of the cranium, and not a single word to say on the more interesting and much more difficult problem of the jaw, and until this mandible has been fully investigated by some expert we cannot accept as final any verdict pronounced on the cranium alone.

Douglas, South Africa,

R. BROOM.

The Energy liberated by Radium.

WHEN radium is in equilibrium with its disintegration products, it is known that the number of atoms of each of the products disintegrating per second is the same, and that this is equal to the number of α - or β -particles emitted by each product per second, according as the transformation is accompanied by α - or β -ray emission respectively. Moreover, in the case of those products (RaB and RaC) which emit γ -rays, Kovarik (*Phys. Rev.*, 23, 559, 1924) has recently established the important result that each disintegrating atom emits only one γ -ray (quantum). The number of γ -quanta emitted per second by the amount of Ra(B+C) in equilibrium with 1 gm. of radium was found to be 7.28×10^{10} , from which we may conclude that each product emits 3.64×10^{10} γ -quanta per second.

Much valuable information on the energy of the γ -rays emitted by radioactive substances has also been obtained by measuring the energy of the β -rays excited by γ -rays incident on various elements, and afterwards applying Einstein's photoelectric equation, but further work will be necessary before our knowledge of the energy of the γ -rays is complete. Recent experimental work by Ellis (*Phil. Mag.*, 50, 521, 1925) has shown that the contribution of the γ -rays from Ra(B+C) to the total heat production of radium together with its short-lived products amounts to about 6.3 per cent, a value which is about 1.6 per cent higher than that hitherto accepted. Theoretical calculations of this heat production have also been carried out, on the basis of the photoelectric data on the energy of the γ -rays, referred to above. Thus Meitner (*Die Naturwissenschaften*, 12, 1146, 1924) finds that the γ -rays from Ra(B+C) contribute slightly less than 9 per cent of the total heating effect of radium (ca. 137 cal./hour/1 gm. Ra), whereas Thibaud (*C.R.*, 180, 1166, 1925) calculates that they contribute slightly more than 5 per cent of the total heat production. The deviations of these calculated values from that found experimentally by Ellis are probably due to the fact that the γ -radiation from these elements is not homogeneous, but consists of several wave-lengths, which means that we must know how much these individual frequencies contribute to the aggregate effect, and on this point there is not complete unanimity of opinion. Moreover, such calculations involve a knowledge of the number Z of atoms of radium disintegrating per second per 1 gm. of the element, and here again there is a divergence of opinion. Meitner uses the value 3.5×10^{10} ; Thibaud uses the value 3.57×10^{10} (Rutherford-Geiger); whilst Ellis (*l.c.*) recently used the value 3.4×10^{10} (Geiger-Werner, *Zeit. f. Phys.*, 21, 197, 1924).

Interesting information on the latter point can be obtained if we attempt to calculate the total heating effect due to 1 gm. of radium alone, i.e. free from its disintegration products. Here the conditions are simplified, for radium does not emit primary β -particles. Moreover, the γ -radiation emitted by radium is homogeneous (cf. Meitner, *l.c.*)— $\lambda = 6.64 \times 10^{-10}$ cm.—and its energy can be calculated if we make what

seems to be a plausible assumption, namely, that the number of γ -quanta emitted per second by 1 gm. Ra has the value Z . The total heat production is obtained by adding this amount to that due to the α - and recoil particles. The results of this calculation are given below, (1) on the basis of Geiger's value of $Z = 3.40 \times 10^{10}$, and (2) on the basis of the value of Hess-Lawson (*Wien. Ber.*, 127, 405, 1918; *Phil. Mag.*, 48, 200, 1924), namely, $Z = 3.72 \times 10^{10} \pm 0.02$.

The energy (E_a) of each α -particle emitted by radium has the value 7.529×10^{-6} erg, that of the recoil particle ($E_r = \frac{m_a}{M_r} E_a = 0.018 E_a$) amounts to 0.136×10^{-6} erg, and each γ -quantum possesses an amount of energy of magnitude 0.296×10^{-6} erg. Thus the total energy liberated per atom disintegrating amounts to 7.961×10^{-6} erg. From this it is a simple matter to calculate the total heat development H of 1 gm. of radium in calories per hour. We obtain the following results:

- (1) for $Z = 3.40 \times 10^{10}$, $H = 23.28$ cal./hour.
 (2) for $Z = 3.72 \times 10^{10}$, $H = 25.47$ cal./hour.

Value of H obtained experimentally = 25.2 cal./hour.

We see, then, that the deviation of the calculated from the experimental value of the heat production of radium amounts to about -8 per cent or +1 per cent, according as we make use of $Z = 3.40 \times 10^{10}$ or 3.72×10^{10} respectively.

Now a consideration of the value 25.2 cal./hour for the heat development of 1 gm. of radium, as obtained by Hess (*Wien. Ber.*, 121, 1419, 1912), indicates that it is more likely to be a shade below than above the true value. The determination was made with nearly $\frac{1}{2}$ gm. of radium, which had been specially purified by Hönigschmid for atomic-weight determinations, and great care was taken to eliminate the effect of the decay products of radium from the result. On the other hand, the possible contribution of the γ -rays from radium to the heating effect was at that time generally regarded as negligible. Recent work, however, shows that it is not so. Absorption measurements with the γ -rays from radium yield three values of μ (in aluminium) for these rays, namely, 354, 163, and 0.27 cm^{-1} . The half-value thicknesses corresponding to these absorption coefficients are 0.002, 0.042, and 2.56 cm of aluminium respectively. Now the thickness of absorbing material in Hess's determination of the heat production of radium was equivalent to 4.9 cm. of material of unit density, which corresponds to 1.8 cm. of aluminium.

It follows that the first two constituents of the γ -radiation referred to above would be completely absorbed, whereas less than half of the third and nuclear constituent would suffer absorption. An exact estimate of the fraction of the total γ -radiation which remained unabsorbed in the experimental determination is not readily obtainable, but it would almost certainly be less than half the total. In other words, since the total heat developed by the γ -radiation from 1 gm. of radium works out to be 0.947 cal./hour, the corrected hourly heat development due to all the rays emitted by 1 gm. Ra, as determined experimentally by Hess, cannot differ much from 25.5 cal., a value which is almost identical with that calculated under (2) above.

A comparison of the above results of theory and experiment thus lend strong support to the essential correctness of the value $Z = 3.72 \times 10^{10}$ for the number of α -particles emitted by 1 gm. of radium per second, and it is significant that Kovarik's work on γ -rays is in substantial agreement with this result.

In the above calculations, I have endeavoured to use the most accurate data available for the various

quantities involved, and it is important that the values used should be stated. They are as follows: (1) Wave-length of γ -rays from radium = 6.64×10^{-10} cm. (Hahn-Meitner); (2) velocity of α -particles from radium = 1.511×10^9 cm./sec. (Geiger); (3) mass of α -particle = 6.595×10^{-24} gm; (4) velocity of light = 3.000×10^{10} cm./sec.; (5) Planck's constant (h) = 6.55×10^{-27} erg sec.; (6) Joule's equivalent = 4.186×10^7 ergs/calorie.

ROBERT W. LAWSON.

University of Sheffield,
November 9

Human Personality and Biochemistry.

A REVIEW of Prof. Louis T. More's "The Dogma of Evolution" (*NATURE*, October 17, 1925, p. 562) contains this sentence.

"The absurdity of some of the attempts to overcome this difficulty quoted by Prof. More, is almost incredible, as, for example, that of Prof. Ritter who maintains that every individual organism is a chemical compound!"

Here are the words in More's quotation from me to which this statement probably refers.

"An essential implication of this proposition is that every living individual organism has the value, chemically speaking, of an elementary chemical substance."

It seems from this that to the reviewer (signed E. W. M.) the words "has the value of an elementary chemical substance" mean the same as the words "is a chemical compound." To me the two phrases are very far from meaning the same thing. But were there no better reason than a desire to debate this point of difference between the reviewer and myself, I should not feel justified in asking *NATURE* for space in which to print even a brief communication in connexion with the criticism passed upon others and me by More and E. W. M. But I think there is a much better reason for requesting such a privilege.

According to this reviewer, the "incredible absurdity" committed by me resulted from the "difficulty of explaining how the typical proportions of this mixture [of compounds]" (*i.e.* of which protoplasm is now known to be composed) is maintained. Where he got the impression that I was trying to "explain" the phenomenon he mentions it is hard to see. For neither the word explain nor any synonym for it occurs in More's quotation from me, or anywhere in the original discussion.

As a matter of fact, my object in formulating the hypothesis quoted by More was very different from what E. W. M. says it was. This I think he could scarcely have failed to recognise had he read somewhat carefully all I wrote on the subject. But since More and E. W. M., and so presumably others who may have read my discussion, have missed by a long way what I was trying to bring out, I wish now to see if I cannot state the point in a nut-shell and so clearly as to ensure against it being misunderstood by anybody else who may chance to be interested in my results on the general subject dealt with.

What I tried to do originally was to bring into recognisably harmonious relation with each other two groups of facts concerning organisms, human organisms especially, which are questioned by nobody of good sense and sound learning, although scarcely anybody is able to see exactly how they can get on together in one and the same individual.

One of these factual groups is human personality; the other is the human organism's ability to continue to live by means of its food substances. How, for example, is it possible for a great Nordic statesman

and his humble negro valet to breathe the same kind of air, drink the same kind of water, and eat the same kinds of solid food year in and year out, and yet one of them go right on being a great Nordic while the other as persistently continue to be a humble negro? If there is any truth in Feuerbach's epigram, "Mann ist, was er isst," how can such a thing be?

What I wrote, essentially, in attempting to throw some light into this dark place, which has drawn the fire of these critics is this. Every elementary substance is different from every other as to its physical attributes and as to the products of its chemical reactions with other elementary substances. Likewise every human person is different to some extent from every other as to many of his physical attributes, and as to his chemical reactions with certain elementary substances, notably with atmospheric oxygen. That these two groups of facts constitute a rather striking resemblance between a chemically elementary substance and a human organism scarcely needs saying in so many words when they are presented in this bald way.

I further directed attention to the idea that the validity and perhaps the significance of this resemblance are increased by drawing consciousness into the comparison. Thus when the conscious organism is deprived of air (oxygen) its consciousness ceases as inevitably and almost as promptly as does the flame of a lump of phosphorus or sulphur under like deprivation. Furthermore, the utter differentiatedness of every person's conscious activity from every other person's, and the consequent possession by every person of a measure of genuine uniqueness, is comparable with the differentiation that characterises the chemical reaction of every elementary substance with every other such substance.

As to its conscious life especially, the definitiveness of every human person is like unto the definitiveness of a chemically elementary substance.

To show that the separate reality of each and every conscious person is comparable with the separate reality of each and every chemically elementary body is the essence of my discussion from which More quotes. What I did was to manipulate, by the methods of description and comparison, certain well-established facts concerning the nature of man and some other organisms, and other well-established facts concerning the nature of certain inanimate bodies, with the view of finding how much they have in common.

If this performance deserves to be stigmatised as "incredibly absurd" materialism, the stigma rests on the facts rather than on me.

The separate and more difficult question of whether such a way of treating the facts really connotes materialism cannot, of course, be gone into in a brief communication like this.

This much may, however, be said. My description of conscious human personality recognises its utter dependence on material substances and atoms, but it also recognises that the worth and dignity of each human person are real in the same sense that the atoms themselves are real. So far as I can learn, materialism has never recognised such a relation between a personality and the atoms of which it is composed.

WM. E. RITTER

Science Service,
Washington, D C,
November 11

PROF. RITTER's further explanation of his meaning leaves me gasping! Apparently I did him an injustice in supposing that he meant to compare the human organism to a chemical compound. What he really intended was to compare each human individual

to a chemical element. Just as each element reacts differently with oxygen and thereby manifests its individuality, so each human being reacts differently to oxygen, and in this his personal peculiarities find their explanation.

We might remark that chemical atoms (barring radioactive transformations) persist and are indestructible, whereas the human being in so far as he consists of matter is a temporary phenomenon. Further comment, however, on this extraordinary comparison appears to be superfluous.

A Surface Catalysis in Photochemical Processes.

DURING the course of an investigation on the photochemical combination of gases, our attention was directed to the marked diversity in the rate of combination of gases such as hydrogen with oxygen, ethylene and carbon monoxide, effected by irradiation in quartz tubes with the mercury vapour lamp, observed by different investigators.

It is a well-established fact that pure hydrogen and oxygen can combine when subjected to radiation of short wave-length, but owing in general both to the weak absorption coefficient of the gases, probably oxygen being the important constituent, and the feeble nature of light at wave-length shorter than the resonance line $\lambda = 2537 \text{ \AA}$ to which such photo-activity is due, the rate of combination is generally small. Indeed at low pressure Dickinson failed to note any combination. Again, if mercury vapour be admitted to the system, Franck and Caro have pointed out that the mercury atoms are activated to the $2p_2$ state by absorption of quanta of light of wave-length $2537 \text{ \AA}$ U., and such activated mercury atoms on collision with hydrogen molecules produce an active modification of hydrogen which can react either with the gases mentioned above or with metallic oxides. It is uncertain at the present time whether this "active" modification so produced consists of activated hydrogen molecules, a point of view held by Mitchell, hydrogen atoms as suggested by Franck and Caro, or an unstable but active mercury hydride postulated by Compton.

When a comparison is made of the rates of these two homogeneous gas reactions obtained by observers such as Franck and Caro, Dickinson and Mitchell, with the relatively high rates obtained by Berthelot and Gaudechon, Baker, and especially Taylor, on illuminating a gas mixture *in the presence of liquid mercury*, it was evident that the discrepancy was too great to be accounted for by variations in the intensity of the line $\lambda = 2537 \text{ \AA}$ U. from the lamps of the different observers. Taylor indeed has recently realised this discrepancy and suggested that combination is in effect a chain mechanism of the type postulated by Christiansen and Kramers. Whilst some species of chain reaction does undoubtedly occur in a few cases, such as in the combination of hydrogen and chlorine, it appears improbable that the diversity of the results between the two groups of experimentalists can be attributed to some unknown factor causing the inhibition in the former, or the propagation of chains in the latter cases.

An investigation of the catalytic effect of a mercury surface in the photochemical combination of these various gas mixtures revealed the interesting fact that combination between these gases is promoted by a mercury surface when illuminated at ordinary temperatures with radiation from a quartz mercury vapour lamp under the conditions of strong emission of the resonance line $\lambda = 2537 \text{ \AA}$ U.

We have likewise made a search for any catalytic effect of metals such as iron, copper, cadmium, and silver, when radiated with the mercury and cadmium

vapour lamp and the iron arc, but apart from the already well-known small increase in the rate of oxidation of reduced iron and copper on illumination, no definite signs of catalytic effects were obtained, possibly on account of the relatively feeble intensity of the resonance lines for these metals in the arcs employed. In the case of mercury irradiated with the water-cooled mercury arc the catalytic effect is, however, most distinct. Thus in a series of experiments with ca. 30 c.c. of hydrogen and oxygen, in an approximate ratio of 2:1, at a total pressure of 300 mm., both in the absence and presence of mercury vapour the rate of combination was so slow that in a period of five hours a change in pressure of less than 1.0 mm. was obtained. In the presence, however, of a layer of mercury 10 cm. long, disposed in the horizontal reaction tube, a change in pressure of 60 mm. an hour was obtained. The rate of change is to a first order proportional to the area of mercury exposed. Amalgamated silver is likewise effective as a catalyst, but amalgamated brass possesses but little efficiency. In this latter case it may be observed that owing to the operation of the forces of surface tension, zinc and not mercury is the predominant constituent of the surface layer.

Whilst in the absence of hydrogen, ozone can be identified by the tailing of the mercury, when hydrogen is present mercuric oxide is formed on the mercury surface and is also deposited on the tube walls.

Auto-retardation of the rate of reaction is to be noted when formaldehyde and its polymerised products from carbon monoxide and hydrogen condense on the previously clean mercury surface. Although ethylene is sensitive to light in the absence of mercury, the combination of this gas with hydrogen proceeds smoothly at a greatly accelerated rate in the presence of the illuminated mercury surface.

The operation of this hitherto unsuspected catalytic action of a mercury surface in the photochemical combination of gases provides a reasonable explanation, so far as can be ascertained from the published information on the experimental methods adopted, for the high rates of combination frequently observed. It must, however, be admitted that the data of Coehn and Tramm do not conform to this view, for a remarkably rapid rate of combination was obtained for pure gases. It is possible that mercury was actually present, being drawn into the reaction vessel from the one ground-in joint with which their reaction system was provided, since their diagram lends support to the view that the joint was provided with a mercury seal.

We have not as yet obtained definite information as to the quantum efficiency of the surface, or whether water vapour is essential for this surface action; it appears, however, to be unnecessary for the operation of the Franck and Caro mechanism.

The Cierva Auto-gyro.

IN his article on the Cierva auto-gyro in NATURE of October 31, Prof. Bairstow repeats an argument originally used against the helicopter, that the longer spiral path of the blades, as compared with the straight path of aeroplane wings, causes a greater expenditure of energy for a voyage of a given length from point to point.

Munk arrives at the contrary conclusion in Technical Note No. 221 of the American Advisory Committee for Aeronautics. On pp 10-11 he writes:

NO. 2929, VOL. 116]

"The average velocity of the helicopter blade is greater than that of the aeroplane wing and this involves greater loss. . . . However, the helicopter makes up again for this by its smaller wing area . . ." and finally, "The loss due to the drag of the [helicopter] wing is accordingly smaller."

I find it difficult to simplify the basis of comparison sufficiently to draw any general conclusion, but am of the opinion that Prof. Bairstow's argument requires considerable modification on the lines laid down by Munk.

A. R. LOW.

London, November 28, 1925

THE argument for relative efficiency of aeroplane v. auto-gyro as given in my article does not depend on the area of the wings used, and it would seem that Munk can only reach his conclusion by imposing on the aeroplane some disability not shared by the auto-gyro. The disability is made clear on p. 11 of the report referred to by Major Low, where we find "the aeroplane wing area is not chosen for the ordinary velocity of flight, but for the much smaller velocity used for taking off and landing, and in consequence is much greater than it would need be for ordinary flight alone". This paragraph means that at high speeds an aeroplane cannot use its wings at the best ratio of lift to drag, and this is a well-known phenomenon. The argument as to the advantages and disadvantages of the two types of craft becomes very technical if carried into this stage, and I cannot press my point further here than as one of opinion backed by the knowledge that experiments have not yet demonstrated the capabilities of the auto-gyro to overcome the disadvantage of the aeroplane to which attention has been drawn by Munk.

Put in terms of lift/drag the difference of statement seems to disappear; on p. 7 of N.A.C.A. Tech. Note No. 221 Munk says: "I proceed now to the energy balance of the tilted propeller. This will give information on the economy of the helicopter. It is enough to analyse the results of tests 136 to 141, which is done in Table VIII. The table shows that the ratio L/D of the propeller is considerably smaller than for ordinary wings . . ." L. BAIRSTOW

The Free Path of Slow Protons in Helium.

POSITIVELY charged hydrogen atoms with velocities acquired by falling through 300 to 900 volts have been found to possess an unexpected range in helium and other gases. With helium pressures so high as 0.5 mm. of mercury, the protons will complete a semicircular path 16 cm. in length and still appear as a positively charged bundle of rays. The magnetic deflexion shows also that they remain charged throughout their entire path. As the free path given by the kinetic theory of gases for a rapidly moving particle is 1.5 millimetres at this pressure, the protons must pass unaltered through more than one hundred helium atoms. The capture of electrons by α -rays of various velocities observed by Henderson and Rutherford, and R  chardt's experiments with canal rays, would lead one to expect a rapid neutralisation of protons of this velocity. The neutralisation of the more rapidly moving particles observed in those experiments has been explained by the presence of a great number of electrons, due to ionisation, with which the particles may combine, and we may account for the absence of neutralisation in the present experiments by the assumption that no free electrons are produced by protons of the velocity used. In fact, energy considerations would suggest the improbability of an

electron leaving a helium atom with an ionisation potential of 24.5 volts, in order to form a neutral hydrogen atom possessing a much smaller ionisation potential.

Singly charged helium atoms apparently do become neutralised, since they rapidly disappear as the pressure is increased. At 0.01 mm. pressure they are much weakened, and are entirely absent at a pressure of 0.027 mm. of mercury. Charged hydrogen molecules disappear at a higher pressure (0.07 mm.) than the charged helium atoms. They are probably dissociated without alteration of velocity or direction, at collisions with the helium atoms, since their disappearance, as the pressure is increased, is accompanied by the appearance of a group of protons with the slow velocity of the original molecules.

Winter Thunderstorms, 1925.

A LARGE number of reports were received in response to an appeal for observations of thunderstorms occurring in the British Isles during the first three months of this year. The following table shows the number of days on which thunder or lightning was reported:

1925.	England and Wales.	Scotland.	Ireland.	British Isles.
January . . .	10	12	10	17
February . . .	20	10	8	23
March . . .	16	5	4	17
Total (3 months)	46	27	22	57

The stormiest areas in England were mainly on or near the south coast, and in Scotland they were in the central part of the west coast. Large areas in the northern and midland counties of England, and a large part of Wales, were free from storms.

The investigation will be continued during the first three months of 1926, and in thanking those who sent information last winter, may I ask for similar reports next year?

A Further Case of Sub-Harmonics.

THAT notes may be produced by the intermittent contact of a tuning-fork and another body, the frequencies being sub-multiples of that of the fork, has been shown in my earlier communications (NATURE, March 8, 1924; *Phil. Mag.*, January 1925). This letter is to point out that such sub-harmonic notes can also be obtained by rubbing with a wetted finger on or near the rim of an ordinary thin tumbler or of a wine-glass. The note most easily obtained corresponds to the fundamental "bell" mode of vibration in four segments, as may be seen by the ripples produced on a little water placed in the glass (one of the four nodal lines ends at or near the moving finger). By pressing harder and moving the finger more slowly, notes of a half, a third, and a quarter of the frequency of the above note can similarly be obtained. All these notes fall in pitch simultaneously when more water is placed in the glass. (Another note may occur, apparently due to the simple torsional vibration of the glass. This note is unaltered in pitch by varying the amount of water.)

The London Skull.

As Prof. Elliot Smith states in his letter to NATURE of December 5, a sample of the blue clay in which the skull was found at Lloyd's has been forwarded to me for examination at the instigation of Mr. Warren B. Dawson.

I am anxious to remove at once any possible misunderstanding regarding the results of my examination. It may have been thought that as I was familiar with the brick-earths in East Anglia, in which Mr. Reid Moir has found so much evidence of Moustertian culture, I might be able to establish some kind of correlation. As I pointed out at once, however, to Mr. Dawson, this was unlikely. The blue clay happens to be lithologically different from the Moustertian brick-earths of Suffolk, but even if it were similar petrographically, I should still regard its indigenous fauna as the only safe basis for correlation and determination of age.

My examination of the inorganic constituents of the clay may throw light on the conditions of deposition and the source of the material. I must leave the question of its age in the competent hands of Messrs. Bromehead and Hinton, who I hope will find it possible to arrive at an agreement.

Early Use of Lightning Conductor.

MR. H. C. BROWNE, in a letter on the early use of the lightning conductor (NATURE, Aug. 15, p. 242), quotes the "Tableau de Paris." Readers of NATURE may wish to refer to this interesting work. The "Tableau de Paris" was published between 1781 and 1788 in twelve volumes, by L. S. Mercier. The chapter quoted by Mr. Browne is of 1783. In the last volume of the collection is another chapter on the same subject, in which Mercier recants his former belief in the lightning conductor; he says: "In a city of 800,000 souls, I have not seen, in forty years, a single person killed by lightning."

Mercier's incredulity in scientific matters culminated, many years later, in a work the title of which speaks for itself: "De l'impossibilité du système astronomique de Copernic et de Newton" (Paris, 1806).

A Gift of Fleuss Vacuum Pumps.

WE have for disposal a few Fleuss vacuum pumps suitable for laboratory experimental work. The pumps can be either hand-worked or power-driven by a belt on the fly-wheel. They occupy a floor space of about 24 in. x 14 in. So far as the number available permits, we should be pleased to give one to any university laboratory or educational establishment in Great Britain where such a pump would be of value for experimental work.

The object of this letter is to make the fact known in the hope that any one desiring one of these pumps may see this letter and communicate with us direct.

Atoms and X-Rays.¹

By Dr. F. W. ASTON, F.R.S.

ISOTOPES AND IONISATION.

THE idea that all atoms of matter might be built of the same primordial units, that is to say, might differ not in material but only in construction, dates back at least as far as Prout. This philosopher endeavoured more than a century ago to show that atoms of all elements were themselves built of atoms of hydrogen. A little earlier Dalton had postulated, in probably the most important theory in the whole history of chemistry, that atoms of the same element were of equal weight. If both these theories were right, the atomic weights of all elements would be comparable with each other as whole numbers. This the chemists soon found was quite incompatible with experimental evidence. They had to choose between the two theories and chose the one that was untrue. In this they were perfectly right, for it is more important that a scientific theory should be simple than that it should be true.

The point cannot be tested by chemical methods, for these require a vast number of atoms, and so can only yield a mean result. The way in which Dalton's postulate was first attacked and shown to be incorrect was in the province of radioactivity, when Soddy showed that lead which was produced from thorium minerals had a different atomic weight from the lead which was produced from uranium minerals. This meant that substances could exist which had identical chemical properties but different atomic weights; these Soddy called isotopes. This reasoning could not be applied to ordinary elements. For these there is only one conclusive test, which is to compare the weights of individual atoms. It is here that positive rays are of such value, for they are atoms carrying a positive charge and moving with so high a speed that they can be detected by a fluorescent screen or photographic plate.

The first experimental comparison of the weights of individual atoms was made by Sir J. J. Thomson by his "parabola" method, in which the rays are subjected to electric and magnetic fields giving deflexions at right angles to each other. Subjected to this test, many of the elements seemed to obey Dalton's rule, giving single or apparently single parabolic streaks expected from groups of atoms travelling with different velocities but all of the same mass. But results obtained with neon suggested that in this gas the atoms were of two different weights 20 and 22, the accepted atomic weight being 20.20. The accuracy of the parabola method of analysis was not sufficient to prove the point, but this was done by means of the mass-spectrograph. With this instrument, by using electric and magnetic fields giving deflexions at 180° to each other, it is possible to focus the rays and obtain a spectrum dependent on mass alone. By measurements of this mass-spectrum it is possible to compare the weights of atoms to one part in 1000. In this way a satisfactory proof was obtained that neon did consist of two isotopes 20 and 22, which, present in the proportion 9 to 1, give the mean atomic weight 20.2. Chlorine, the chemical atomic weight of

which is 35.46, was found to consist of two isotopes, 35 and 37. Many of the elements, such as carbon, oxygen, nitrogen, etc., were found to be "simple," that is, to consist of atoms all of the same weight, but even more were found to be "complex," mixtures of two or more isotopes. Selenium, krypton, cadmium and mercury each have six, tin probably eight, and xenon possibly nine isotopic constituents. In all, fifty-six out of the eighty known non-radioactive elements have been analysed into their constituent isotopes or shown to be simple with the results given in the table.

By far the most important result of these measurements is that with the exception of hydrogen, the weights of the atoms of all the elements measured, and therefore almost certainly of all elements, are whole numbers to the accuracy of experiment, namely, about one part in a thousand. Of course, the error expressed in fractions of a unit increases with the weight measured,

¹ From the presidential address delivered before the Röntgen Society on November 3.

but with the light elements the divergence from whole numbers is extremely small. This generalisation, which is called the *whole number rule*, has removed the only serious obstacle to the electrical theory of matter. It enables us to restate Prout's original hypothesis with the modification that the primordial atoms are of two kinds—protons and electrons, the atoms of positive and negative electricity. The proton is very much smaller and heavier than the electron, actually about 1850 times as heavy. According to the nucleus atom theory which we owe to Sir Ernest Rutherford, all the protons and about half the electrons are packed very close together to form a central positively charged nucleus, round which the remaining electrons circulate, somewhat like planets round a sun. All the spectroscopic and chemical properties of the atom depend on the positive charge on the nucleus, which is the excess of protons over electrons. This is clearly the number of planetary electrons in the neutral atom; it is called the *atomic number* and is actually the number of the element in the periodic classification—1 for H, 2 for He, 3 for Li, and so on. The whole-number weight of the atom, on the other hand, will be the total number of neutral pairs of protons and electrons it contains. This is also the number of protons in its nucleus, and is called the *mass-number* of the atom—1 for H, 4 for He, 6 and 7 for the isotopes of Li, and so on. Atoms are isotopic, that is, belong to the same element, when their nuclei have the same net positive charge, but they may have a different total number of protons, and so different weights.

We picture the atom as consisting of a central nucleus and an outer system of electrons, but when we come to inquire into the dimensions of the electrical particles themselves in relation to the dimensions of the atoms they compose, we are faced with a very surprising result. The protons and electrons are infinitesimal compared with the atom. To convey any direct idea of the numerical relations is almost hopeless, and were we to construct a scale model of the atom as big as the dome of St. Paul's, we should have some difficulty in seeing the electrons, which would be little larger than pin heads, while the protons in the nucleus would escape notice altogether as dust particles invisible to the naked eye. If we represent the nucleus of a helium atom as the size of a pea, its planetary electrons would be about a quarter of a mile away. Experimental evidence leaves us no escape from the conclusion that matter is empty. An atom, even of so heavy an element as lead, is as empty as the solar system and only occupies the spherical space we allot to it by virtue of the rapid and continuous rotation of its outer electrons. Led by the knowledge that under certain conditions these outer electrons could be stripped from the atom, and the nuclei thereby enabled to approach closer to each other, Eddington was able to predict that in certain stars matter could attain a density thousands of times greater than the greatest we know. This prediction has been strikingly verified by recent observations on the companion of Sirius, which at the same time have afforded another signal triumph for Einstein's relativity theory.

We have heard a good deal of loose talk in recent years of "splitting" the atom. Whenever you draw your fountain pen from your pocket you split countless millions of atoms in the sense that you violently tear

planetary electrons away from them, by the friction between the ebonite and the cloth. This form of splitting is called ionisation. In it the atom suffers no sort of permanent injury. It simply captures the first electron it can to replace the one it has lost, and after notifying the world at large of its recovery by a wireless signal, it goes on exactly as before. In such a solid as copper, the exchange of electrons from one atom to another can be effected with the greatest freedom, and it is the passage of these loose electrons which constitutes the ordinary electric current. I suspect that the high conductivity of the negative glow, and of flames, is due to an exchange of a somewhat similar kind.

I mentioned the despatch of a wireless signal sent by the atom on repair of its injury. The type of this radiation depends on the extent of the damage done. For superficial effects it is light and radiant heat: for deeper and more violent effects it is X-rays. The displacement of the innermost and most tightly bound electrons gives rise to the hardest X-rays. The tightness of binding depends on the nuclear charge, so that for the emission and absorption of the hardest rays the heaviest elements must be employed. This property of the atom has already been dealt with by Sir Oliver Lodge in his address two years ago. It is to be emphasised that in all such cases we are only concerned with the outer electrons. With the nucleus it is a very different state of affairs. To dislodge any part of this requires violence of an altogether higher order, but if it is done the whole atom is changed, and changed permanently. This is no longer ionisation but transmutation.

TRANSMUTATION OF THE ELEMENTS.

Transmutation of the elements, so long sought by the alchemists, takes place spontaneously in the radioactive atoms, the nuclei of which are unstable and periodically eject helium nuclei and electrons, which are the well-known alpha and beta rays. Several claims of artificial transmutation of elements have been made recently in serious scientific journals. I will deal with the more doubtful ones first. Three years ago it was stated that helium was formed when a tungsten wire was deflagrated by an intense discharge. Sir Ernest Rutherford pointed out the extreme improbability of any disruption of the tungsten nucleus under these conditions, and a careful repetition of the experiments, with greater precautions, proved that he was right. Quite recently a claim has been made that helium has been produced by transmutation in a vacuum tube discharge. If true, this would be the greatest discovery in history, but the detection at the same time of neon, another atmospheric gas, is, to my mind, a very suspicious circumstance, and when these alchemists seriously suggest that success or failure may depend on the use of a particular form of obsolete make and break, my scepticism is increased.

A much more interesting case is that of the liberation of gold from mercury by electric discharge, even in an ordinary mercury vapour lamp. Here similar experimental results have been obtained by several investigators in different parts of the world, and the quantities of gold produced are remarkably large—large enough as we shall see to dissipate the hope, so confidently expressed, that it is formed by transmutation of the mercury atoms owing to the addition of an electron to

their nuclei. This claim was supported, I confess much to my surprise, by a well-known authority, on the ground that since the nucleus is positively charged, it would be quite easy to fire an electron into it. This is pushing the analogy of the sun and planet system to unjustifiable length. We know that a planet directed towards the sun would actually fall into it, but if every time an electron was directed towards a nucleus it fell into it and was absorbed, how could matter have a permanent existence at all?

We know there must be some mechanism in Nature which prevents such a collapse taking place in this simple manner. Even if we grant the theoretical possibility, there are still fatal practical objections. The addition of an electron to the nucleus of one of the isotopes of mercury will turn it into an atom of gold, but cannot alter its weight appreciably. Now the atomic weight of the so-called artificial gold has been determined by Hönigschmid, and agrees within experimental error with the value 197.2 assigned to ordinary gold. Quite recently, by means of a new and more powerful mass-spectrograph, I have been able to resolve the isotopes of mercury, and so determine its composition, which was previously in some doubt. I find that it consists of 198, 199, 200, 201, 202 and 204. There is no isotope 197 previously suspected. This fact, combined with the atomic weight, makes it quite certain that no transmutation of the kind claimed could produce the gold found. This is ordinary gold which must have been present in the mercury from the start. I understand that this view has now been shown to be right by the failure of the experiment when sufficient care is taken to eliminate all traces of gold from the mercury beforehand.

Unless our views on the structure of nuclei are very wide of the mark, failure in such experiments is inevitable, for the forces employed are ludicrously inadequate to cause disruption. The work of Rutherford, Chadwick, Ellis and others leaves no doubt that just as the dimensions of the nucleus are almost inconceivably small—the radius of that of aluminium is probably less than 4×10^{-13} cm.—so the forces binding together its component parts are gigantic and to be measured in millions of volts. Such forces are not yet available in the laboratory. They are, however, provided, on an atomic scale, in the form of the alpha particles shot out of radioactive atoms, and with these Rutherford has succeeded in producing real and definite transmutation. The method consists in bombarding the atoms with the swiftest alpha particles, which are helium nuclei with a velocity of more than 100,000 miles per second, which corresponds to an energy of many millions of volts. In order to effect a disintegration, these projectiles must make a direct hit on the nucleus. When this happens in the case of most elements lighter than potassium, a proton is dislodged from the nucleus, which is thereby transmuted into another element.

These observations have recently been strikingly confirmed by Blackett, who, using the beautiful Wilson fog-track method, has actually succeeded in photographing the disintegration of nitrogen nuclei struck by swift alpha particles. As I have already pointed out, the dimensions of the nucleus are minute compared with those of the atom. It can be calculated that an alpha particle colliding with an atom will only hit the nucleus

once in about ten thousand million collisions, so that although each alpha particle makes about 200,000 collisions in completing its track, a very large number of photographs had to be taken. Actually some 400,000 tracks were photographed and eight disintegrations detected. In these the thin track of the dislodged proton could be clearly seen, and a somewhat unexpected feature brought out is that in each case the projectile is retained by the target. The nitrogen nucleus loses one proton but captures the helium nucleus fired at it, and so would appear to become an isotope of oxygen of atomic weight 17. No such body is known in Nature, which suggests that the atom so formed is not permanently stable.

ATOMIC ENERGY.

In the possibility of artificial transmutation lies the hope of one day releasing the so-called "atomic" energy. The whole-number rule is not mathematically exact, and it has been shown by direct measurements on the mass-spectrograph that an atom of helium, which consists of four protons, two nuclear electrons and two planetary electrons, weighs nearly 1 per cent. less than four atoms of hydrogen, each of which consists of one proton and one electron. The number of particles is identical, and the change of mass is ascribed to the different way they are arranged, and is called the packing effect. The theory of relativity tells us that mass and energy are interchangeable, and that if a mass m is destroyed, a quantity of energy equal to mc^2 is produced, where c is the velocity of light. Hence, if we could transmute hydrogen into helium, we should produce energy in quantities which, for any sensible amount of matter, are prodigious beyond the dreams of scientific fiction. For one gram atom of hydrogen, that is the quantity in 9 c.c. of water, the energy is

$$0.0077 \times 9 \times 10^{20} = 6.93 \times 10^{18} \text{ ergs.}$$

Expressed in terms of heat, this is 1.66×10^{11} calories, or in terms of work 200,000 kilowatt hours. In a tumbler of water lies enough power to drive the *Mauretania* across the Atlantic and back at full speed.

Here we have at last a supply sufficient even for the demands of astronomers; indeed, there is now little doubt that the vast supply of energy radiated by the stars can be kept up for centuries by the loss of an insignificant fraction of their mass. Whether this process is a degradation of hydrogen into helium, or the complete annihilation of matter by coalescence of its protons and electrons, is at present unknown. How long it will be before man is able to effect transmutation of matter into energy, and to what uses he will put such vast potentialities, are interesting subjects for debate. If scientific knowledge maintains its present rate of progress, the balance of probability is in favour of ultimate success, but this appears so far off that almost any speculation may be permitted. It may be that the operation once started is uncontrollable, and that the new stars which flare out from time to time in the heavens are but an intimation broadcast to the universe, of the first successful large-scale experiment on a far-distant world. It may be that the highest form of life on our planet will one day discover supreme material power, or cataclysmic annihilation, in the same ocean wherein, we are told, its lowest forms originally evolved.

Physics in Agriculture.¹

By Dr. BERNARD A. KEEN.

THE study of the physical properties of soil has a fundamental place in the application of science to agriculture. It occupied an important position in the early days of agricultural science, and, after a lengthy eclipse in the latter half of the nineteenth century, when Liebig, Lawes and Gilbert, and others were establishing the modern agricultural chemistry and biology, it again came into prominence, owing to the recognition of the colloidal properties of the soil. The older concepts have been examined from this point of view, and it appears that the soil must be regarded not as a mass of comparatively inert grains over which water is distributed in a thin film, but as particles the surface of which is coated with colloidal material. The composition of this material is complex. It is a mixture of organic and inorganic substances derived from the decomposition of organic matter, and the weathering of clay, respectively, and it modifies very largely the deductions on the relations between soil and its moisture content made from the older hypothesis.

A soil can be easily divided into a few groups or fractions of different average size, depending on the velocity of fall in water. This process is known as mechanical analysis. It is a routine procedure in a soil survey and, combined with ecological and meteorological observations over the area, enables the expert to suggest improvements in the agriculture. In the case of undeveloped countries, this examination is essential if the agriculture is to be built up on sound lines. A striking example of the value of such a survey is afforded by the recent classification of Africa into areas according to agricultural potentialities, made by two American workers. The information was limited and the divisions are only approximate, but the very fact that it was possible to make them at all on such restricted information, shows the power and flexibility of the method.

In research investigations, the simple procedure of mechanical analysis must be replaced by more exact methods, in which the distribution of particles is expressed as a continuous function of the effective radius. One method depends on measuring the gradually increasing weight of particles settling on a pan immersed in a suspension of the soil in water, and from these data the distribution curve can be derived mathematically. The method is not yet perfect, because the settling particles that would eventually reach the liquid under the pan are naturally caught by the pan, whereas those in the annular space fall freely. In consequence, a

density difference is established which sets up currents in the liquid, and the particles are deflected from their proper course.

For the purpose of this work, and for other studies, the Soil Physics Department at Rothamsted has developed an automatic and continuous recording analytical balance, illustrated in Fig. 1. A magnet is suspended from one arm, and the current through the solenoid is adjusted to keep the balance in equilibrium. The adjustment is automatic and is effected by using the motion of the balance beam away from equilibrium to complete subsidiary circuits which operate electromagnets controlling clockwork mechanism, that moves a sliding contact backwards or forwards along a slide wire. The current through the solenoid is, therefore,

FIG. 1.—The Odén-Keen automatic recording balance.

changed by the requisite amount. When the contact reaches the end of the slide wire, a third circuit is completed, and a phosphor bronze ball of known weight is automatically added to the magnet arm. The sliding contact rapidly returns to its zero position and the cycle of operations recommences. The resistances are so arranged that the relation between weight and length of slide wire across which the solenoid is connected is practically linear. Hence a pan attached to the sliding contact and resting on a rotating drum, gives a continuous record from which the change in weight can be inferred.

The treatment of the flow of water through soil, in an analogous manner to the flow of heat or electricity through conductors, presents considerable difficulties, because the quantities corresponding to conductivity and potential (which for heat and electricity are practically independent of external conditions and current density) are not independent of the moisture content, the state of packing and the colloidal content of the soil. Although the difficulties of theoretical and practical investigation are great, much attention has

¹ Based upon a lecture on "The Physicist in Agriculture, with Special Reference to Soil Problems," being the ninth of the public lectures on physics in industry, arranged by the Institute of Physics, and delivered on November 25.

been devoted to the problem because of the practical applications, especially in areas under irrigation, where it is essential to make the best use of the available water, and yet to avoid the concentration of deleterious "alkali" on the soil surface resulting from an excessive upward movement of soil moisture. In regions with adequate rainfall, recent experiments at Rothamsted indicate that the depth from which water can ascend by capillary action, and thus become available for plant growth, is not very great. This emphasises the value of those cultivation operations designed to conserve the moisture in the upper regions of the soil.

The importance of the soil water relationships resulted in many additions to the original broad

closely related to the behaviour of the soil under the action of cultivation implements, and they can be readily interpreted on the assumption that the colloidal material in soil forms a coating over the larger inert grains. Thus, the shrinkage of a plastic mass of kaolin, which normally follows a different course from that of soil, can be made closely to simulate the latter if a small amount of silica gel is previously precipitated on the surface of the kaolin particles.

In the field, the integrated effect of plasticity, cohesion, and surface friction between soil and a metal surface may be measured by a dynamometer in the hitch between the implement and the horse, or tractor. The drawbar pull thus recorded is found to vary con-

FIG. 2.—Lines of equal draw-bar pull over a supposedly uniform field.

divisions of soil moisture into gravitational, capillary, and hygroscopic moisture. They were based on the assumption that the soil grains could be regarded as inert, but the recognition of the colloidal properties of soil has destroyed the validity and physical significance of these additions. Further, it has been shown that the vapour pressure of moist soil reaches its saturation value at a moisture content well below the values obtained for the so-called "equilibrium points" of soil moisture. This suggests that the moisture relationships are best expressed by other properties of moist soil, such as cohesion and plasticity, because variations in these factors are to be expected at moisture contents above the value for saturation vapour pressure. These properties have the further advantage that they are

siderably even on areas that to visual inspection are quite uniform. In a comprehensive field test, variations of more than 30 per cent. were found, even when the average drawbar pull of plots 66 ft. $\times$ 33 ft. was considered. For individual furrows the differences were much greater. The results are well illustrated by Fig. 2, where the "contours" of equal drawbar pull have been mapped from the results on a scale plan of the field. This variation is of obvious importance in competitive or comparative implement trials, for which, as an essential preliminary, a dynamometer survey should be made of the selected area. Other experiments show that the variations from point to point persist unchanged from season to season, and are not sensibly affected by manuring, with the exception of organic

manures. The variations in drawbar pull figures are also closely related to the amount of drainage and to the early stages of plant growth.

It is found that the drawbar pull is comparatively unaffected by speed of cultivation. Thus for tractor ploughing, an increase from $2\frac{1}{2}$ to 4 miles per hour, which would mean a 60 per cent. greater area ploughed in a given time, only involves a 7 per cent. increase in

drawbar pull. It is improbable that the cost of the extra fuel necessary to give this increased pull would be more than a small fraction of the saving in labour costs due to increased speed of work. The design of tractors run at higher speeds without undue wear and tear, and of implements to perform satisfactory work at high speeds, should present no insuperable difficulties.

The Geology of the New Mersey Tunnel.

By Prof. P. G. H. BOSWELL, University of Liverpool.

ON December 16 H.R.H. Princess Mary inaugurated the work of excavation for the new tunnel under the River Mersey, sanctioned by Parliament last August. As is well known, a railway tunnel of invert form and 26 ft. in width has long been in existence; it was begun in 1881 by the Mersey Railway Company and completed some years later. The new tunnel is to be a highway and will be the largest of its kind. The major part of the tube will be circular in section, with an internal diameter of 44 ft., the road-way being constructed so as to take fullest advantage of the width. It will thus provide a four-way road for slow and fast two-way traffic, with side-walks of about 4 ft. for purposes of traffic control, etc. The cost of the tunnel is to be 4,750,000*l.*, half of which will be provided by the Ministry of Transport in view of its highway character.

The line of the tunnel is to be roughly parallel to and about 150 yards north of the existing tunnel, its direction being about N.E.-S.W. The total length of tunnel will be rather more than two miles, of which about three-quarters of a mile will lie beneath the river.

At the Birkenhead end the entrance is to be near the Birkenhead Woodside Railway Terminus, and thus close to the docks. A suitable gradient of 1 in 30 will be obtained by a spiral descent. On the Liverpool side the tunnel will bifurcate, the northern branch ascending by a spiral gradient of 1 in 30 to the docks north of the pier-head, and the southern branch by a fairly straight stretch, of gradient 1 in 20, to an entrance in the heart of the city.

Throughout its course the tunnel will lie in Triassic sandstone and the overlying glacial deposits. On the Birkenhead side, under the River Mersey and for about 550 yards from the dock-walls on the Liverpool side, the rock belongs to the Middle Bunter Sandstone (or "Pebble-beds," though pebbles are scarce in the district). The beds dip at a low angle eastwards. The last 330 yards of the southern branch on the Liverpool side may be expected to lie in the Upper (Soft) Mottled Sandstone of the Bunter, which is here thrown down by a fault against the Middle Sandstone.

The latter is a firm, well-bedded rock, excellent for purposes of excavation, for it will stand well; the Upper Sandstone is rather soft. Both rocks, however, are renowned for the copious water-supply yielded by them.

It will be remembered that the Mersey estuary narrows considerably where Birkenhead and Liverpool

are situated. Indeed, a rock-bar is responsible for the consequent ease of communication between those ports. Higher up the river, the overburden of glacial drift thickens, and, as the late T. Mellard Reade demonstrated, a deep channel of drift occurs at Widnes. As a result of his study of minor channels of drift in the area of the Liverpool and Birkenhead docks, Mellard Reade declared, before the Mersey railway tunnel was cut, his belief that they drained into the main buried channel, which would thus extend down the Mersey estuary, through the rock-barrier to the sea. He claimed, with good reason as the sequel showed, that geologists could pre-see, and warned the engineers that the channel of drift must be expected in the course of their operations. The channel was struck on the down-grade portion of the tunnel about 90 yards from the Liverpool side, and 44 ft. below the present bed of the Mersey, its base being closely 95 ft. below O.D. An unavailing attempt was made to avoid it, but fortunately the lowest 6 ft. of the channel (which was cut into for a length of about 66 yards) proved to be a stiff purple Boulder Clay. This clay yielded an excellent roof, and, unlike the sandstone, gave no trouble from water.

Another prediction, even more puzzling to those to whom the geology was not familiar, was that of the late G. H. Morton of Liverpool, who drew a geological section across the Mersey estuary and inferred the presence of a north-south fault with a westerly down-throw, under the bed of the river. This fault was struck in due course near the place assigned to it by Morton.

Trial-borings in the roof of the railway tunnel under the middle of the river proved a thickness of at least 15 ft. of Bunter Sandstone. The level of the top of the new tunnel in the part beneath the river will be nearly the same as that of the existing tunnel (approximately 106 ft. below O.D.). With the information made available by Mellard Reade and Morton, and the precision given to it by the excavations for the railway tunnel, and with the knowledge which has accumulated since (the officers of H.M. Geological Survey having re-surveyed the area just before the War), the engineers of the new enterprise will be fully forewarned of possible difficulties. But nobody, least of all a geologist, would care to predict the exact course, changes in depth, or lithological variation from clay to sand or gravel in a buried channel of glacial drift. There is no reason to doubt, however, that the new undertaking will prove successful.

Obituary.

PROF. A. FRIEDMANN.

IT has been briefly announced that Prof. Alexander Friedmann, director of the Central Geophysical Observatory, Leningrad, died of typhus fever on September 16, 1925, at the early age of thirty-seven years.

It is remarkable that under the auspices of the Academy of Sciences of Leningrad, which has recently celebrated its two-hundredth anniversary, the keen interest of Russia in scientific activities has been maintained throughout the stress and strain of war and revolution. The chief centres of geophysical activity before the War were the Central Physical Observatory at Leningrad and the Aeronautical and Magnetic Observatory at Pavlovsk (now Slutsk). The latter found itself between two armies after the revolution; but, with considerable difficulty, the work was maintained. From these centres the vast meteorological organisation of the Russian Empire had been controlled. It was naturally hampered a good deal by war conditions, but is being rapidly reinaugurated. After the death of Prince Boris Galizin, provisional arrangements were made for the scientific direction of the organisation; Prof. Obolensky was director for some time, and up to February of this year Prof. Weinberg was in charge.

At the congress on Applied Mechanics at Delft in April 1924 Russian representatives were present, and the number of papers which were offered overflowed the meeting-room and were made available in manuscript in the reading-room of the congress. Many of the papers were presented by Prof. Friedmann. He had graduated in 1910 at St. Petersburg, studied aerodynamics under Prof. Bjerknes in Leipzig, joined the Observatory at Pavlovsk, volunteered for the War as observer in the flying corps, was promoted to take charge of the aerological service of the army, and in 1918 became professor in the University of Perm. But in 1920 he returned to Leningrad as senior physicist at the Central Observatory, re-named Geophysical, of which he became director early in 1925. "A man of extraordinary mathematical capacity, he deliberately forced himself to experimental work in order to verify his results. He was entirely devoted to science; he worked hard himself and claimed hard work from his colleagues." In 1924 he started at the Observatory a new periodical, *The Journal of Geophysics and Meteorology*, wherein geophysical papers are printed in Russian with a brief summary in one or other of the foreign languages. His principal contributions to science are on "The Vortical Motions of the Atmosphere" in a periodical which he started as professor at Perm; "On Vortices in Liquids with variable Temperature," which he presented to the Mathematical Society of Kharkov; "On Differential Equations for Turbulent Motion of a Compressible Fluid," at the Congress of Applied Mechanics at Delft. He also contributed to modern mathematical physics papers on the curvature of space.

During Friedmann's short tenure of the directorship of the Central Geophysical Observatory he reanimated the organisation in an extraordinary manner. He was to have come to London for the meeting of the Upper Air Commission in April last; but at the last moment

found himself unable to leave Leningrad. His activity was, however, effectively represented by Dr. Moltchanoff, the director of the Aerological Observatory at Slutsk. Almost every phase of the subject was covered by one or other of the series of papers presented in Friedmann's name or in those of his colleagues. Since that meeting many letters have been received from him about the establishment of geophysical observations in various parts of Russia; the last of them, dated July 25, announced the creation of a geophysical observatory at Jakutsk as a local branch of the Central Geophysical Observatory, meteorological and aerological at first, with the intention of its becoming astronomical, optical, and magnetic in time.

Friedmann's untimely death is a serious loss for Russian geophysical science; but regard for his memory will certainly impel his successors to carry on the work which excited his unbounded enthusiasm.

NAPIER SHAW.

MR. W. R. DYKES.

WE regret to record the untimely death of Mr. William Rickatson Dykes, secretary of the Royal Horticultural Society, at the early age of forty-eight years. Motoring with his wife near Woking, his car skidded, collided with a lorry, and he was thrown out, sustaining severe injuries to his ear and right arm. Attempts to save the latter failed, and he died of syncope, following the amputation of his arm at the shoulder, on Tuesday, December 1.

Mr. Dykes was born on November 4, 1877, the second son of Mr. Alfred Dykes, and educated at the City of London School, at Wadham College, Oxford, where he took classical honours, and the Sorbonne. He became an assistant master at Charterhouse in 1903, and remained there until the end of 1919, when he was elected to succeed the late Rev. W. Wilks as secretary of the Royal Horticultural Society. Under his secretaryship the Society has continued the growth started in 1888, and Mr. Dykes had recently taken a considerable part in furthering the plans (which are now well forward) for the building of a new and larger hall for the Society's meetings. His name, however, will be remembered, not so much for his work as a teacher, or as secretary of the Royal Horticultural Society, but chiefly for his devotion to the genus *Iris*.

Mr. Dykes had remarkable powers of concentration, an inquiring mind, a love of attempting to overcome difficulties in the cultivation of his plants, and facility in expressing himself in writing; and all of these he brought to the service of his favourite plant. While at Charterhouse he collected and grew all the species of *Iris* he could procure, and studied them minutely from both the cultural and the botanical sides. The mantle of Sir Michael Foster fell upon him, and one might almost say that Dykes had a double measure of the spirit that imbued that great iris lover. He was not content to follow authority, and took the utmost pains to investigate every small point that cropped up. He had correspondents wherever irises grew wild, and made himself acquainted with more than one foreign language in order to put himself in direct touch with first-hand information gathered by those

familiar with the plants in their native homes. He went to their native homes himself so far as he could in his vacations, and he made a fuller use of the garden in investigating relationships between diverse forms than probably any one before him, not only in this genus, but also in any other. His enthusiasm for the genus infected many another, and his many writings in gardening papers helped to spread the knowledge he had gained far and wide. In 1913 he published his great monograph on the genus, and it at once took its place among the best monographs upon a single genus which had appeared anywhere in the world; and in addition to this he wrote two other smaller books on the Iris family, which have gained wide appreciation. More recently, two other genera have competed in his affections with the Iris, and in the garden at Sutton Green, which he had recently acquired, he had collected very many species of tulip and of crocus, and he intended to study the tulip as he had the iris.

His last book was a translation of "La Taille Lorette," which will help to make Lorette's methods of pruning more familiar to English readers.

Dykes showed how invaluable an aid the garden may be in elucidating problems in relationship. He enriched the genus he made his own by raising many fine varieties, and he was doing the same with tulips.

The Veitch memorial medal and the Victoria medal in horticulture were both conferred upon him, largely on account of his work upon irises, the latter only a few days before his death.

We tender to his wife, whose interest and skilful pencil so greatly helped him, our deepest sympathy.

SIR ATHELSTANE BAINES.

WE regret to record the death of Sir Jervoise Athelstane Baines, C.S.I., the distinguished authority on Indian ethnography, which took place at Kidlington, Oxford, on November 26. Sir Athelstane Baines was in his seventy-ninth year, having been born on October 17, 1847. He was the son of the Rev. Edward Baines, and was educated at Rugby and Trinity College, Cambridge. He joined the Indian Civil Service in the Bombay Presidency in 1870, when the first attempt to enumerate the Indian population, which extended from 1867 to 1872, was in progress. In the one-day enumeration of 1881, Baines was deputy superintendent of the census in the Bombay Presidency. The value of his work in this capacity led to his appointment as superintendent for the whole country in the next decennial census of 1891. The task of organisation occupied him for three years. This and his general survey of the results summarising the various State and Provincial reports, which was at once widely recognised as the work of a brilliant ethnographer and statistician, laid the foundations for much of the work of his able successors, Sir Herbert Risley, Sir Edward Gait, and Mr. Marten. Indeed to his inspiration, directly or indirectly, can be traced much of the admirable ethnographical work which has been done by members of the Civil Service. As a result of his census work, Baines was appointed to prepare the Decennial Report on Moral and Material Progress to 1891, and in 1894-5 to

be secretary of Lord Brassey's Opium Commission. He was awarded the C.S.I. and retired in 1895.

On settling in England, Baines continued his ethnographical work, which included studies from various aspects of the three decennial Indian enumerations which have followed his retirement. He was a valued contributor to the proceedings of the Royal Statistical Society, of which he was president in 1909-1910. He also took part in public administration, being elected an alderman of the County of London and a member of the Oxfordshire County Council for 1917-1922. He was knighted in 1905.

DR. HAROLD W. NICHOLS.

DR. HAROLD WILLIAM NICHOLS, a radio research engineer of Bell Telephone Laboratories, died on November 14 at his home in Maplewood, New Jersey. Dr. Nichols was born in Iowa on February 23, 1886. He received his education at Armour Institute of Technology, Chicago, and at the University of Chicago. In July 1914, he joined Bell Telephone Laboratories in New York City. He rapidly achieved distinction in the radio research activities of that organisation, and during the War, he was in charge of its radio work. During recent years he has been identified prominently with the investigations of ship-to-shore radio telephone service and of short waves in radio communication. He was recognised as an authority on "fading"; his papers on this phase of radio are distinct contributions to the art. He took a leading part in the transatlantic radio telephone tests in 1923, and for a lecture on this subject received the Fahie Premium from the Institution of Electrical Engineers. He had twenty inventions pertaining to the radio art to his credit and nine applications are now pending.

Dr. Nichols was a member of the American Institute of Electrical Engineers; the American Mathematical Society; the American Physical Society; the Institute of Radio Engineers; and the Sigma Xi and Eta Kappa Nu fraternities. His associates in the Bell Telephone Laboratories regard his death as a distinct loss to the profession as well as a great personal loss to themselves. He was a man of pleasing personality; an efficient and untiring worker, noted for his judgment and insight into all phases of the art of radio.

WE regret to announce the following deaths:

Dr. Johan August Brinell, Bessemer medallist in 1907 of the Iron and Steel Institute, whose name is associated with the hardness testing of materials, on November 17, aged seventy-six years.

Prof. Joseph Brough, formerly professor of mental and moral science at the University College of Wales, Aberystwyth, and the author of "The Study of Mental Science," on December 7, aged seventy-three years.

Dr. Edmund Knecht, associate professor of technological chemistry in the University of Manchester, editor of the *Journal of Dyers and Colourists* and author of numerous works on bleaching, dyeing and other aspects of textile manufacture, on December 8, aged sixty-four years.

Current Topics and Events.

THE National Academy of Sciences and the National Research Council of the United States announce the forthcoming publication of the International Critical Tables. The first volume is to appear early in 1926 and is to be followed by four other volumes, comprising altogether about 2500 pages. The tables have been edited by Dr. Washburn, with Drs. Dorsey, West, Bichowsky, and Klemenc as assistant editors, who have had the co-operation of some three hundred experts in different parts of the world, but mainly drawn from the United States. According to the instructions to these experts, the tables are to differ in an important respect from many of the existing tables of physical and chemical constants. Instead of recording all or most of the determinations of a given constant which have been made, the co-operating experts were requested to give the most probable value of the constant after a critical consideration of all the determinations available. If this has been generally done with good judgment, the tables will be of great value to science. In a leaflet issued by the editors, the contents of the first volume, and the projected contents of the remaining volumes, are given. It is evident that very special attention is given to the needs of the technologist. The arrangement of the first volume is curious: an article on crystal structure is followed by articles on "dispersoidology, sweetening agents, odoriferous materials," and then by one on radioactivity. The published price of the set of five volumes is 60 dollars, but up to the appearance of the first volume early in 1926, members of scientific and technical societies, government departments, educational institutions, public libraries, etc., can subscribe at 35 dollars. The editorial expense of the tables, about 170,000 dollars, has been contributed by American industrial firms and benevolent foundations.

CORNELL UNIVERSITY, New York, has received an anonymous gift of 250,000 dollars, the income of which is to be used for the benefit and advancement of teaching and research in chemistry and allied fields. The gift is to enable the University to carry out a plan formulated by Prof. L. M. Dennis, Head of the Department of Chemistry, whereby prominent men of science will be invited to Cornell, each for one or two semesters, to present recent advances, and the methods and results of their own investigations. A private research laboratory will be placed at the disposal of the non-resident lecturer, who will thus be enabled to instruct a limited number of properly qualified students in his special field. The lecturers will be chosen so that different branches of chemistry or of allied sciences will be presented from term to term. The first incumbent of the lectureship in chemistry will be Prof. Ernst Cohen, professor of physical and inorganic chemistry in the van 't Hoff Laboratory at the University of Utrecht, Holland, who will be at Cornell during the second semester from February 1 until June 1, 1926. Prof. Cohen is the author of many books and pamphlets, comprising lectures and texts in the fields of inorganic and

physical chemistry, and biographical studies of various distinguished chemists, including his famous predecessor, J. H. van 't Hoff. The original investigations of Prof. Cohen and his co-workers cover a wide range of topics in thermodynamics, thermochemistry, electrochemistry and piezochemistry. Prof. Cohen's researches upon metastable and allotropic forms of the elements have attracted particularly wide attention.

PROF. S. PARKER SMITH, of Glasgow, read an interesting paper to the Institution of Electrical Engineers on December 3 on an "all-electric house." The house he described was the ten-roomed house in which he lives. The total annual cost for heating and cooking, hot water, lighting and power last year amounted to only 43l. 8s. although neither coal nor gas was used. Seeing that about 16,600 electric units were used the average cost per unit works out to about $\frac{1}{4}$ ths of a penny. In Glasgow arrangements can be made for heating water continuously between the hours of 11 P.M. and 8 A.M. at a price of $\frac{1}{4}$ ths of a penny per unit. In order to get good thermal storage it is necessary to design a well-lagged tank. Cork lining was found well suited for this purpose, the fall in temperature during the daytime being less than 1° F. per hour. The hot-water tank installed had a cubical capacity of 87 gallons, the average consumption per person for all purposes being about 15 gallons per day. The tank is fitted with a thermometer marked "high," "medium," and "low" to indicate in which position the switch has to be placed in the evening. In summer, it is sometimes only necessary to switch it on to the "low" position. This method of heating water economically is well known in districts which have a hydro-electric supply, and it is interesting to notice that it is making progress even when steam turbines are used. The Corporation of Greenock is offering energy for heating hot water during the night time at a farthing per unit. The scheme for ventilation adopted by the author was to draw fresh air into the rooms through air bricks behind the electric fires in the recesses, and to get rid of the vitiated air by means of a wooden grid let into the frieze and communicating with the flue in the external chimney. In all houses in or near towns, work is caused by the dirty or dusty air which surrounds them. It would therefore be better to use a small electric fan and a suitable filter to clean the air. The author points out that the absence of coal fires in a house may make it possible to dispense with one domestic servant, and so not only more than repay the total cost of the electric energy, but also lighten the domestic labour problem.

THE first ordinary meeting of the Electroplaters' and Depositors' Technical Society was held at the Northampton Polytechnic Institute on December 9, when Mr. S. Field read a paper on electrodeposition. He pointed out that there is a great need of organisation and co-operation by those engaged in the science and art of electrodeposition. The history of the art goes back for a hundred years, and the greatest

credit belongs to Faraday for his discovery of the laws of electrolysis. The great progress that has been made of recent years is due to the greater attention that has been given to scientific principles. The systematic research that has been made for addition agents has greatly improved the deposition of tin, lead, iron, cobalt, cadmium and chromium. The practical applications also have increased. A striking application is the copper matrices used for moulding gramophone records. Another recent application is the deposition of iron and nickel so as to repair the worn parts of machinery. When the metal deposited has to withstand mechanical wear, further investigation is needed. There are still too many unsolved problems in the practical processes, some of which would doubtless yield to organised research. The work should be undertaken by men who can devote their whole time to the problems. The position of the electroplating industry is unsatisfactory. There is neither standardisation of nomenclature nor of method. It is hoped to replace the many so-called formulæ for plating solutions by a few comparatively simple scientific formulæ. By organisation, research, standardisation and discussion it is hoped to advance the interests of the whole industry. Prof. F. G. Donnan, president of the Faraday Society, presided at the meeting and welcomed the formation of the Society. It was announced that permission to use rooms in the Northampton Polytechnic for meetings had been obtained.

A GROUP of activities of the Soviet Republics, referred to in a recent issue of the *Bulletin of the U.S.S.R. Society of Cultural Relations with Foreign Countries*, which is of special interest to anthropologists, is connected with the more primitive peoples of what was formerly the Russian Empire. An attempt is to be made to settle the nomads of Kazakistan Republic (Kirghiz Steppes) by the establishment of cultural and educational points which will serve as bases of settlement. The nomad Karagasses of S.W. Irkutsk Province, the remnants of the ancient Samoyed tribes who once inhabited the Upper Yenisei, and of whom not more than 500 are left, are to be protected and their culture adapted to modern conditions. Already, by being brought into the co-operative movement, they have been placed in a position to dispose of the products of their hunting expeditions to greater advantage. A Red Cross expedition has been sent out to study their conditions, social, economic, and sanitary, and will pay special attention to the possibilities of making available medical service. Further, a number of cultural bases are to be established among the Samoyeds, Ostyaks, Voguls, Tunguses, and other peoples of the north, which will provide education, medical and veterinary services, and shops for the supply of primary necessities. A special expedition has been sent to the basins of the Lena, Yenisei, and Obi, for the purpose of studying the life of, and conditions among, other small peoples of these areas. A report of the results of these activities will be awaited with interest. It is well known that conditions among these tribes and peoples have for long been bad, and it may be hoped that the material organisation of the

Soviets, of which the reports are not encouraging, may be equal to carrying out these measures of amelioration. On the scientific side, to be of any wide utility, much greater expedition in the publication of results than has been shown hitherto is urgently needed.

EARLY skating this winter in Great Britain coupled with the keen November frost and unusually early snow-falls, as well as the strong northerly gales, have given an impression that no such weather has occurred in November for many years, and some would take us back to 1890, when the great frost of 1890-91 commenced on November 25 and lasted until January 22. The Greenwich Observatory records published in the Registrar-General's returns enable a full survey of the daily temperatures for November. The mean for the whole month was $40^{\circ} \cdot 7$ F, which is $3^{\circ} \cdot 3$ below the normal for the thirty-five years 1881-1915. The mean of the maximum or day temperatures was $46^{\circ} \cdot 0$ and the mean of the minimum or night readings was $35^{\circ} \cdot 3$. In November 1923 the mean temperature at Greenwich was about 2° colder than this year. The maximum or day temperature was below 40° on 10 days, this year only on 5 days, and the minimum or night temperature fell to 32° or below on 12 nights in 1923 and only on 10 nights this year. The absolute minimum shade temperature in November 1923 was $22^{\circ} \cdot 7$, this year $24^{\circ} \cdot 9$. The mean temperature for November was also lower than this year in 1921, 1919, 1915, and 1910, but these are the only years since 1880. Snaps of cold weather still seem persistent, on December 4 the thermometer at Greenwich was below the freezing-point throughout the twenty-four hours, and on December 5 the minimum temperature was $21^{\circ} \cdot 4$, which is the lowest in December since 1920. An increase is shown in the deaths from influenza, the deaths in London being 22 in the week ending December 5, and in the hundred and five great towns of England and Wales the deaths numbered 100.

PRELIMINARY announcements have now been issued of the Kansas City meeting of the American Association for the Advancement of Science, to be held on December 29-January 2, under the presidency of Prof. M. I. Pupin, of Columbia University, New York. This will be the eighty-second meeting of the Association, but the first occasion on which it has visited Kansas City. General sessions for the whole gathering include the address of the retiring president, Dr. J. McKeen Cattell, on "Some Psychological Experiments"; the fourth annual Sigma Xi Lecture, by President F. D. Farrell, of the Kansas State Agricultural College, on "A Desert becomes a Garden"; an address by Prof. Dayton C. Miller, of the Case School of Applied Science, on "The Michelson-Morley Ether-Drift Experiment, its History and Significance"; the third annual Josiah Willard Gibbs Lecture of the American Mathematical Society, by Prof. James Pierpont, of Yale University, on "Some Modern Views of Space"; discussions on the rôle of science in education and on the relations of engineering to the fundamental sciences; and a lecture by Dr. F. R. Moulton, of the University of Chicago, on "The Origin and Evolution of Worlds." Popular citizens' lectures are also being arranged. The third annual

American Association Prize of 1000 dollars is to be awarded for "some noteworthy contribution to scientific advancement presented at the meeting" Last year this prize was divided between two scientific workers, but this will not be done in future. A publicity office for the release of news to the Press is being organised in association with Science Service, and a comprehensive exhibition of apparatus and books has been arranged.

THE library of the Chemical Society will be closed for the Christmas Holidays at 1 P.M. on Wednesday, December 23, and will reopen at 10 A.M. on Tuesday, December 29.

LIEUT.-GENERAL SIR WILLIAM FURSE, K.C.B., has been appointed Director of the Imperial Institute, in succession to Sir Richard Redmayne, who has been acting as Director during the period of reorganisation and amalgamation with the Imperial Mineral Resources Bureau. Sir Richard now becomes chairman of the Advisory Council of Minerals of the Institute. The appointment of Sir William Furse as Director is in accord with the recommendation of the committee of inquiry into the Imperial Institute, presided over by Mr. W. Ormsby-Gore, that the director of the Institute should be an administrator officer rather than a scientific or technical expert.

By virtue of the Importation of Plumage (No. 1) Order, 1925, the names of the Common Cormorant and the Common Shag have been added to the Schedule to the Importation of Plumage (Prohibition) Act, 1921, which contains the names of certain birds the plumage of which may be imported without licence. The Board of Trade accordingly desires it to be known that as from December 10 it will be possible to import the plumage of the above-mentioned birds without Board of Trade license.

THE following officers and new members of council of the Royal Physical Society of Edinburgh have been elected for the session 1925-26: *President*: Dr. James Ritchie; *Vice-Presidents*: Dr. Marion I. Newbigin, Prof. J. A. Thomson, Mr. Wm. Williamson; *Secretary*: Mr. H. Maxwell Vickers; *Assistant Secretary*: Prof. J. Russell Greig; *Treasurer*: Mr. Thos. V. Campbell; *Librarian*: Mr. J. Kirke Nash; *New Members of Council*: Mr. T. Cuthbert Day, Prof. T. Hudson Beare, Mr. P. F. Kendall, Prof. Donald C. Matheson, Rev. J. M. McWilliam.

PROF. A. P. KNIGHT, chairman of the Biological Board of Canada, writes that since his letter on "The Losses in Trout Fry after Distribution" appeared in NATURE of October 17, p. 573, he has had the report on the distribution and losses of trout fry for the past summer (1925). He states that 4000 were distributed in a brook on Prince Edward Island, and at the end of three months, only 27 per cent. of these were alive. The seining showed 300, more or less adult trout present in the stream, 80 fundulus, 31 salmon parr, and 15,000 two-spine stickleback. The presence of these fish natural to the stream, and the lack of adequate supply of natural food, probably accounts fully for the heavy loss of 73 per cent. of the total number distributed.

THE Norman Lockyer Observatory, Sidmouth, is offering a research studentship in astrophysics of the value of 150*l.* per annum for one or two years to a student with a knowledge of spectroscopy. The astronomical and laboratory instruments and material of the Observatory will be at the disposal of such a student for the purposes of practical work; while the large number of negatives of stellar spectra and other observational data which is available for study, together with the extensive library, will provide valuable material for more theoretical research work. The opportunity thus offered should be of great value to a post-graduate student who wishes to apply his knowledge to the study of astrophysical problems and to undertake research work in this subject. Further particulars can be obtained from Capt. W. N. McClean, 1 Onslow Gardens, S.W. 7.

A CHADWICK lecture on "encephalitis lethargica (sleepy sickness) in England" was delivered by Dr. Salusbury MacNalty on December 9. The lecturer said that this disease made its appearance in England in the spring of 1918 and has since become increasingly prevalent, no less than 5040 cases, with 1419 deaths, occurring in England and Wales last year. For practical purposes the disease is a new phenomenon, though certain epidemics in the past may have been examples of it. It is probably caused by a minute filter-passing micro-organism which causes an inflammatory process in the brain, to which the chief clinical features are due. The question of the evolution of the organism was raised, and the possibility was suggested that the central nervous system of man to-day is more vulnerable than in former centuries, owing to the fatigue and strain of modern life.

At the Court of Governors of the London Hospital on December 9, the Chairman of the Hospital announced that an anonymous donor had given the large sum of 50,000*l.* for the purposes of medical research in that institution. It is not yet known how the money will be spent. The material for investigation of disease is superabundant at the London Hospital, and it is to be hoped that part at any rate of the money will be expended in individual or concerted effort to solve some of the disease mysteries on the spot where the necessary material exists. It would, in our opinion, be a mistake to fritter away the money, as is often done, in giving grants to a number of young men to produce amateurish work. It is to be hoped that the London Hospital will eventually be able to give a good account of work done and results achieved through assistance afforded by the recent gift.

IN our issue of December 5, p. 828, we printed an announcement from *Science* that the triennial prize for 1925, for the best original work contributing to scientific advancement in the technical applications of electricity offered by the Fondation George Montefiore of Liège, had been awarded to Dr. J. B. Whitehead, of Johns Hopkins University, Baltimore. We have since received information showing that this was one of four awards. The jury of award decided that no memoir submitted merited the single prize of

22,500 francs. The prize was divided and awarded to Mr. F. Creedy, electrical and mechanical engineer, London, for papers on "Some Developments in Multi-speed Cascade Induction Motors" and "Variable Speed Alternating Current Motors without Commutators" (6000 francs); Prof. J. B. Whitehead (4000 francs); and to Mr. Checholowsky, electrical engineer, Antwerp, for his "Study on Operating and Releasing Times of Telephone Relays" (4000 francs). An exceptional prize (2000 francs) for the description of "A New Form of Converter" was awarded to Mr. Raymond Wilmotte, London, in virtue of article 5 of the Foundation permitting the jury to allot a prize to a thesis showing a new idea capable of important developments in electrical engineering.

THE London County Council publishes each year an Annual Report and volumes of Accounts, Estimates, Statistics, etc. These publications, however, do not appeal to the great mass of Londoners, and the Council is therefore publishing a series of booklets on "The London County Council and what it Does for London," of which that entitled "Public Health" (Hodder and Stoughton, Ltd., price 6d. net) has

recently been received. It deals in three chapters with main drainage, disease prevention, and treatment of disease, respectively, and gives a popular summary of what the Council has done and is doing for these aspects of public health. The booklet is well produced and illustrated, including a map showing the drainage system of London, and is very readable.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Test assistant at the Aeroplane and Armament Experimental Establishment, R.A.F., Martlesham Heath, Suffolk—Secretary to the Air Ministry, Aadalstr House, Kingsway, W.C.2 (January 4). Technical assistant for the Aerial Photographic Department—Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (January 9). A principal officer of the University of London—Secretary to the Senate, University of London, South Kensington, S.W.7 (February 1). Several men possessing good scientific training and technical experience—Secretary, Chilian Nitrate Committee, Friars House, New Broad Street, E.C.2.

Our Astronomical Column.

DAYLIGHT FIREBALL.—Mr. W. F. Denning writes: "On November 25 at 4^h 5^m P.M., when the sun was shining, a fine meteor was seen by several persons from Cornwall and Devon. It was directed from the south-west and disappeared in the north sky at a somewhat low altitude. It left a train as it passed with moderate velocity across the heavens, and with an estimated duration of 3 seconds. The meteor was quite conspicuous and appeared like a brilliant silver ball descending at an angle of about 35° as seen from Brentor, near Tavistock. The observations are not sufficiently exact for accurate computations to be made of the real path. The height was, however, probably about 77 to 41 miles and the velocity about 34 miles per second, radiant near β Bootis or, farther back in the line of flight, at Corona (233° + 34°). The position of the meteor was over the sea W.N.W. from Fishguard to over Carmarthen in S. Wales. This meteor was the second object of the class observed in sunshine this year, the previous one being on June 4, 4^h 10^m P.M."

THE ERROR OF NEWCOMB'S POSITION OF THE EQUINOX.—All the leading fundamental observatories agree in finding a large correction (amounting to a second of arc) to the position of the equinox given by Newcomb. Prof. Eichelberger and others have concluded that this error is increasing, and that Newcomb's rate of precession is wrong. Mr. R. T. Cullen, in *Monthly Notices of the Roy. Ast. Soc.* (vol 85, No. 9), gives reasons against this conclusion. He shows that when allowance is made for two changes of practice at Greenwich, the errors of equinox cease to be progressive. These changes are, the application of variation of latitude and the introduction of the travelling wire micrometer. The annual part of the variation of latitude causes a systematic shift of the equinox as deduced from observations of the sun, and the use of the travelling wire micrometer has altered mean personality of the observers in the solar observations. Removing the effect of these corrections from the recent observations, the error of Newcomb's equinox since 1851 is found to exhibit no progressive change. The reality of the present error of 1" in the equinox is not denied, but it is concluded to arise not from a wrong

rate of precession, but from the omission from the early solar observations of certain corrections which are applied to the recent ones.

COMETS.—The comets of Van Biesbroeck and Peltier-Wilk are still readily observable with small instruments, the latter being the brighter. The orbits of both comets are now known within narrow limits, that of Van Biesbroeck has been improved by Messrs. G. Merton and A. C. D. Crommelin, using their observations of the morning of December 10. The following elements (referred to the equator) are near the truth, but need slight adjustment.

$$\begin{array}{rcl} T & 1925 \text{ Oct. 1 } 9848 \text{ U.T.} \\ \omega' & 94^\circ 2' 43.1'' \\ \Omega' & 340 \quad 3 \quad 53 \quad 2 \\ i' & 70 \quad 18 \quad 20 \quad 6 \end{array} \left. \vphantom{\begin{array}{l} T \\ \omega' \\ \Omega' \\ i' \end{array}} \right\} 1925 \text{ } 0$$

$$\log q \quad 0.185531$$

An ephemeris from these elements is not yet available, but that from the Möller-Stromgren orbit will suffice for finding the comet with a little sweeping.

EPHEMERIS FOR OH.

	R.A.	R.N. Decl.	log r.	log Δ .
Dec. 18.	12 ^h 6.3 ^m	25° 48'	0.2615	0.1647
26.	12 2 8	23 50	0.2772	0.1538
Jan 3	11 56 5	22 0	0.2929	0.1431
11	11 47.3	20 17	0.3085	0.1329

The comet is now high enough for observation soon after midnight.

M. A. Schaumasse has discussed in detail the several returns of Borrelly's Comet in recent Nos. of the *Journal des Observateurs*. In No. 10 (Vol 8) he gives the predicted orbit for the present apparition

$$\begin{array}{rcl} T & 1925 \text{ Oct. 8 } 193 \text{ U.T.} \\ \omega & 352^\circ 25' 25.42'' \\ \Omega & 77 \quad 2 \quad 7.10 \\ i & 30 \quad 30 \quad 40.29 \end{array} \left. \vphantom{\begin{array}{l} T \\ \omega \\ \Omega \\ i \end{array}} \right\} 1925 \text{ } 0$$

$$\log q \quad 0.1424289$$

Period 6.885463 years.

Recent observations give a correction of +0.60 day to T.

Research Items.

ORIGIN OF ENGLISH GOTHIC STYLE—An interesting suggestion, which is not without attractions for students of racial psychology, was put forward by Mr. H. E. Irving Taylor to explain the "perpendicular" style in English Gothic in a paper presented to the Society of Engineers on December 7. After showing how "curvilinear" tracery has gradually developed from the desire to obviate the objection to unsightly spaces of bare stone which often exist when the original single lancet windows are gathered together as a composite window within one frame, he pointed out that in England the curves of the typical gothic window of France quickly gave way to the "rectilinear" or "perpendicular" framework. The chief explanation of this deviation from the natural development was undoubtedly a suddenly awakened predilection in England for Bible history told pictorially through stained glass. Pictures demand a straight rather than a curved framework, while a long or narrow-paned window best suited the human figure, and as windows increased in size owing to the diminished light given by stained glass, straight rather than curved lines were required to give strength.

THE RITE OF VIGIL OF THE OSAGE TRIBE—The thirty-ninth annual report of the Bureau of American Ethnology embodies an account by Francis La Flesche of one of the most important rituals of the Osage tribe. The rite of vigil is one of the "seven ceremonial divisions" of the tribal war rites that partake of the seven degrees. These religious rites were formulated during a long period of time in which, according to tribal tradition, the people were established, after a long period of military control, in a civil form of government under hereditary chiefs whose duties included keeping peace and order within the tribe. Two versions of the rite are here given, one belonging to the Puma gens and the other to the Peace gens. A number of songs are interspersed, of which translations are given as well as the music as recorded by Miss Alice Fletcher. The long and impressive ritual leads up to a climax in which an official friend of the initiate foretells the success or the reverse of the tribe from the manner in which a sacred bird lies on the ground as it falls from his hands. This supplicatory rite was employed on various occasions: first collectively by the whole tribe, when all the people cried to Wa-kon'-da, the great creative power, at dawn, noonday, and sunset; second, when the tribe determined on war, a man was chosen to perform the rite for the people as a part of the preparation; third, when a man lost a wife or near relation; fourth, when a man was being initiated into the mysteries of "weaving of the portable shrine," one of the seven degrees of the tribal war rites; and fifth, by the woman appointed to weave the shrine for him. This rite she had to continue all the time she was engaged in weaving, usually four days. On the other hand, the rite when employed in connexion with the death of a relative might last as long as two years.

THE BIOLOGY OF THE COMMON ROCK BARNACLE—Sven Runnström contributes (*Bergens Mus. Aarbok*, 1924-25), an account of the biology and development of the common rock barnacle of the sea shore, *Balanus balanoides*, based on observations made at the biological station of the Bergen Museum. The eggs are usually fertilised about the end of October and develop in the mantle chamber of the parent from which they swarm out as nauplius larvæ in the first half of March, moulting in a few hours to give rise to the second nauplius stage. How many further moults occur during the free swimming period—

which lasts about a month before the cypris stage settles down—was not ascertained. Early in April 1923 the author saw a large swarm of cypris larvæ and suggests that they had just issued from the parental mantle cavities—an exceptional condition. The development of the plates is carefully traced up to the condition in the adult, and a general survey of the formation of the plates in the Balanomorphs is given. The growth of the young Balanus is followed. A week after fixation and metamorphosis, the young Balanus is 1 to 2 mm. in diameter, by the end of June, 3 mm. in the middle of October, 4.5 mm., by the end of November, about 6 mm., and in March, *i.e.* at the end of the first year, 9 mm. in diameter. During the second year, greater growth in height occurs and little extension of the diameter. The ovary and testis of the hermaphrodite individuals are ripe in examples about a year and a half after metamorphosis, *i.e.* in October, and after the larvæ have escaped in the following March the majority of the parents die at the age of two years, but a few may live to the following autumn, *i.e.* to an age of three years, and produce another batch of eggs and young.

THE MOSQUITOES OF EGYPT—Under the foregoing title, Mr. T. W. Kirkpatrick, senior entomologist to the Egyptian Ministry of Agriculture, has recently published an extensive bulletin on mosquitoes (pp. xii + 224 + 24 plates + 2 maps. Cairo: Government Publications Office, 1925. 30 P.T.). The volume is the outcome of a request by the Anti-Malaria Commission of Egypt that a survey of the mosquitoes of the country be undertaken by the Entomological Section of the Ministry of Agriculture. In June 1924 Mr. Kirkpatrick was detailed for the work and was only given one year for its completion. During this brief period he has managed to gather together a good deal of useful information, and has paved the way for future control measures. Egypt is a country containing but few species of mosquitoes—a fact which is probably due to its isolation by barren deserts. The list of indigenous kinds now includes twenty-two species, or fewer than are met with in Great Britain. The larvæ and pupæ of these various species are all known and described, and practically all the waters wherein they are found gave pH values on the side of alkalinity. No correlation was found by Mr. Kirkpatrick between the pH values of the waters (which nearly all lay between 7.5 and 9) and the species of mosquitoes found to breed there. The most mosquito-ridden parts of Egypt are the oases of the Western Desert. Next in order would come the Fayum, followed closely by the Canal Zone (excepting Ismailia) and the Wadi Tumilat. The work of the Suez Canal Co., between the years 1901 and 1903, has resulted in the eradication of mosquitoes and the consequent disappearance of malaria from Ismailia and its immediate environs. This locality was once infamous as a most prolific breeding-ground for these insects.

A DISEASE OF DOUGLAS FIR—The Douglas fir (*Pseudotsuga Douglasii* Carr) is now extensively cultivated in Great Britain, and was at one time regarded as a tree remarkably free from serious epidemic pests. Unfortunately, it is losing its good reputation in this respect. One of its most serious enemies is a fungus now known as *Phomopsis Pseudotsugæ* Wilson, a fungus which has had many other names, but of which a full description, with notes upon its cultivation and upon the synonymy, has recently been published by Dr. Malcolm Wilson, reader in mycology, University of Edinburgh, as Bulletin No. 6 of the Forestry Commission. The disease is most

dangerous to young plants, so that infection in the nursery particularly has to be guarded against. Cankers are fairly frequent not far above ground level, and there is considerable reason to assume entry of the organism through a wound. Mechanical damage when planting, or during forestry operations generally, is evidently a source of danger, and the removal of dead wood and pruning operations need to be carried out with care. Rare instances of the disease are also recorded by Dr. Wilson for Japanese larch, European larch, and *Abies grandis* Lindl.

AIR-COOLED STORAGE ROOMS FOR APPLES—Special Bulletin No. 146 of the Agricultural Experimental Station of Michigan State College, by Roy E. Marshall, is a description of the warehouses used for the storage of apples in Michigan. A detailed account is given of the principles involved in the air-cooled storages of apples. This method is extensively employed by growers and growers' organisations with less than about 25,000 bushels of fruit for storage, as the cost of cooling the rooms by mechanical refrigeration in such cases becomes excessive. The construction and insulation of the storage houses is discussed in detail. Especial attention has to be paid to ventilation, for upon this depends the cooling, the regulation of the humidity, and the removal of deleterious gases given off by the fruits. The method adopted is to take air in through several openings or air intakes built in the walls just above the ground level or near the floor of the structure, and provide outlets through ventilators which extend from the ceiling of the fruit room out through the roof of the building. Both inlet and outlet flues are equipped with tight doors which serve as dampers to permit either the entrance of, or to exclude, the outdoor air. When the outdoor air temperature is lower than that in the storage room or of the fruit, the air inlet doors and those of the outlet flues may be opened, permitting the warmer air of the storage room to pass out through the flues. All openings are tightly closed whenever outdoor temperature is higher than that inside the room. It is stated that the most satisfactory humidity conditions are obtained with earth or clay floors to the stores. A relative humidity of 85 per cent. is recommended. To increase the humidity the floors are wetted, and to decrease the humidity the room is ventilated with colder air.

SHOT-FIRING IN MINES.—Scientific research is very often in the nature of a gamble. The capable professional researcher is sometimes much more interested in some private research than he is in his routine work. This does not mean that he neglects his routine work. On the contrary, he may do it remarkably well, but he does not devote to it labour outside his official hours. The prizes obtainable by success in private research are of far greater value than those obtainable by successful research on lines laid down by a committee. It is therefore politic from every point of view that successful team research should be encouraged. Such a research is recorded in Paper No. 11 of the Safety in Mines Research Board (London: H.M. Stationery Office, 1925, 1s. net). This paper describes a valuable research on "Electrical Exploders for Shot-Firing in Coal Mines." The means generally employed for detonating an explosive are the electric detonator and the magneto-exploder. In this research not only the minimum currents required to ignite detonators and to ignite fire damp are investigated, but also novel means are suggested for generating currents which will lie between these limits. It is found, for example, that if a broad band of copper of suitable thickness be wrapped round the armature core of a high voltage magneto-exploder, before winding, the machine can be made inherently

safe. Machines constructed in this way have proved entirely satisfactory. The designs of existing machines are criticised, and improved designs are suggested. In particular the advantages of using a small rotating magnet of cobalt steel and a stationary armature winding are pointed out. The possible use of modern dry batteries for shot-firing is considered. A battery of eight dry cells weighing only a few ounces would have a life of about three months when used for low voltage fuse-head ignition. A new form of exploder consisting of a single winding and a single dry battery is described and has been found to be safe and satisfactory in everyday use with high voltage fuse-heads. The experimenters and the sub-committee have to be congratulated on the results of their labours.

OXIDES OF BARIUM.—An account of a new peroxide of barium by M. Carlton is contained in the *Journal of the Chemical Society* for October. It is prepared by the action of an excess of hydrogen peroxide on barium hydroxide solution cooled below 20° C. The product is an unstable cream-coloured powder, which has vigorous oxidising properties. The peroxide was analysed by heating in nitrogen, passing the oxygen liberated over weighed heated copper, and weighing the residue as barium dioxide. When carbon dioxide was used the residue consisted of barium carbonate. Wet analysis was carried out with acid potassium permanganate solution. The results of analysis indicated the formula BaO_3 .

LATENT HEAT OF OXYGEN-NITROGEN MIXTURES—Experiments on the latent heat of vaporisation of liquid oxygen-nitrogen mixtures are described in the *Proceedings of the American Academy of Arts and Sciences*, vol. 60, No. 4, October 1925, by L. I. Dana. A definition of the latent heat of vaporisation of mixtures is adopted which corresponds with the production of vapour of the same composition as the liquid. A special apparatus, with electrical heating, was used. The results are tabulated, and a curve is drawn showing the latent heats from pure nitrogen to pure oxygen, mixtures being intermediate between these limits. The latent heat of evaporation of liquid oxygen (1 atm.) was found to be 51.01 gm. cal. (15°), that of liquid nitrogen 47.74 gm. cal. There is a maximum on the curve at 51.23 gm. cal. corresponding with 80 per cent. oxygen in the mixture.

ELECTRO-DEPOSITION OF CHROMIUM—At the Royal Society soirée last May, much attention was attracted by an exhibit of chromium plated objects by the Metropolitan Vickers Company. We learn from a paragraph in "Science Notes" in the December issue of the *Forum* that the Westinghouse Company of America has now been exhibiting many applications of this metal. The electro-deposition of chromium is accompanied by great difficulties, and although it is a simple matter to obtain a deposit, yet the practical production of smooth and uniform deposits has only been achieved in a very few instances. The surface when produced under the best conditions is very bright and silvery, although with a bluish tinge. It is remarkable for its resistance to tarnishing agents even in very impure atmospheres. The Westinghouse Company is using a thin deposit of chromium on the reflectors for automobile headlights. Recent experiments described in a paper to Section B (Chemistry) of the British Association show that the resistance of chromium to attack by sea-water or by spray is very high, a fact which was not at first expected, as it is known that the metal is easily attacked by hydrochloric acid. It appears that most of the difficulties in the production of smooth chromium deposits can be overcome. The great hardness of the metal, in addition to its superior power of resisting corrosion, gives it advantages over nickel.

The Oudtshoorn Meeting of the South African Association for the Advancement of Science.

THE twenty-third annual meeting of the South African Association for the Advancement of Science was held at Oudtshoorn on July 6-11, 1925, under the presidency of the Right Hon General J. C. Smuts. The meeting was well attended, eighty papers were read, and there was a number of exhibits. Joint meetings of sections were held for Prof. C. G. S. de Villiers' demonstration of Rudolf Martin's anthropometrical instrumentarium and for Prof. H. B. Fantham's paper on "Some Factors in Eugenics, together with Notes on some South African Cases." After the conclusion of his presidential address, Gen. Smuts presented the South Africa Medal and grant to Dr. R. B. Young, professor of geology in the University of the Witwatersrand. A popular lecture on "Fossilised South Africans" was given by Prof. R. A. Dart, and a public lecture on "Thomas Henry Huxley, his Life and Work" (in honour of the centenary of Huxley's birth) was delivered by Dr. Annie Porter. There was a reception by the Mayor and Mayoress of Oudtshoorn and visits to various places of scientific interest in the neighbourhood.

The president of the Association, General J. C. Smuts, gave as his presidential address, "South Africa in Science" (see *NATURE*, August 15, p. 245). He pointed out the desirability of a South African, as opposed to a European, point of view in science. Using the Wegener hypothesis of continental drift and Darwin's hypothesis of a southern and not northern origin of the fauna and flora of Africa, the relations of South Africa with other southern land masses were traced, its affinities being rather with South America, India, and Australia than with the northern hemisphere. The peculiar Cape flora appears to be rather a survival of the great flora of a southern hemisphere than the remnants of one of northern origin. The geology of South Africa is paralleled, both now and in Mesozoic times, with that of South America. The same applies to zoology. In palæontology there is more need for comparative study. Meteorology and climatology were considered, and the need for an Antarctic meteorological station for South America, South Africa, and Australia was indicated. The address concluded with a plea for the encouragement and Government recognition of research.

The presidential address to Section A was delivered by Mr. R. J. van Reenen on "Development of Irrigation in the Union of South Africa." The development of various phases of irrigation, irrigation legislation, and the institution of irrigation districts were considered. The rôle of the State in relation to irrigated land settlement was discussed, and it was urged that the State should settle irrigable land and privately owned land in excess of the owner's ability to cultivate. State loans, the growth of capital invested in irrigation, and the need for providing settlers were mentioned. Further necessary developments were noted, such as improved marketing facilities, encouragement of co-operation, and provision of factories for utilising raw products. The need of systematised water storage and its value to the stock farmer was emphasised, and a plea for more economic use of water generally was advanced.

"Soil Formation and Classification" was the subject of Dr. B. de C. Marchand's presidential address to Section B. The origin, properties, composition, and distribution of soils were discussed. The rôle of hydrolysis in soil formation was indicated. The degree of reaction, fate of the products, admixture and influence of organic matter, residue of plant growth, all determine the nature of soil. Climate as the deter-

minant of the rate and nature of mineral decomposition, and the transference of substances from one layer to another, were discussed, and also the effect of arid and high rainfall conditions. Climatic soil types in the Transvaal and the influence of climate and rainfall there on soil formation, where the soils are largely endodynamomorphic, were fully treated. The general tendency is to the formation of lateritic types of soil. One important European soil-forming factor, earthworms, is absent from the Transvaal. The fundamental classification of soils of the country is an essential preliminary to a systematic agricultural survey.

The president of Section C, Mr. E. Parish, dealt with "Problems in Agriculture in South Africa," more from the point of view of scientific agriculture than agricultural science. The adoption of mixed farming was advocated as of primary importance, the present system of crop production being compared with what occurred in the United States when land was plentiful and soil depletion and spoliation ensued. Conservation in South Africa is essential. Farming can be intensified by increasing production per unit of labour and by the supply of agricultural machinery at lower rates. Farming under irrigation was considered and the need of suitable crops in irrigated areas indicated. Technical education is a necessity for farmers, and specialised technical training is required for different sections of farming. Provision for agricultural research, freed from routine and administrative work, was urged.

Prof. J. E. Duerden, president of Section D, took as his subject, "Genetics and Eugenics in South Africa: Heredity and Environment." The special problems of South Africa in relation to heredity and environment in connexion with human beings and domestic stock were outlined. Hereditary constitution and environmental influences are both important, and change in one affects the other. In agricultural stock, blood improvement is going on, but better conditions of maintenance are necessary. Variations in parts of ostrich plumes and merino wool show the diversity resulting from differences in nutrition, though from the same germ plasm. The limitations of germ plasm and environment were discussed. The interactions of the white race and the Bantu were considered; "indigent" whites were regarded as products of unfavourable environment and the presence of the primitive native. The rôle of the white races in South Africa was considered to be that of a benevolent aristocracy of ability. The extreme importance of genetics and eugenics to South Africa was emphasised.

"The Present Position of Anthropology in South Africa" was the presidential address to Section E, delivered by Prof. R. A. Dart, who pointed out that in South Africa every one is bound to have anthropological interests. A brief historical résumé of the discoveries at Boskop, Oldaway, Broken Hill, Zitsikama, and Taungs showed that the negroid is not the primitive South African stock. The various fields of anthropological study in South Africa were noted. Philology needs attention in view of numerous native tongues, official bilingualism, Arab, Malay, and Asiatic populations. Ethnology needs much study, as do also native music and arts. Physical anthropology deserves attention in order to obtain an understanding of the laws that govern racial divergence. The address concluded with an appeal for fostering and retaining an African and not a European outlook in regard to African problems.

Prof. H. A. Reyburn chose "Psychology and

Grammar" as the subject of his presidential address to Section F. He discussed language from the psychological point of view, showing that in grammar, confusion arises between the mechanism of the language and the function that mechanism fulfils. Accidence and syntax, considered psychologically, break down these distinctions. The definitions of some of the parts of speech were discussed and their unsatisfactory nature demonstrated. The conception of different grammatical categories, with reference more especially to the work of Jespersen, was critically examined. Language as applied logic was discounted and a plea made for the psychological study of language. A suggested scheme for the re-study and re-writing of grammar was outlined.

It is only possible to note briefly the interesting papers and exhibits given before the various sections.

In Section A, Prof. G. H. Stanley gave a paper on a method of determining the relative resistance of paving materials to wear by subjecting flat pieces of equal area of the various materials to the grinding action of horizontally rotating steel discs. Mr. R. J. van Reenen gave an account of the apparent regularity of wet and dry years in South-West Africa, a series of dry years occurring at thirty-five years' intervals, coinciding with the Brückner cycle. Dr. J. Schonken discussed effective rainfall. A paper by Mr. A. G. Hoyer dealt with star streaming and the structure of the universe.

In Section B, Dr. B. de C. Marchand and Mr. C. R. van der Merwe gave an account of the fractions separated by mechanical analysis from some Transvaal soils, the differences between the clays from the red and black soils being determined. Mr. W. Torrance described a prehnite vein in the dolerite at Grootfontein, Middelburg, C.P., due to percolating waters depositing their load in a fissure in the dolerite. Mr. G. Ingham contributed a paper on the relative availability of phosphatic fertilisers on acid and non-acid soils, this being generally low on acid soils and high on non-acid ones. A note on the banded ingredients of South African coal was given by Prof. J. A. Wilkinson. Mr. B. J. Smit and Dr. T. J. Naude gave a paper on fumigation with liquid hydrocyanic acid, and Mr. E. George presented papers on phenol 5-methyl-isatein, phenol phthalamein, phenol umbellein, and resorcinol umbellein, and on the preparation of umbelliferone.

In Section C, Dr. E. M. Robinson described the bacteria of the *Clostridium botulinum* C type and their distribution, with notes on his work on lamsiekte. Mr. J. F. V. Phillips gave an account of the ecology of *Platylophus trisohatus* as seen in the Knysna forest. Mr. L. Verwoerd described some South African Hymenogastraceæ. Prof. P. A. van der Bijl described some new South African fungi and also gave a preliminary report on the fungi of the Knysna district in his herbarium. A paper on the retardation of the ripening processes of pears at high temperatures was contributed by Dr. F. J. de Villiers, who finds that 30° C. appears to be the optimum for ripening. Mr. J. F. V. Phillips contributed a paper on plant phytometers and the use of indigenous tree seedlings in this capacity in practical forestry. Mr. A. Stead presented a note on the fructifying action of heat on the pineapple, so many as twenty small fruits have been obtained from one plant. Dr. F. J. de Villiers discussed the differential freezing of pear tissues, and Miss E. Stephens demonstrated the plants obtained by her from cultures of dried mud.

In Section D, Prof. H. B. Fantham gave an account of some more parasitic Protozoa found by him in South Africa, including herpetomonads from new molluscan hosts and flagellates from various veld

rodents that transmit plague. The interesting ciliate, *Discomorpha*, has been obtained from the intestine of a horse. Prof. E. H. Cluver gave a paper on cardiac mortality in Johannesburg and at the Coast, showing from statistics that such mortality in Johannesburg, despite its altitude, is less than at the Coast. Miss N. F. Paterson summarised her experiments on the effects of differences of hydrogen-ion concentrations on the development and longevity of certain mosquito larvæ. Prof. J. E. Duerden and Mr. V. Bosman gave an account of their biometric analysis of wool fibres, establishing the proportion of various sizes of fibres in a staple. Prof. E. Warren dealt with amitosis and fragmentation of nuclei in the development of the spider, *Palystes*, in which four types of chromosomes occur. Prof. C. G. S. de Villiers gave an account of recent researches on the breast-shoulder apparatus of certain Anura, both living and extinct. Prof. R. W. M. Mettam gave a note on the occurrence of a muscle of doubtful origin found by him in the foot of a horse. Mr. H. H. Curson notified the occurrence of *Trypanosoma vivax* in Bechuanaland, this being one of the three parasites of nagana. The histology of the lining of the stomach of the ostrich was described by Miss G. T. Brock. Prof. A. J. T. Janse described the anatomy of a gynandrous form of the butterfly, *Precis sophia*. Mr. J. F. V. Phillips gave an account of the natural history of the herd of Knysna elephant. The locust-fungus, *Empusa grylli*, and its effects on its host were described by Dr. S. H. Skaife, who finds that the epidemic among the locusts stops on the cessation of the rains. Dr. F. G. Cawston gave a note on the radulæ of some fresh water molluscs. Prof. C. G. S. de Villiers gave a demonstration of Rudolf Martin's improved instrumentarium for anthropometrical investigation. Prof. H. B. Fantham and Miss N. F. Paterson reported on their further work on the Protozoa of certain South African soils, in which the seasonal variation in the protozoal fauna of waterlogged soils, and those of waterlogged soils from mining areas were noted, as were various environmental effects. Prof. Janse gave a paper on the systematics of the Lepidoptera. Dr. Annie Porter reported that *Limnæa truncatula* serves as an additional host for *Fasciola hepatica* in South Africa.

A joint meeting of Sections C, D, E, and F was held for a paper by Prof. H. B. Fantham on "Some Factors in Eugenics, together with Notes on some South African Cases." Selective birth-rate and selective death-rate, differential birth-rate in different strata of society, and racial admixture were discussed, and notes on some cases of inheritance of certain well-marked physical and mental characteristics and of the results of racial admixture were given.

In Section E, Mr. C. van Riet Lowe gave an account of the kinds and distribution of stone implement workshops in the Orange-Free State. Mr. A. J. H. Goodwin discussed the Capsian affinities of the South African later Stone Age culture; he considers that the Smithfield and Pygmy industries in South Africa are culturally the same as the North African Capsian one. Prof. R. A. Dart described the round stone culture in South Africa. An exhibit of copies of numerous Bushman paintings from the Kei River was arranged by Brother Otto, and Prof. E. H. L. Schwarz exhibited tracings of Bushman paintings from the Clanwilliam District. Mr. J. Hewitt's paper dealt with stone implements from various sites in the Cape Province, representing different cultural developments. Prof. Dart gave a note on Makapansgat, where beds of fragments of fossilised bones, too small for identification, occur. Mr. G. D. Lang gave a further report on the Zitzikama material and described another skeletal find in an ancient Roorberg

mme-working Mrs. J. D. Laing contributed remarks on the temporo-mandibular region in the Boskop, Strandlooper, Bushman, and negro peoples. Anthropometric measurements of the skeleton of the Boskop race were given by Mr. H. S. Gear, and the brain of the Boskop race was discussed by Prof. Dart, who also exhibited casts of the Taungs skull and a Boskopoid skull obtained by Prof. M. R. Drennan from a subject in his dissecting-room at the University of Cape Town. Miss E. Dora Earthy gave a paper on the rôle of the father's sister among the Va-Lenge of Gazaland. Mrs. A. W. Hoernlé discussed the sib in Southern Bantu marriage ceremonies, showing the deep-seated nature of the relation of the sibs and their relation to lobola, which involves the contracting parties, the sibs, and the ancestral spirits. Mr. E. C. Randell described a supernumerary molar tooth in a Bantu. Mr. H. Q. F. Thompson described the custom of amputation of part of one of the fingers by the Zulu-Xosa groups of Bantu. Mr. G. D. Laing gave an initial report on somatometric investigations among the natives recruited for the Witwatersrand. Mr. C. Dawson described the Neanderthaloid foot of the Zuurberg Bushman. Father Huss and Brother Otto discussed the origin of Bushman paintings at the Kei River. Mr. I. Schapera gave a paper on stylistic affinities of Bushman art, stating the criteria for comparison of

Capsian, North African, and Bushman art. Mr. F. R. Paver traced Asiatic influence on early South-East African development from various records. Mr. S. Zuckerman gave a note on a superficial scraping of the floor of a rock shelter in the Cape Midlands.

In Section F, the normative character of ethics was discussed by Prof. G. H. T. Malan. Mr. C. Graham Botha gave a paper on the distribution of South African fauna in relation to place-names, indicating the former distribution of animals now extinct. He also described social customs in South Africa during the eighteenth century, such being influenced both by Holland and the East Indies. Prof. R. D. Nauta gave a paper on the Spanish Cid. Dr. F. G. Cawston gave notes on some removable causes of unemployment and crime. Mrs. C. G. Botha described some minor experiments in the unconscious. Dr. A. Barradas gave statistics of mortality in Lourenço Marques for the past seventy years. Mrs. Mabel Palmer traced the evolution of the organisation and technique of adult non-vocational education. Mr. C. S. Richards gave a critical paper on the Kammerer-Vissering Report and the position of the Reserve Bank, the proper function of which was outlined.

The next annual meeting of the Association will be held at Pretoria, under the presidency of Dr. E. T. Mellor, in July 1926. H. B. FANTHAM.

Transmission of Power.

AN interesting analysis of the problem of the transmission of power is contained in a paper read by Mr. G. Constantinesco before the North-East Coast Institution of Engineers and Shipbuilders on December 4. The author is well known in engineering circles as the inventor of the method of transmitting energy by "wave transmission," in which the liquid does not circulate. He formulates the following fundamental laws governing any transmission of power: (1) Energy can be transmitted from one point to another only at the expense of a definite loss. (2) There is a minimum loss in any given system or method of transmission which cannot be decreased by any conceivable improvement in the system. (3) The transport of energy is possible only by circulation or oscillation, and there is a minimum amount of matter necessary for such transport. Such minimum is also independent of present or future methods of transmission, and depends only on the amount of energy, distance of transport, and change of form of the energy.

There are three broad classes of systems of power transmission, namely, mechanical, fluid, and electric. The author takes a few random problems of power transmission and first shows that the efficiency curve for any electric system can be drawn irrespective of the particulars of the transmission considered. The curve appears as an invariant when the units of measure are taken as the minimum possible loss and the critical voltage for which this minimum loss occurs. He then gives a lengthy investigation of hydraulic transmission and shows that the whole curve of efficiency is also an invariant, and that once the maximum "peak" possible efficiency is known, the whole behaviour of the transmission can be predicted. There is a handicap to high efficiencies in fluid transmissions owing to the unavoidable loss in changing the energy abruptly from one form to another. Thus, if the energy is available at the shaft of a prime mover in the form of a rotating torque, the transformation of this into hydraulic energy is accompanied by a definite loss, which is independent of the means by which the transformation is made.

The peak efficiency of transformation depends only on fixed constants defining the fluid itself. The same conclusions are reached in the transmission of energy by use of gases.

The efficiency curves for electric, hydraulic, and gas transmissions show the same fundamental property, namely, they are invariables of very nearly the same shape.

Experimental data regarding mechanical systems are not complete, but Mr. Constantinesco thinks that the figures would not be very different from those relating to electric and hydraulic transmissions. Peak efficiencies of a very high order are found to-day only in mechanical transmissions. There is an absolute limit to the possible peak efficiency which the author is inclined to think has already been reached in some mechanical transmissions such as link motions, gear wheels, and the like. Efficiencies of the order of 95 per cent. are practical possibilities for almost any sound mechanical transmission of moderate power when carefully designed. Hydraulic and electric transmissions may be credited with 85 per cent. This small difference in peak efficiencies is sufficient to make a relatively important difference in average efficiencies. From the efficiency point of view alone, there appears to be no doubt that mechanical transmissions are superior to electric or fluid transmissions, and if the latter can replace in certain cases mechanical transmissions, it is only from the point of view of convenience.

With one single exception, in each field, electric, fluid, and mechanical, rotary power cannot be transmitted from one point to another except by periodic or intermittent impulses. The exception is when the power is transmitted through a material body rotating at uniform speed and transmitting a constant torque along its axis of rotation. A more general statement of this *postulatum* is: "Any transmission in which the output energy differs in shape from the input cannot be accomplished without the power being transformed at one stage or another into periodic impulses." The author considers that the relations which are the basis of electric current theory form the

fundamentals of a new science of applied mechanics. The application of these relations to long-distance transmissions by liquid columns and to acoustics has enabled him to duplicate practically every manifestation of electric transmissions, and led to the invention of the "wave transmission" method of transmitting energy and also to the synchronising of machine guns on aeroplanes so as to enable them to fire through the propeller.

Electric transmissions are at present in want of higher peak efficiencies in order to come up to the level of their mechanical equivalents. No doubt progress is still possible provided electrical engineers will not develop the habit of mechanical engineers of ignoring the fact that there is still plenty of work to do, both theoretical and practical, on old neglected avenues. Fluid transmissions have a fairly uphill task to overtake either electric or direct mechanical transmissions. Mechanical transmission at present seems to offer the most promising field for obtaining immediate and substantial results.

Mr Constantinesco's paper is long, and full of speculations which cannot fail to be of interest to engineers who are concerned with the many problems of power transmission.

Food and Fattening of Oysters.¹

THE material eaten by an oyster consists of minute organisms and other matter floating freely in the water, and present in the surface soil on which oysters occur. Mr R. E. Savage has studied qualitatively and quantitatively the contents of the stomachs of oysters in relation only to the organisms and material found floating near the bottom of the sea in two localities, namely, the Main Channels of the River Ore in Suffolk and the adjacent Butley Creek. These situations were chosen because there was reason to believe that oysters fattened much more readily in the Creek than in the Channels. Data were obtained by exhausting the alimentary canals of usually six oysters once a month and taking one ten-minute sample of plankton from each bed once a month for a period of 13 months. From his restricted material, the author has extracted highly interesting facts and results, but the value of the latter is diminished by the absence of continuous contributory—and not necessarily quantitative—observations on the beds. In any estuarine problem the influence of tide and time should not be ignored. The author found that the material ingested by the oysters in the localities examined consisted of 90 per cent. or more inanimate matter ("organic detritus"), and a searching volumetric and numerical analysis of the animate food is given. He also finds that the feeding period extended from July to October or November, with a short season of brisk feeding during August and September, and that in the remainder of the year little food was found. The suggestion adopted that the absence of feeding in winter may be due to the effect of low temperatures on the ciliary and muscular feeding mechanisms is well worth definite examination. There was a definite difference in the quality and quantity of the animate food in the situations chosen.

In analysing the results for these two regions, the author finds (1) that the total food consumed is approximately equal in volume, but that (2) the percentage volume (quantity) of animate food is four times as large in the Creek (where fattening occurs) as in the Channels (where fattening is less

satisfactory; the italics are ours), and that (3) the proportion of diatoms in the food of oysters from the Creek is greatly in excess of animals, while the proportion of animals in the food of Channel oysters is greater than that of diatoms. No proof is produced of better results in fattening in the Creek, where the food was mostly diatoms, and proof is unfortunately required since "fattening" is, in our present knowledge, highly capricious. The author concludes "that there is an apparent relation between consumption of diatoms and fattening," and "suggests that fattening is due to diatoms and growth to inanimate food."

The suggestion that fattening is due to diatoms (in this case mainly *Nitschiella*) is probably true for the particular locality studied, but on the author's data the difference in quantity of animate food might equally well account for a difference between "fattening" and "less satisfactory fattening." The reviewer holds the view that the problem of fattening will not be solved by a mere consideration of food. Fattening is chiefly a storing up of the surplus products of metabolism—mainly as glycogen—presumably for general purposes, but is also in part due to proliferation of the sex-organ. Hence the whole activities of the living animal, namely, growth, breeding, environmental conditions, as well as feeding, must be considered. A simple illustration will prove this: oysters which have recently grown a great deal of shell (and have been actively breeding) have mostly poor "fishes," i.e. are not fattened, whereas poorly grown dumpy or semi-dumpy oysters, taken in nearly equal proportions in the same hauls of the dredges as the well-grown ones, have large plump fishes, that is, are very well fattened, as the following figures,² which have been confirmed in larger numbers, will show.

Thirty-one oysters of average size 66 mm. x 67 mm. and average new growth 20 mm. had an average "fish" weight of 5.3 grams, whereas dumpy oysters ranging to a maximum size of 53 mm. x 68 mm. and with an average growth of 6 mm. had an average fish weight of 7.5 grams. Larger oysters 83 mm. x 81 mm. with average new growth 29 mm. had average fish weight 9.7 grams, but a typical large dumpy oyster 68 mm. x 75 mm. with 5 mm. new growth had a fish-weight of 13.5 grams.

J. H. O.

¹ Taken from Report on a Survey of the Oyster Beds in the Estuary of the Fal with Notes on the Biology of the Oyster, p. 91, January 1925. See also NATURE September 26, p. 486, where a review of the Summary published for the Falmouth and Truro Corporations was noticed.

Voltaire and Medicine.

IN the first part of a paper on "Voltaire and Medicine" read before the section of the History of Medicine of the Royal Society of Medicine on October 21, the president, Dr. J. D. Rolleston, quoted the words of the celebrated Berlin physiologist Prof. Emil Du Bois-Reymond, who in an address on Voltaire in his relation to natural science, attributed the neglect of this philosopher in the nineteenth century to the apparently paradoxical fact that we were all in a sense Voltairians without knowing it. "The ideals of tolerance, mental freedom, dignity and justice for which Voltaire had fought . . . had become a natural element of life like the air we breathe, which we only notice when we are deprived of it." Dr. Rolleston's paper dealt with Voltaire's relations to individual doctors and the medical profession as a whole, including some account of Voltaire's various illnesses. He contracted a severe attack of small-pox at the age of twenty-nine years, but apart from influenza and pneumonia he does not appear to have had any other

¹ Ministry of Agriculture and Fisheries. Fishery Investigations. Series 2, Vol. 8, No. 1, 1925. The Food of the Oyster. By R. E. Savage. Pp. 50+3 plates (London: H.M. Stationery Office, 1925) 8s net.

acute infectious disease. He was subject to chronic dyspepsia from an early age, and frequently suffered from catarrhal bronchitis, often associated with deafness and aphonia. He frequently complained of febrile attacks which may have been malarial in origin. His death at the age of eighty-four years was probably due to uræmia following cystitis secondary to enlargement of the prostate which was found on post-mortem examination.

Voltaire was brought into contact with medical men on numerous occasions, both professionally and socially. During his stay in London (1726-29) he appears to have been acquainted with several leading medical men of the time, especially Sir Hans Sloane, Mead and Freind, as well as with other medical fellows of the Royal Society, especially Arbuthnot and Pemberton. He was himself elected F.R.S. in 1743. Among the numerous doctors whom Voltaire consulted the best known are Silva, physician to Louis XIV.; Boerhaave, whose name frequently occurs in Voltaire's works, especially in connexion with chemistry; and Tronchin, whom he described as the greatest physician in Europe and the only one who understood Nature.

Voltaire's works, particularly his correspondence, the "Dictionnaire Philosophique," his tales, and to a less extent his historical works, miscellaneous essays and pamphlets, abound with references to the medical profession. Many allusions are to be found to the masters of medicine, such as Hippocrates, Rhazes, Servetus, Harvey and Sydenham, as well as to celebrated anatomists such as Vesalius, Ruysch, Bartholin and Vieussens, but the medical works with which Voltaire was most familiar was probably that of Astruc on the venereal disease. The passages in which he indulges his satirical humour at the expense of the profession are few and unimportant in comparison with those in which he expresses his admiration and gratitude, and apart from the tales are chiefly to be found in his correspondence, where they are probably not to be taken too seriously. On the other hand, Voltaire was scathing in his denunciation of quacks, and vented his ridicule on many superstitions and erroneous doctrines connected with normal and morbid processes, particularly spontaneous generation, which was upheld by Needham and combated by Spallanzani.

University and Educational Intelligence.

GLASGOW.—The University Court on Thursday, December 10, appointed to the chair of natural philosophy Dr. Edward Taylor Jones, professor of physics in the University College of North Wales, Bangor. In 1899 he succeeded Prof. Andrew Gray in the latter chair; and now succeeds him in Glasgow also. A distinguished pupil of Prof. Gray at Bangor, he graduated with the highest honours in the University of London. With the aid of an "1851 Exhibition" research scholarship, he proceeded to the University of Berlin, where he worked under Profs. Kundt, du Bois, Rubens, von Helmholtz, Planck, and Fuchs. His important memoir on "Electromagnetic Stress" procured him his doctorate. Returning to Bangor in 1896 he was appointed lecturer, and afterwards professor of physics. He has also held in succession the administrative posts of Dean and Chairman of the Faculty of Science, representative of the Senate on the Council, member of the University Court of the University of Wales, and Vice-Principal of the College. Prof. Taylor Jones has published some thirty papers on electrical subjects, in particular on electrical oscillations, coupled circuits, the singing electric arc, and the triode valve generator, all having

important bearings on wireless telegraphy and telephony. He is recognised as having placed the theory of the induction-coil on a sure basis, and his book on that subject is the standard treatise. He also co-operated with the Internal Combustion Engine Subcommittee of the Advisory Committee for Aeronautics. He will take up his duties in Glasgow at the beginning of next term. He is fifty-two years of age.

LIVERPOOL.—Miss Winifred E. Frost has been appointed to the Herdman Memorial Scholarship for 1925.

Dr. T. P. Hilditch has been appointed to the Campbell Brown chair of industrial chemistry. The appointment is in the first instance with special reference to research on oils, fats, and waxes. Prof. S. H. Gaiger, of the Veterinary College, Edinburgh, has been appointed to the William Prescott chair of the care of animals with special reference to the causation and prevention of disease.

In a lecture delivered on December 4, Prof. G. H. Henderson, of the University of Glasgow, advocated that chemists should endeavour to educate the public to the value of their profession to the community and its importance in national welfare. He would like to see a unified body controlling all chemists and speaking for the profession as a whole.

MANCHESTER.—Prof. A. H. Gibson has been elected Dean of the Faculty of Science. The following appointments have been made:—Dr. J. C. Smith to be assistant lecturer in chemistry; and Mr. J. C. Brierley to be assistant lecturer in engineering drawing (Faculty of Technology). Dr. E. N. Mottram has been awarded the Sir Clements Royd Memorial Scholarship in chemistry.

PROGRAMMES have now been issued of the annual meetings of the Science Masters' Association and of the Association of Women Science Teachers. The Science Masters' Association meets at King's College for Women, London, on January 5-7, under the presidency of the Right Rev. C. W. Barnes, Lord Bishop of Birmingham. The presidential address will be delivered on the first evening of the gathering, and the general programme includes lectures by Dr. T. Slater Price on "The Sensitivity of the Photographic Plate," and by Prof. Leonard Hill on "Sunshine, Open Air, and Health," and discussions on "Science and Citizenship," to be opened by Mr. W. D. Eggar and Mr. O. H. Latter, and on school science examinations, to be opened by Mr. D. J. Berridge, Mr. E. Nightingale and Mr. E. G. Laws. Invitations have been accepted for parties to visit the laboratories of the General Electric Company and also the National Physical Laboratory, while there will be the usual exhibition of apparatus and books by members of the Association and by publishers and instrument-makers. The annual general meeting of the Association of Women Science Teachers will be held on February 6 at St. Paul's Girls' School, London. The programme includes a demonstration by the Visual Education Society of educational films and an address by Miss Coward on the teaching of hygiene in schools. Miss Bond is to move a resolution "that in view of the fact that for the majority of pupils the General School Examination (School Certificate) terminates their study of Botany, it is desirable that the Syllabus in Botany be amended as follows: (1) The number of Families should be very much reduced, and the ability to use a Flora should take the place of most of this detailed knowledge. (2) The life histories of, at least, one Alga and a Fern should be included in the Syllabus. These should be simply treated so as to need only a small amount of microscopic work."

Early Science at Oxford.

December 21, 1683. Mr. Ballard was desir'd to try some experiments, in ye Holy daies, in order to the solution of the question: Whether cast-Iron will draw ye needle, as readily as that which is forg'd? Dr. Smith was pleased to shew us some observations, which he made in his voyage to Constantinople, año 1668; when among other things, ye Dr. observed a great number of Porcpisces, which almost covered a good part of ye Propontis, from ye Seraglio point, towards ye Islands, that lye over against the bay of Nicomedia; for which reason (as also because he never heard that any Dolphins are caught there by ye Greeks, the good fishermen; nor saw any sold in their Markets) He thinkes, that Solinus, cap 12, is to be understood of Porcpisces, not of Dolphins; although he says (speaking of ye Bosphorus, and Hellespont) hæc profunda *Delphinus* plurimos habent. As for that vast quantity of water, which runs into ye Mediterranean, he conjectures that a great part of it may run out again, by an under-current, at ye Strait's mouth.

Wee then examin'd ye effects of a distillation of brine, from salt of Tartar, which Mr. Ballard at ye request of ye Company had performed; The brine was made of a pint of common water, and $\frac{3}{4}$ of white salt, which, after sufficient heating, was distill'd from Salis Tart: $\frac{3}{4}$: we saw about $\frac{1}{2}$ lb. of ye distilled water; it was not in ye least brackish, but rather like an emulsion of sweet almonds.

1686. A Letter from Dr. Bagley to Mr. Musgrave was read: it gave an account of the dissection of ye *Hedghog*, male and female.

An account of a *horn* growing on the head of one Mary Davies of Soughal, of Wyrehall Hundred in Cheshire, aged 71. in 1668. The compasse of the horn at the root was 3 inches and more than half; the length of the horn layd out straight 5 inches and a half. An account of the Duke of Tuscany's *Diamond*, which weighs 138 carats.—An account given by Dr. Plot of *ale* made with *Walnut leaves* instead of Hops in Staffordshire: there being great scarcity of these, last Summer; he says 'twas pleasant and kept very well.

The Society resolved that *Aristarchus* be printed in Greek and Latin at ye charge of this Society; Dr. Plot having promised to provide paper, and Mr. Deeds to collate the MSS.

A resolution of a question of compound *Interest*, at one operation of Logarithms, likewise a solution of this problem viz. from the different weights of the same heavey body in different fluids.

December 23, 1684. Mr. Musgrave acquainted ye Society concerning ye colour of ye liquor conveyed by ye Lacteals. In this letter he endeavors to prove, that a great part of ye Chyle passes *pellucid* through ye Lacteals, (contrary to ye opinion of those, who thought it to be *always white* in those vessells); and that a pellucid Liquor *Refluus* does constantly fill some of them, when no flash of Chyle can be supposed to extend them. He then read Dr. Lister's answer to this Letter; The Dr. is willing to think that the *liquor Refluus* may be of ye nature of *Lympha* but he takes ye greatest part of what fills the Lacteals in sicklie and empty animals to be Pituita, and sometimes Bilis.

Mention was made of a proposall of Dr. Lister's, which was to try Kunckel's experiment [of coagulating milk, by adding spirit of wine to it,] both with a spirit, drawn from pure Nants-Brandy, and also with a spirit drawn from an eager wine: it being possible, as ye Doctor thinks, that ye experiment may succeed with ye one of them, and not with ye other.

Societies and Academies.

LONDON.

Faraday Society, November 16.—E. D. Campbell: A study of the correlation of the permanent magnetism and specific resistance of some pure iron-carbon alloys.—J. A. V. Butler: Co-ordination and co-valency. The formation of co-ordinated complexes cannot be due in general to the tendency of the central atom to attain the configuration of the next higher inert gas. The electrons contributed by co-ordinated groups form a distinct group round the central ion. A distinction is drawn between (a) *Co-valency*: the mutual sharing of electrons by two atoms so as to complete already existent groups, therefore involving negative valences, and (b) *Co-ordination*: the formation of a new group of electrons outside the last group represented in the ion. It is proposed to use the specific term *co-ordination valency* for the number of co-ordinated groups. It is assumed that the co-ordination electrons enter the main "quantum group" next to that represented in the central ion.—J. R. Partington and N. L. Anflogoff: An improved form of electric vacuum furnace. A vacuum furnace of the Ruff type was used for studying reactions at high temperatures. The reacting substances, if solids, are contained in a graphite crucible turned from the same material as the hot tube and maintainable either in a high vacuum or in an atmosphere of an inert or reacting gas. The issuing gas is capable of analysis.—J. R. H. Coutts and E. M. Crowther: A source of error in the mechanical analysis of sediments by continuous weighing. The low density of suspension immediately below the balance pan after the sedimentation has proceeded for a few minutes inevitably sets up a flow of liquid which interferes with the free vertical fall of the particles. With the large narrow-rimmed pans hitherto used, the observed yields are appreciably below the theoretical values. With the pan close to the base there is a very rapid change of yield with very small changes in the position of the pan.—Donovan Werner: A simple method of obtaining the size distribution of particles in soils and precipitates. The method has been developed in researches on the reaction mechanism during the formation of precipitates. It has been necessary to know the total surface of a precipitate as a function of time while the precipitate is forming. At first the particles can be measured by an ocular micrometer, but just as the particles become larger and more irregular in size during the precipitating process, at the same time forming aggregates, it becomes correspondingly difficult to get values sufficiently exact. The measuring of the velocity of the sedimentation gives an "accumulation curve," and from this curve the size distribution can be calculated according to the mathematical theory developed by Odén.—F. G. Tryhorn and W. F. Wyatt: Adsorption by coco-nut charcoal from alcohol-benzene and acetone-benzene mixtures. Adsorption isotherms for each component of such mixtures have been determined at 20°. By an analogous method, measurements have been made of the composition of the vapours in equilibrium with mixtures of the above liquids at 20°. A comparison of the results of adsorption by charcoal from the liquid and the vapour phases supports the conclusion that an adsorbed film in equilibrium with a saturated vapour must be also in equilibrium with the liquid in contact with that vapour. Alcohol is selectively adsorbed from all mixtures of alcohol and benzene. From acetone-benzene mixtures, acetone is selectively adsorbed from mixtures containing up to 72 molar percentage

of acetone in the vapour phase. Above that value benzene is selectively adsorbed to a slight extent.—F. L. Usher: The nature of the interfacial layer between an aqueous and a non-aqueous phase. Experiments were undertaken to obtain information on the question whether the ions bearing a charge of opposite sign to that of the non-aqueous phase are movable only as a complete layer, or whether some or all of them are independent; and secondly, on the extent to which the observed behaviour of aqueous suspensions is in agreement with the consequences deduced from the answer to the former question. They deal (1) with the determination of the total charge on the particles of a suspension by neutralising it with a measured quantity of ions bearing a charge of opposite sign, and (2) with the effect of electrolytes in modifying the surface charge.

Geological Society, November 18.—W. L. F. Nuttall: A revision of the Orbitoides of Christmas Island (Indian Ocean). A complete revision has been made of Jones's and Chapman's species. Six species of *Lepidocyclus*, one species of *Miogypsina*, and one of *Spirocyclus* were identified. The lepidocyclines possess no pillars in the lateral chamber-layer, and the two megalospheric forms have the embracing type of primordial chamber restricted to the subgenus *Eulepidina*. These species are found in Limestone C, as defined in the Christmas Island monograph (British Museum, 1900), which is classified as Lower Miocene. A *Discocyclus* has been found in Limestone B as well as in A, no orbitoides having been hitherto discovered in the former. This indicates that these beds are both of Eocene age.—W. Campbell Smith: The volcanic rocks of Christmas Island (Indian Ocean), with chemical analyses by E. D. Mountain. There were two periods of vulcanicity in Christmas Island. The older lavas are overlain by a limestone now proved by Mr. W. L. F. Nuttall to be Eocene. These upper lavas are overlain by a limestone with Orbitoides referred by Mr. Nuttall to the "older Miocene" of Rutten. All the lavas, both Eocene and Miocene, are considered to belong to a single petrological series. The rocks resemble very closely certain Tertiary and Permo-Carboniferous lavas from New South Wales. On the other hand, no analyses of rocks from Java and Sumatra are found to compare with those of the Christmas Island rocks.

Linnean Society, December 3.—F. J. Lewis: Preliminary account of a fungus in the tissues of Coniferæ. The results refer particularly to *Picea canadensis*, which has been collected from many habitats and varying in age from small seedlings to trees more than two hundred years old. The cortex of the youngest rootlets is penetrated in every direction by fine hyphæ, which not only enter the living cells, but grow through the middle lamellæ of the walls. They also penetrate the endodermal cells, and in some cases almost fill the lumen. Older rootlets from which the primary cortex has been cast off show the cells of the broad pericycle filled with fine branched hyphæ. In the unopened bud the fungus is localised in certain enlarged cells irregularly distributed above the crown near the base of the embryonic leaves. As the meristematic cone bearing the embryonic leaves elongates, the fungus spreads upwards from the region of the crown forming a network of infested cells.—Papers on the collections made during the expedition of H.M.S. *Sealark*.—Hugh Scott: The Ciidæ (Coleoptera) of the Seychelles. Ciidæ are small or minute beetles, usually of almost cylindrical shape, which are found boring in fungi, often in very large numbers. The present report enumerates 20 species, 18 of which were found in the Seychelles proper,

while one was found both in the Seychelles and Aldabra, and one in Aldabra only. Taking the Seychelles species as a whole, more than half were found exclusively in the endemic forests at high elevations, and these insects are probably endemic; among the few species taken in cultivated places are the only forms (three in number) known to occur outside the islands.—D. J. Matthews: Physical oceanography of the Indian Ocean. A well-marked discontinuity layer occurs at nearly all the serial positions, and its presence appears to be independent of whether the station lies in the south equatorial current or not. At one position the current impinging on the bank north of the Farquhar Group at about 800 fathoms causes mixing at all depths, which lowers the temperature near the surface and increases it on the bottom by one degree Centigrade. The surface salinities are intimately connected with the currents and winds. The low salinity water which lies across the eastern entrance to the Gulf of Aden is present at all times, and is partly due to the current northwards along the east coast of Africa.—S. T. Burfield and E. J. W. Harvey: Four genera of Chætognatha were found. Of *Sagitta*, which contains 22 or 23 species generally considered valid, 14 species are represented. Of the 32 valid species of the phylum, 18 occur. The limitation of the number of species in the group is thus amply confirmed by this large collection.—C. J. van der Horst: The collections contain 18 species of the Eupsammidae.—R. Douglas Laurie: Anomura from the West Indian Ocean. The Anomura were taken from localities between 3° and 21° S. Lat., and between 51° and 73° E. Long. They comprise 48 species distributed among the tribes Hippidae (1), Galatheidae (24), and Paguridae (23). The collection presents a typical Indo-Pacific faunas. A fair proportion of the species are, however, now recorded for the first time from localities so far west in the Indo-Pacific Ocean. The three species of the present collection which reach the western coast of America, namely, *Petrolisthes lamarcki* (Leach), the deep-sea form *Parapagurus pilosimanus* Smith, and the land form *Cænobita rugosus* H. M. Edw., are three of the four which spread also to the Atlantic.—H. Britten: Coleoptera, Ptiliidae of the Seychelles. The Ptiliidae (or Trichopterygidae) are the smallest of all beetles, and the various species found in the Seychelles range in length from 0.5 to 0.9 mm. Thirteen species are enumerated from these islands.

PARIS.

Academy of Sciences, November 9.—J. Costantin: An experiment with mountain-grown potatoes. It appeared probable that seed potatoes grown in the mountains and sown in the plains would be more proof against disease than ordinary potatoes. Some experiments made in 1925, although perhaps on too small a scale, confirmed this view.—Charles Richet, Oxner, and J. Richard: Raw meat and cooked meat diet for fish. Experiments showing that for fish as for mammals, cooking meat diminishes its nutritive value.—Léon Guillet: The influence of deformations on the transformations of certain light aluminium alloys. Study of the changes brought about in duralumin and in aluminium-copper-manganese alloy by wire drawing.—de Sparre: Calculation of the maximum ram stroke in a pipe feeding a turbine with strong reaction for a constant velocity of closing.—Jean Tilho: The probable area of the maximum extension of the Aleutian sea.—J. Schokalsky: An oceanographic expedition to the Black Sea. Observations were made during 1924 and 1925 at 72 stations, the data obtained including depth, specimens taken on the sea floor, and determinations

of temperature, salinity, density, dissolved oxygen, sulphuretted hydrogen, hydrogen ion concentration, colour and transparency, as well as biological observations. The Black Sea can be considered as being divided into two layers, a superficial one of 200 metres containing water diluted by the inflow of numerous rivers, whilst from 200 metres to 2000 metres, the whole mass of water has a higher salinity and density than the upper portion.—Guntner: A lemma of M. Poincaré.—Mandelbrojt: Remark on the mode of generation of functional isogenes.—Const. Parvulesco: The dynamics of spiral nebulae.—B. Nikitine: The distribution of the plankton of the Black Sea. The lower limit of appearance of the plankton is 200 to 225 metres. The principal influence on the vertical distribution of zooplankton is the temperature. In the case of the phytoplankton, besides the temperature there are the effects of variations in the quantities of inorganic nitrogen, phosphates, and silicates.—Paul Pascal: The magneto chemistry of closed chains. The experimental values for the molecular magnetic susceptibility for eight types of homocyclic and heterocyclic chains are compared with the figures calculated from the ordinary rules of additivity. In the polymethylene rings, the effect of non-saturation varies with the number of carbon atoms in the ring and is zero for the pentamethylene series. It is pointed out that the reductions in the molecular diamagnetism are in agreement with the predictions of Baeyer's strain theory.—E. Jouguet: Waves of shock and irreversible residual combustion.—J. Cournot and K. Sasagawa: The viscosity of some alloys at high temperatures.—H. Perpéro: The action of gaseous ammonia upon phosphorus chlorides. An attempt to prove that the primary action of ammonia upon the chloride PCl_5 is $\text{P}(\text{NH}_3)_3$.—V. Auger and T. Karantassis: Complex salts of stannous iodide with the iodides of rubidium and caesium. Preparation and analyses of the compounds RbSnI_3 , RbSn_2I_5 , CsSnI_3 , and CsSn_2I_5 .—B. Bogitch: The refining of mattes. The action of sodium sulphate.—A. Mailhe: A new method of bleaching petrols produced by cracking or by catalysis. Yellow petrols containing unsaturated hydrocarbons can be refined by digestion at the boiling point with stannous chloride.—Er. Toporescu: The cracking of ozokerite. Details of cracking experiments in which anhydrous aluminium chloride was used as a catalyst.—Albert Kirmann: The action of metallic sodium on bromoethylene derivatives. The bromoethylenes $\text{R} \cdot \text{CH} : \text{CHBr}$ and $\text{R} \cdot \text{CBr} : \text{CH}_2$ react with sodium giving the hydrocarbon $\text{R} \cdot \text{CH} : \text{CH}_2$, the acetylene derivative $\text{R} \cdot \text{C} \cdot \text{CH}$, and small quantities of higher boiling point condensation products. The yields of the various types of hydrocarbon do not admit of a simple theoretical explanation.—A. Demolon: The clay material of the quaternary muds.—A. Demay: Two new forms of quartz in petrosiliceous porphyrys; lamellar quartz and spherulites with granular quartz.—P. Lejay: Storm disturbances of the electric field and their propagation at a great distance.—Jean Piveteau: The signification of the sternum of the vertebrates. From three examples studied (*Feylinia*, *Sphenodon*, *Tangasaurus*) it is concluded that it is not possible to consider the sternum as a morphological entity, and that it can only be defined from a physiological point of view.—R. Anthony: A brain of the foetus of *Megaptera boops*.—Raymond Poisson: Some observations on *Anisops producta*. The adult *Anisops* may prove to be a useful auxiliary in the battle against *Anopheles*.—Emile F. Terroine, R. Bonnet, and A. Hée: The energy yield in the development of various plant organisms as a function of the amount of oxygen in the surrounding medium.—Henri Piéron: Is the Bunsen-Roscoe law applicable

to the luminous stimulation of the invertebrates? Experiments made on the effect of light on *Mya* (movement of retraction of the siphons) proved that the Bunsen-Roscoe law does not hold.—Robert Lévy: The hæmolytic properties of the pedicellar processes of certain urchins.—Mme. Anna Drzewina and Georges Bohn: The acidification of the medium by cellular cytolysis.

ROME.

Royal Academy of the Lincei, Communications received during the vacation, 1925.—F. Zambonini and R. G. Levi: Investigations on the isomorphism of the molybdates of the rare earth metals with those of calcium, strontium, barium, and lead.—Mineo Chini: Determination of the isogonal trajectories of a system of lines in certain surfaces.—Bruno Finzi: Considerations on the irrational motions of liquid laminae.—E. Raimondi: Dynamic effect of a current flowing between a plate and an indefinite plane wall.—U. Crudeli: Method of resolving a fundamental problem in the theory of the stationary slow motion of viscous liquids.—Rita Brunetti: Continuous absorption along an optical series and the structure of the discontinuity of absorption at high frequency.—V. Ronchi: Measurement of double stars with a grating interferometer.—G. Bargellini: α -Phenyl- β -methylcoumarins. Descriptions are given of a series of products obtained by condensing various ortho-hydroxy-substituted acetophenones with sodium phenylacetate and acetic anhydride.—Remo de Fazi: Syntheses in organic chemistry by means of radiant energy. (i.) Photosynthesis of $\alpha\beta$ -triphenyllactic acid. This acid is formed by the addition of a molecule of benzophenone to one of phenylacetic acid under the influence of light.—G. Scagliarini and E. Brasi: Additive compounds of tin and titanium halides with organic bases.—G. Checchia-Rispoli: Vertical diffusion of *Orbitoides s str*—Tullio Carpanese: The epidote of Monte Rosso di Verra (Monte Rosa group)—A. Clementi: The osmotic pressure of the hæmo-lymph and tissues of *Helix A.* during lethargy.—Giuseppe Russo: The curve of development of a xylophagous coleoptera, *Chaetopelmus vestitus*.

VIENNA.

Academy of Sciences, October 22.—Papers on electrolytic conductivity in molten metal alloys.—XI. R. Kremann, H. Krieghammer and P. G. Rehenburg: Na-Hg alloys of various composition.—XII. R. Kremann, H. Krieghammer and A. Trostek: Bismuth-tin alloys.—XIII. R. Kremann and O. Baukovac: Tin-cadmium alloys.—XIV. R. Kremann and J. Dellacher: Attempts at electrolysis of alloys of aluminium with magnesium, antimony, zinc and silver.—XV. R. Kremann and O. Baukovac: Attempted electrolysis of metallic sulphides and of phosphides.—XVI. R. Kremann and K. Bayer: Electrolysis of alloys of silver with Sn, Sb, Bi and Pb.—E. Steinach, H. Heinlein and B. P. Wiesner: Release of the sexual cycle, development of sex characters, rejuvenating effect on the senile organism of extracts of ovary and placenta. Experiments on rats and guinea-pigs. In the last two years experiments have been carried out with extracts of gonads and other organs, and in testing the effect of these extracts the criteria chosen have been the development of sexual characteristics in animals castrated in infancy, the rejuvenating effect on senile females and also the release of the sexual cycle. A stable substance has been obtained from the ovary and from the placenta which on injection produces these effects.—A. Smekal: On the constitution of the mono-crystalline state of aggregation. The ideal crystal lattice

differs greatly in its properties from those of the actual single crystal. It is assumed that real crystals have numerous pores and zones of disturbance. Complexes of some thousands of molecules seem to form higher units in crystallised bodies. (See also a lecture at the Danzig Physics Congress.)

Official Publications Received.

Forest Bulletin No 66 (Economy Series): A Note on the Working Qualities of some Common Indian Timbers. By H. E. Kinns. Pp. iv + 43. (Calcutta: Government of India Central Publication Branch) 10 annas; 1s.

Memoirs of the Department of Agriculture in India. Chemical Series, Vol. 8, Nos. 2, 3, 4: Investigations on Indian Opium, Nos. 4, 5, 6. No. 2: Further Experiments on the Influence of Manures on the Yield and Morphine Content of the Latex from the Opium Poppy, by Dr. Harold E. Annett and Har Dayal Singh; No. 3: Experiments on Oil-Content of the Seed of the Opium Poppy; and No. 4: Studies on the Ash Constituents of Indian Opium, by Dr. Harold E. Annett and M. N. Bose. Pp. 25-51. (Calcutta: Government of India Central Publication Branch) 8 annas; 10d.

Commonwealth of Australia. Bureau of Meteorology, Melbourne. Bulletin No 16: Australian Hurricanes and related Storms, with an Appendix on Hurricanes in the South Pacific. Prepared by Dr. Stephen S. Visser and D. Hodge. Pp. 54+3 charts. (Melbourne: H. J. Green.)

Government of India: Department of Industries and Labour, Public Works Branch. Triennial Review of Irrigation in India, 1921-1924. Pp. ii+43. (Calcutta: Government of India Central Publication Branch.) 1 rupee; 1s 9d.

Glass Research Association. Bulletin No. 14, August: A Review of the Work of the Association, 1920-1925. Pp. 106. (London: Wilfrid C. Smith, Liquidator, 48 Coptall Avenue.)

Department of the Interior: North West Territories and Yukon Branch. Canada's Arctic Islands: Log of Canadian Expedition 1922. By J. D. Craig; with an Appendix, Aviation in the Arctic, by Major R. A. Logan. Pp. 27. Canada's Wild Buffalo: Observations in the Wood Buffalo Park. By Maxwell Graham; with an Appendix, A Reconnaissance in the Home of the Wood Buffalo, by F. W. Seibert. Pp. 17+2 maps. Local Conditions in the Mackenzie District 1922. By J. P. Moran. Pp. 19+1 map. (Ottawa: F. A. Acland.)

Tide Tables for the Pacific Coast of Canada for the Year 1926: including Foca Strait, the Strait of Georgia, and the Northern Coast; with Data for Slack Water in the Navigable Passes and Narrows and Information on Currents. (Twenty-sixth Year of Issue.) Pp. 72. (Ottawa: F. A. Acland.) Free.

Tide Tables for the Eastern Coasts of Canada for the Year 1926: including the River and Gulf of St. Lawrence, the Atlantic Coast, the Bay of Fundy, Northumberland and Cabot Straits; and Information on Currents. (Thirtieth Year of Issue.) Pp. 76. (Ottawa: F. A. Acland.) Free.

Report on Norwegian Fishery and Marine Investigations. Vol. 3, No. 5: Marking av Sei i Nordland sommeren 1921 beretning avgit til Fiskeridirektøren. (Summary in English.) Av Oscar Sund. Pp. 24+3 plates. (Bergen: A.S. John Greigs Boktrykkeri.)

Queensland Department of Mines: Queensland Geological Survey. Publication No 275: Index to Publications No 267 to 274 (Vol. 8 of New Series). By Miss M. G. Wood. Pp. 39. (Brisbane: Anthony James Cumming.)

Memoirs of the Department of Agriculture in India. Veterinary Series, Vol. 3, No. 6: Nasal Granuloma in Cattle. By Prof. V. Krishnamurti Ayyar. Pp. 159-166+9 plates. (Calcutta: Thacker, Spink and Co; London: W. Thacker and Co.) 1 rupee; 1s 6d.

Department of Agriculture, Straits Settlements and Federated Malay States. Bulletin No. 37: The "Mouldy Rot" Disease of Hevea Brasiliensis in Malaya. By F. W. South and A. Sharples. Pp. ii+31+4 plates. (Kuala Lumpur.) 50 cents.

Memoirs of the Department of Agriculture in India. Entomological Series, Vol. 9, Nos. 1, 2 and 3. No. 1: A Contribution towards a Monograph of the Indian Conopsepterygidae (Neuroptera), by Dr. C. L. Withycombe; No. 2: Papers on Indian Tabanidae—vi: The Bionomics and Life-Histories of some of the Common Tabanidae of Pusa; and No. 3: Some Observations on the Life-History and Habits of Phycus brunneus, Wied. (Family Theredidae), by P. V. Isaac. Pp. 80+11 plates. 22 rupees; 4s. Chemical Series, Vol. 8, No. 1: The Quality and Yield of Tobacco as influenced by Manual and other Operations. By J. N. Mukerji. Pp. 26. 8 annas, 9d. (Calcutta: Government of India Central Publication Branch.)

Ceylon Administration Reports for 1924. Department of Agriculture: Report of the Director of Agriculture for 1924. Pp. D52 (Colombo)

The Institution of Civil Engineers. Engineering Abstracts prepared from the Current Periodical Literature of Engineering and Applied Science, published outside the United Kingdom. Supplement to the Minutes of Proceedings of the Institution. Edited by W. F. Spear. New Series, No. 24, July. Pp. 194. (London.)

Proceedings of the Academy of Natural Sciences of Philadelphia. Vol. 77: Fishes from Natal, Zululand and Portuguese East Africa. By Henry W. Fowler. Pp. 187-268. (Philadelphia.)

Department of Commerce: U.S. Coast and Geodetic Survey. Serial No. 818: Terrestrial Magnetism—The Earth's Magnetism. By Daniel L. Hazard. (Special Publication No. 117.) Pp. 52+6 plates. (Washington: Government Printing Office.) 15 cents.

The Brooklyn Institute of Arts and Sciences. Brooklyn Museum Science Bulletin, Vol. 3, No. 3: Revision of the New World Species of the Tribe Donacini of the Coleopterous family Chrysomelidae. By Charles Schaeffer. Pp. 45-165. 1 dollar. Vol. 3, No. 4: Notes on certain Books of Unusual Interest in the Blackford Collection of the Brooklyn Museum. By E. W. Gudger. Pp. 167-172. (Brooklyn, N.Y.)

The Manchester Steam Users' Association for the Prevention of Steam Boiler Explosions, and for the Attainment of Economy in the Application of Steam. Memorandum by Chief Engineer for the Year 1924. Pp. 52. (Manchester.)

Boletín de la Sociedad Geológica del Perú. Tomo Primero. Pp. vi+126+31 lám. (Lima.)

The Government of the Philippine Islands: Department of Agriculture and Natural Resources, Bureau of Science. The Mineral Resources of the Philippine Islands for the Years 1921, 1922 and 1923. Issued by the Division of Geology and Mines, Bureau of Science. Pp. 63. (Manila: Bureau of Printing.)

Canada. Department of Mines: Geological Survey. Memoir 146, No. 126 Geological Series. Retreat of the Last Ice-Sheet in Eastern Canada. By Ernst Antevs. Pp. iv+138+9 plates. (Ottawa: F. A. Acland.) 25 cents.

Proceedings of the Liverpool Geological Society. Session the Sixty-sixth, 1924-25. Part 2, Vol. 14. Edited by C. B. Travis. Pp. xxi+99-105+plates 5-9. (Liverpool.) 5s.

Department of the Interior: U.S. Geological Survey. Mineral Resources of the United States in 1924 (Summary Report). Introduction by Frank J. Katz; Statistics assembled by Martha B. Clark. Pp. ii+103A. (Washington: Government Printing Office.)

Department of the Interior: U.S. Geological Survey. Water-Supply Paper 529: Surface Water Supply of the United States, 1921. Part 9: Colorado River Basin. Pp. v+181+2 plates. 25 cents. Bulletin 766: Spirit Leveling in California, 1896-1923. Pp. ii+748. 80 cents. Bulletin 781A: Paleozoic Formations penetrated by Wells in Tishomingo County, North-eastern Mississippi. By M. N. Bramlette; with Notes on Paleozoic Rocks encountered in a Well near Florence, Alabama, by H. D. Miser. Pp. 12+1 plate. (Washington: Government Printing Office.)

Last of Memoirs, Maps, Sections, etc., published by the Geological Survey of Great Britain and the Museum of Practical Geology to 30th June 1925. Pp. 115+5 plates. (London: H. M. Stationery Office; Southampton: Ordnance Survey Office.) 1s. net.

Development Commission. Fifteenth Report of the Development Commissioners for the Year ended the 31st March 1925. Pp. vi+198. (London: H. M. Stationery Office.) 2s. 6d. net.

Memoirs of the Geological Survey of India. Vol. 50, Part 1: Descriptions of Mollusca from the Post-Eocene Tertiary Formation of North-Western India; Cephalopoda, Opisthobranchiata, Siphonostomata. By the late R. Vredenburg. Pp. xii+350+xvi+13 plates. (Calcutta: Government of India Central Publication Branch.) 5.6 rupees; 8s. 9d.

Forest Bulletin No 65 (Silviculture Series): Tables for Bark Deductions from Logs. By S. H. Howard. Pp. ii+11. 8 annas; 4d. Forest Bulletin No. 64 (Economy Series): Summary of Results of Laboratory Experiments with different Wood Preserving Antiseptics (Results of 14 Years' Experiments). By S. Kamesam. Pp. ii+23+5 plates. 1.12 rupees; 3s. (Calcutta: Government of India Central Publication Branch.)

Diary of Societies.

FRIDAY, DECEMBER 18.

SOCIETY OF MEDICAL OFFICERS OF HEALTH (at the Medical Institute, Newcastle-upon-Tyne), at 5.—Prof. H. Kerr: Industrial Hygiene from the point of view of Public Health Administration.—Sir T. Oliver: Industrial Hygiene from the point of view of the Physician.—G. France: Industrial Hygiene from the point of view of the Works Director.—Capt. J. Robinson: Industrial Hygiene from the point of view of the Welfare Supervisor.

INSTITUTE OF TRANSPORT (North-Western Local Section) (at the Midland Hotel, Manchester), at 6.30.—E. G. Garstang: Transport in Connection with the Fishing Industry.

SOCIETY OF DYERS AND COLOURISTS (Manchester Street), at 7.—Prof. E. Knecht: The Effect of Oxidation, of Cotton of Glucose and other Carbohydrates by

SOCIETY OF CHEMICAL INDUSTRY (South Wales College, Swansea), at 7.15.—E. E. Ayling:

SOCIETY OF DYERS AND COLOURISTS (Scottish Restaurant, Glasgow), at 7.15.—J. Marsden:

AERONAUTICAL ENGINEERS (at Royal Society of Institution of Mechanical Engineers (York Philosophical Hall, Leeds), at 7.30.—Prof.

Early Mental Disorder.

IN continuation of our previous comments (NATURE, November 28) upon conditions of research in mental disorder, it may serve a useful purpose to describe, from a constructive point of view, some further practical aspects of the problem, and to show their bearing upon each other.

At the close of the War the Maudsley Hospital in London, like many others which had been put to army purposes, returned to civil use as a special institution under the London County Council for the treatment of early mental cases. At the same time, the pathological laboratory of the London Mental Hospitals was housed under the same roof. Thus was constituted an organisation for scientific investigation in vital relationship with one for observing and treating the earliest signs of insanity. From the first, no person admitted as an out-patient or to the wards of the Hospital was certified insane either before admission or during treatment by the hospital staff. Residence in the Hospital was a purely voluntary matter, and the divorce from legal procedure for compulsory detention was absolute. Patients seek advice and treatment in the same sense as they seek relief from purely physical symptoms at a general hospital; and, precisely as in a general hospital, admission to the wards may follow reference by a physician or attendance at the out-patient department of the Hospital.

Little imagination is needed to realise the differences between a voluntary mental hospital of this kind and other voluntary hospitals. There are peculiarities inseparable from responsibility for the welfare of persons who, from a medical if not a legal point of view, may not be strictly accountable for their actions. There are also the limitations inseparable from public control, to which general hospital physicians and surgeons are not subjected. But above all is a difference which even alienists themselves, trained for the most part in the shifts and inconveniences associated with sole care of hundreds of mental patients of all sorts and conditions, do not always appreciate. In general hospitals, except in comparatively rare cases, diagnosis is made relatively rapidly, and treatment, apart from mornings in the surgical theatres, and such measures as can be handed over to subordinates, takes actually little time. Fifty patients share the attentions of clinical clerks, houseman, assistant and chief, and the treatment of out-patients often entails further appointments to the staff. In mental disease it is recognised that if there is a physical cause, primary or contributory, it is obscure. Hence, even from a physical point of view, every patient in a hospital for the treatment of early mental cases is potentially in the position of the

rare, difficult cases of general hospital practice. Add the exhaustive and intimate personal investigation into history and behaviour indispensable to establish the past and present mental condition of every patient, and it is clear that to fulfil the first of its functions the special mental hospital should be staffed not less but more generously than any other kind of existing hospital, and by men of equal specialist competency, one with another, wholly responsible for their own cases. This is not an ideal but a necessity.

Treatment, however, is not the sole function of the voluntary mental hospital. Every person enabled to carry on his own, or any, avocation in society means a social saving of the work of two, and the importance of any improvement in medical efficiency here is obvious. But possibly the greatest opportunity in relation to the small voluntary hospital is for the observation of the early signs of disorder and the turning of the knowledge thus gained to scientific use. A passage in Lugaro's "Problems in Psychiatry" has special application in this connexion.

"In practice," he wrote, "it is not possible to limit one's attention to one single branch of a complicated subject, and all great pioneers of science have dived deep into two or more branches of knowledge with equal success and skill. There is a physics and a chemistry, but pure physicists and chemists do not exist. Anatomy can be separated from function, but the anatomist must be conversant with the latter. The physiologist does not understand his science without anatomy. But in no science do so many sciences dovetail into each other as in psychiatry. Therefore the alienist must—as much as the time at his disposal and his individual capacity permit—take an active part in work developing in neighbouring fields of research, cultivate other sciences and help them to progress, in order to further the progress of his own."

Every serious worker among the mentally disordered is in the position of such a pioneer. The foundations of his science have yet to be laid. They cannot be laid among the chronic insane; but only by the minute study of the developing disorder: otherwise as well seek the origin of species in the anatomy of a single type.

All these advantages are capable of being shared by the admission wards of the large mental hospitals, although the fact of legal certification goes very heavily against the establishment of relations in which freedom and candour predominate over fear and suspicion between patient and doctor. Setting aside the empty charge so commonly made against the institution of early treatment centres, that they attract the hysterical and neurotic patient—as though a surgeon might disdain to treat cut heads—it is frequently alleged that the admission wards of large asylums are now in reality such centres. There is every appearance of truth in this contention, excepting

the essential appearance of similarity of aim and result. Certification is a legal, not a dividing, line. Little as we know of the real nature of such disturbances, we do know that the most maniacal behaviour is quite consistent with ultimate and even early recovery. Many early cases, and as many that are recoverable, reach the admission wards of asylums.¹ This fact alone links into an organic unity the principles of early treatment wherever it is carried out.

The characteristics of the small voluntary hospital are not exclusive. What is needed is that such centres as the Maudsley Hospital should be less special than they are. Large and important as their sphere might be, provided always that they were adequately equipped for their complex function, there must remain the social necessity for compulsory detention of some persons even in acute stages of disorder. Their treatment entails its own problems, and offers as profitable a field for investigation into fundamental problems as any. It would be a grave mistake to remove all responsibility for the solution of mental problems from asylum staffs.

Like so many other great social problems, the question of the advancement of our knowledge of mental disorder is fundamentally one of money. Without the clear recognition that the organisation of ordinary medical practice cannot appropriately be applied to mental disease, and that psychiatry cannot progress without adequate endowment, no considerable advance is possible.

Labour and Primitive Economics.

Primitive Labour. By L. H. Dudley Buxton. Pp. viii + 272. (Methuen and Co., Ltd., 1924.) 7s 6d. net.

UNDER the surface storms which have for some time been troubling the once calm waters of anthropology—as the contest concerning the origins of marriage, the differences of opinion about totemism, the fight between diffusionists and evolutionists—there has taken place a much more radical change in method, aim, and argument. More and more has the substance of serious anthropological work come to consist of sociological analysis of primitive culture. The nature of primitive organisation, the types and phases of economic activities, the relations between the economic and the religious aspect, or between magic and practical arts and pursuits, are now studied as empirical problems and not as pretexts for reconstruction and hypothesis. The new anthropology aims at the

¹ During 1924, 22,758 persons were admitted to County, District, and County Borough Mental Hospitals, and 6751 were discharged recovered. If transfers and readmissions are excluded from consideration, the proportion, per cent., of recoveries to admissions in 1924 was 34.3 per cent. The number of certified insane in London County Mental Hospitals in 1924 was 19,269. The figure was given inaccurately in NATURE, November 28, p. 775.

understanding and explanation of culture rather than at the establishment of "origins," "contacts," and "diffusions"; it moves exclusively in the realm of ascertained fact and avoids conjecture; it can yield results applicable in practice and not mere speculations of purely antiquarian interest.

Of all such positive subjects, primitive economics has been perhaps most neglected, in Great Britain at least; while within this subject the problem of primitive labour has scarcely been touched at all. It is a great privilege for a writer to be able to take up an entirely new question. His is naturally the duty of summarising all the preparatory and relevant work done, of formulating the problem, of making his original contribution, of setting the task for his successors. Unfortunately, it cannot be said that the author of the present work has fulfilled any of these tasks in a satisfactory manner. It would be impossible even to frame the problem on the basis of his contribution.

In order to do this it is important to have a clear definition of the concept with which we are dealing. What is *labour*? The reader of Mr. Buxton's book will find no definition, and the word is used loosely with a variety of meaning to cover "invention," "industries," "pursuits," and is usually identified in a cryptic manner with "arts of life," which, I take it, covers any form of activity whatever. (Ch. i.; also pp. 14, 63, 248, 250, 264-265 *et passim*.) But to identify labour with activity in general is, from the outset, to confuse the issue. For is it not in the harnessing of human energies, in the disciplining of purposeful and systematic activity, devoted to culturally valuable ends, that any real advance consists? It is only after we have distinguished labour from purely animal instinctive movement on the one hand, and from recreational and sportive activities on the other, that the problem emerges. Even in the satisfaction of his wants, such as search for food, provision for clothing and shelter, man may act instinctively on the animal pattern, or else reach his goal by culturally standardised types of behaviour. It is only the latter which I suggest should be regarded as forms of labour in the science of culture.

The anthropological problem, therefore, would be: What is the relation, at various stages of development, of the unregulated activities to those standardised by custom, and what part within the latter is occupied by work devoted to the production of concrete cultural values? For it is the achievement of something tangible and useful which must enter also into the definition of labour. In the first place it will be, of course, the satisfaction of man's primary wants: the search for food and its preparation; the procuring of raw materials for clothing, weapons, and direct objects of use. To this the lowest savage adds certain material

goods which are not for consumption, but really belong to the primitive forms of capital—implements, arrangements for storing and preserving food, traps, hunting weapons, and so on. To define the savage, therefore, as Mr. Buxton does, by the fact that he "has no means of acquiring more wealth than he can carry about on his person or on the persons of his family" (p. 9), is incorrect even in regard to the most primitive man known, and would exclude from the inquiry all the most important facts about middle and higher savagery. Again, even amongst the lowest savages, there is work devoted to the production of what might be called luxuries—objects of art and monuments of culture—personal ornaments, paintings, and rude sculpture, stone memorials and graves, objects of cult and ritual. We may, therefore, define labour as purposeful systematic activity standardised by tradition and devoted to the satisfaction of wants, the making of means of production, and the creation of objects of luxury, value, and renown.

If, however, labour is distinguished from other activities by its purpose, the question emerges: What is it that, in culture, drives man to strenuous, prolonged, and very often unpleasant effort? Here the problem of labour can be treated only against the background of the psychological problem of value. What are the effective incentives to effort? In what way are they related to instinctive drives and how far are they transformed by culture? It is obviously futile to discuss labour except as a part problem of economics. The early forms of labour are intimately correlated with the manner in which economic value came into existence. In fact, the inquiry has to burst the bounds even of the widest economic analysis and to consider how other motives, above all those of magical and religious character, have pushed man towards certain pursuits, established new values for him, and thus given him new forms of labour. The ingenious hypotheses of Eduard Hahn about the origin of domesticated animals and about the connexion between higher agriculture and religious cult; the views of Grosse about the influence of family life on economic pursuits; the recent contributions of Max Weber and Richard Thurnwald, form already a body of knowledge upon which any writer who treats of the problem of labour must take his stand. All this important research is unmentioned by the writer of the book under review.

From our definition of labour it also results that this type of activity, since it does not run on the lines of instinct and play, must involve a certain amount of resistance on the part of the organism. In other words, as we all know—and even the savage would agree with us—work is unpleasant. In primitive culture we find

indeed that man works very erratically, sometimes with the greatest efficiency, sometimes in a very unsatisfactory manner. A closer analysis shows that the efficient work is very often due to what might be called a palliative concomitant, some stimulant which carries man over the fatigue, tedium and monotony, over the need of recurring effort. An excellent study of this subject in one of its aspects has been given to us in Karl Bücher's "*Arbeit und Rhythmus*" (1899, 2nd ed.). No student of the problem should neglect this work, and had Mr. Buxton read it carefully and inspired himself with its methods he might have given us some data at least from the extremely rich inventory of the various concomitant stimuli, such as rhythm and music, drugs, work in company, emulation and example, importance of effective leadership and the use of rewards, material and moral.

The stimulating influence of work in company or of work under compulsion must be strictly kept apart from another and much bigger subject, that of the organisation of labour. Culture consists not only in the greater efficiency of effort, nor yet in the standardisation of this effort only, but also in the co-ordination of activities. The most primitive societies must have had a tradition of labour as well as a tradition of knowledge, belief, social organisation, and art.

Continuity in work transcends the limits of individual life, since not only the implement, the knowledge of material surroundings, but also the mode of working, the tricks of trade, and even the morals of hard and industrious labour must ever be engrained by the elder in the younger generation. This obviously implies some social organisation upon which the transmission of workmanship and education in work could have been based. This probably also led to the simplest forms of co-operation, those between the old and weak yet experienced on one hand, and the strong novices on the other. Since again transmission of workmanship must have been associated with kinship and marriage, the earliest forms of organised labour were to a great extent associated with the relation between husband and wife and parents and children.

The isolated household economy, however, was never the exclusive form of production even in the most primitive tribes. Prof. Karl Bücher, who develops an evolutionary scheme of human industries, would like to place at the beginning an even more primitive type of existence, that of isolated search for food. This is unquestionably a fictitious conception; even in simple search some order if not organisation is necessary. The roaming-grounds of every group are subject to the exclusive though collective rights of this group. Within this territory the very natural conditions such as the seasonal abundance of food, the advantages of system-

atic search, the technicalities of many proceedings in food-collecting, must have imposed a number of rules, dictated by knowledge and enforcing order and rudimentary forms of co-operation. The observations about food-collecting which I had opportunities of making among a number of Papuan and Melanesian tribes in New Guinea gave me the conviction that even among more primitive food-gatherers some organisation of labour must exist. The mere psychological factor which makes isolated search exceedingly tedious, and search in groups stimulating, refreshing, and more effective, would lead to the same conclusion. It is difficult to imagine collective work done in dead earnest, subject to natural conditions and guided therefore by knowledge and experience, which would be entirely unorganised.

There is, however, even a weightier reason for eliminating the concept of isolated search or of independent household economy. Culture stands and falls with the strength of tradition, with the quantity and quality of all that is transmitted from one generation to the other. A society cut up into independent families would, therefore, mean a tradition split into a number of extremely thin and precarious threads of cultural continuity. So that even in the lowest stages of development a society which would at least seasonally congregate, come into contact collectively, compare their practices and perhaps exchange material goods as well as ideas, would have a good cultural advantage over an atomised society. Moreover, a community which would be always ready to mobilise for defence or aggression, or in case of natural catastrophes, would always have a great advantage over its neighbours. This explains why we find in every savage community, described with sufficient accuracy and detail, periodic regular gatherings for religious, festive, or warlike purposes.

We are unfortunately not informed in what way the commissariat of such big gatherings is run. Yet it is clear that in a society like the Central Australians, who lead apparently a hand-to-mouth existence, and have to roam over big tracts of country in small bands in order to survive, some extraordinary economic feats must be performed if the hundreds of blacks who congregate for months for an Engwura or an Intichiuma ceremony have to be fed by those who are not busy in the ritual. There is here obviously a conundrum of the first order in primitive economic theory—not to speak of the practical difficulties to the blacks themselves—and yet our authorities who have given page after page of ceremonial detail have passed it over completely! So helpless is the first-hand observer in the absence of theoretical inspiration; as a field-worker, I may be allowed to say so. In any event, the

fact, of big periodical gatherings among the most primitive tribes forces us to the conclusion that they have elaborate forms of economic organisation, more especially of organised labour. What is more, if they can organise on exceptional occasions, surely they must have some habits of organised work in their daily existence as well.

When we come to slightly higher stages, a great deal of collective and organised effort is required in such pursuits as communal hunting and fishing, any form of tropical agriculture, or the building of dwellings and canoes. In the case of such societies, we have at our disposal quite a respectable number of observations, and it would be possible to treat the subject not only tentatively so as to stimulate research, but also to advance certain positive conclusions. When a number of people work together at the clearing of the scrub, at the cutting down of a tree, or at the construction of some object, the question first arises—by what interest are they moved? Does every one receive some share, or even an equal share; or are they impelled by some *esprit de corps*, some unselfish motive of common good? The problem of incentive in communal labour leads therefore immediately into problems of ownership. Anthropology has perhaps discussed this problem more carefully than any other of primitive economics, but the relation between labour and prospective use and advantage still awaits to be competently treated, and more particularly to be freed from the ill-defined and misleading concept or word "Communism."

This is the place to attempt at least a tentative definition of what is understood by organised labour. In savage societies with a slightly higher culture, there are many tasks which transcend the forces of one individual; yet when several people co-operate, if there is not to be confusion, they must first of all be placed spatially and their respective contributions synchronised or placed into a sequence. In the simplest collective work, such as common clearing of bush, the pulling of a log, the planting of a garden or weeding, the people distribute themselves, and there are some means, either by personal arrangement or by customary signalling, of synchronising the pull of the log, of systematising the complete clearance of the bush, of ensuring an even distribution of the seed in the ground.

In more complex activities, however—imagine a canoe in rough weather, a fishing-team at work, a fighting force manœuvring—there is a necessity not only of spatial and temporal co-ordination, but also a dovetailing of the individual contributions to the common task. According to personal capacity, according to the position at that moment, according to social status, the various members of the organised team act each in the prescribed manner. There is among them, however, one

whose task is not so much a special part of the common labour as the guidance of the whole. This is the leader. Leadership is necessary in certain enterprises, because of special knowledge, experience, and mental qualities; in others because of the need of one person to signal or indicate the sequence of events; in others again out of sheer deference to rank, status, and power. In primitive societies, moreover, there is one important element associated with control of work, that is the influence of magic. Magic indeed not only very often supplies the title to leadership, but seems to be one of the most important principles in the organisation of labour by supplying the stimulus, indicating the sequence, and commanding belief and subordination to the man in charge. We may, therefore, define the organisation of labour as the sum total of the factors which command the spatial and temporal placing of tasks; the distribution and dovetailing of functions, and, again, the integration of these functions by customary schemes, mutual agreement, and leadership.

The problems of organisation, therefore, would refer to the modes in which tasks are apportioned, to the nature of leadership, to the relation between technical and social rules, knowledge, and social prerogatives, finally to the study of magic as the controlling principle of labour. All this, however, would be futile if it were discussed without reference to the economic distribution of profits. For it is the inequality of labour, coupled with the inequality of gain, which forms, at the beginnings of civilisation, the foundations of progress. The best modern work in field anthropology establishes the importance of the economic factor in the foundation of political power, of rank, and of all forms of cultural eminence. The conditions as we know them from north-west America, from many African tribes, above all from Oceania, and more especially from Melanesia, reveal the accumulation of wealth as one of the strongest social incentives, the economic and ceremonial handling of valuables as one of the motives round which big social achievements crystallise, and the beginnings of a "leisured class" as the carrier of culture. The chief very often acts as a sort of tribal banker. All that Mr. Buxton has to say on this important subject is that "the chief's duties usually lie in other directions than those connected with arts of life" (p. 17), a statement succinct but not correct.

What has been said might perhaps be summarised in the statement that primitive labour has a technological aspect which leads to a disciplining and co-ordination of activities. This again implies from the earliest stages an organisation of labour which must be studied in its sociological context as well as with reference to the tribal economies. This, once more, leads to the psychological analysis of incentive, concomitant stimulus to

labour, value, and ownership. Mr. Buxton disregards the sociological, the economic, and the psychological problems. The technological aspect is treated only in a fragmentary descriptive manner. As a matter of fact, the second and third parts of the book, which are frankly descriptive—they consist to some extent of personal reminiscences told in a vivid and unassuming manner—are, within their limits, better perhaps than the more ambitious first part. That rapid impressions and anecdotal reminiscences as scattered throughout this volume have little anthropological value as field work, need scarcely be said. In the first part (pp. 1-72) we miss the formulation of the problem, even an approximate definition of terms and any consecutive argument. We remain under the impression that the book has been very rapidly written when we are told, for example, that "the house, then, will protect from the weather and provide a place wherein to live" (p. 60), or "clothing, therefore, may be considered at least in part as one of the arts of life" (p. 61)—and in such statements the book abounds. We feel that the art of omission has been neglected in writing it. To quote one more dictum: "Intimately connected with the arts of life, yet hardly forming one of them, may be grouped that type of craftsmanship which devotes itself to ornament and relaxation" (p. 63). How "relaxation" can be a form of craftsmanship or how craftsmanship is to be excluded from the "arts of life," passes my comprehension.

Disappointing also, in a book like the present, is the almost entire neglect of the most important works touching upon the subject. The names of Dargun, Ed. Hahn, Bücher, Schurtz, Cunow, Grosse, Laveleye, Lewinski, Thurnwald, and Max Weber are not mentioned. This is the less to be excused since there are in existence excellent brief resumé of the work done so far—to mention only "Die ethnologische Wirtschaftsforschung," by Pater W. Koppers, in *Anthropos*, 1915-16, and "Die Gestaltung der Wirtschaftsentwicklung von ihren Anfängen heraus," by R. Thurnwald, in "Erinnerungsgabe für Max Weber," Band i., 1923, both with excellent bibliographies.

The problem of labour, therefore, still awaits its theoretical launching. This is so much the more urgent since observations will not be forthcoming until the theory has erected a number of hypotheses, suggested a series of questions, and goaded the interest of field-ethnographers by a number of more or less extravagant assertions. It would be highly desirable that the subject of labour should be well under the control of theory and of empirical study, for it is one of practical importance in Colonial legislation and in the regulation of the manner by which native races are to work for or with the white man.

B. MALINOWSKI.

The Arts of Husbandry.

Actual Farming: its Processes and Practice. By W. J. Malden. Vol. 1. *The Farm: its Nature and Treatment.* Pp. 207. Vol. 2. *Croppings, Pastures and Weeds.* Pp. 295 + 11 plates. Vol. 3. *Live Stock, Labour and Marketing.* Pp. 240. (London: Ernest Benn, Ltd., 1925.) 50s. net.

THE task of writing a treatise covering the whole art of husbandry as it appears to those many sorts of farmers who practise it must necessarily be a formidable one. There is so very much to be said and so many points from which the same facts may be viewed, that the work may easily develop into an encyclopedia. From time to time courageous men have appeared who have endeavoured to capture and to set upon paper all that curious mass of information and tradition which, when seasoned with common-sense and intuition, goes to make up a farmer's professional equipment. Such classics as "The Book of the Farm," or in a lesser way Fream's "Elements of Agriculture," are the result of such bold projects in the past, and it must be admitted that in so far as the written word has any influence at all upon the development of practical farming, they have proved their usefulness.

Mr. W. J. Malden, who is already well known as a writer on grassland farming and sheep and has an unusually wide personal experience of farming both in its practical and more definitely scientific aspects, has endeavoured to deal with the same subject in its more recent developments. His book is quite well-named, for its appeal is wholly to the working agriculturist and not at all to the man of science. Mr. Malden thinks as a farmer and feels as a farmer, and one can but regret that he does not write so well as some of those predecessors in agricultural literature from whose works he quotes. Many who read these three volumes will regret that the means of expression is not equal to the knowledge displayed in them.

The arrangement of so large a work is itself a matter of great difficulty, and in this particular the author has adopted a plan which should appeal to that body of his readers who may require his book as a work of reference. The whole is divided into three volumes, each with a sub-title which expresses its general purport. The first of these deals with the farm, its nature and treatment, the second with croppings, pastures and weeds, and the third with live stock, labour and marketing. The further subdivision into chapters is well done on lines which are familiar to students of agricultural literature. The first volume is probably the most valuable of the three, for some of the aspects of farming found in it are those which receive too little attention from contemporary writers.

Mr. Malden's view of the relation of the farmer to the rest of the community is one that is not uncommon among farmers, but is seldom adequately expressed. He says that "the farmer has every one as a critic," and that he has to carry on an extremely complex business and an unending war with the climate, in face of the freely expressed opinions of the mass of his uninstructed fellow-countrymen. Open criticism, even when it is ill-informed, matters very little when it is not accompanied by power of one sort or another. In this case of the farmer, the critics represent that urban majority which must influence the political views of any government to a very great degree. Farming and politics are widely removed from each other in most respects, but political neglect or misunderstanding can make the farmer's task very much more difficult than it need be.

The attitude of farmers towards change and so-called agricultural progress is very generally misunderstood, and Mr. Malden finds space to express a view which will gain support among those who have some knowledge of farming conditions, and of the ill-conceived and expensive reforms which are sometimes urged upon agriculturists. The history of agricultural development in Great Britain during the past fifty or sixty years shows that great progress has been made in the application of the sciences to the business of farming, and that the farmer of to-day is in a far better position to solve his problems of crop and animal husbandry than was his great-grandfather. Unfortunately, a closer study of the course of progress reveals the fact that this advance has been made at very great cost, and that a large number of individuals have been ruined in the process. So many well-meaning but unwise people, and so many interested rogues, have set out to advise farmers in the development of their businesses; so much incomplete discovery and unbalanced recommendation has been lavished upon agriculture, that the sturdy conservatism of the farmers might very well have become hardened to an incredulous contempt for all new ideas. That this has not happened is well shown by the present development of agricultural education and research, which depends upon the support of farmers all over the kingdom. Mr. Malden quotes from Wren Hoskyns to show that real progress finds a welcome on the farm as elsewhere, and that apparent lack of enterprise is often only wise caution on the part of the farmer. The beginning is worth quoting again:

"Ye ardent go-aheads! who expect every new argument to tell at once—every intellect to yield at first onset, every new plan to be tried by everybody—learn to wait: and you will find that there is much more chance of your notion being overtaken than overlooked, much more likelihood of your having to reclaim than to reassert a single hint that was ever good for anything."

Abt. 2: *Physikalische Methoden*, Teil 1, Heft 5. *Photometrie*, Tyndall-*Photometrie*, *Zeitmessungen*, Von Paul Hirsch. *Colorimetrie*. Von Heinrich Kessler. Pp. 619-736+xvi. (Berlin und Wien: Urban und Schwarzenberg, 1925.) 5.70 gold marks.
- (2) *Optische Messungen des Chemikers und des Mediziners*. Von Dr. Fritz Löwe. (Technische Fortschrittsberichte: Fortschritte der chemischen Technologie in Einzeldarstellungen, Band 6.) Pp. xi+166. (Dresden und Leipzig: Theodor Steinkopff, 1925.) 6 gold marks.

RAPID developments have taken place during recent years in the application of optical methods in various branches of science. For the efficient utilisation of such methods, the investigator or practitioner requires a knowledge of the functions and possibilities of the various instruments that are available for use in his particular sphere of work. To meet these requirements, modern textbooks professing to give a complete treatment of any subject usually contain a full account of suitable instruments and of the method of using them. As an alternative to the inclusion of elaborate instrumental details in a comprehensive treatise on any branch of science, the preparation of separate monographs dealing with the development of the instruments and their specialised applications has much to commend it. Revised editions of such monographs are more easily produced and more readily purchased, and the student or investigator can select those which deal with that branch of the subject in which he is most directly interested. The two books before us provide an example of each method.

(1) The first forms a small section of the second volume of a thirteen-volume treatise on methods and technique in biology, many parts of which have already been noticed in our columns. Two chapters are devoted to photometry and Tyndall photometry or the measurement of the scattering of light by extremely small particles held in suspension in the medium through which the light is passing. The theoretical treatment is adequate and the main types of instruments are well described; but many of the most recent developments are omitted and little information is given on the application of the instruments in particular cases. No attention is paid to the attempts which have been made to place photometry on a more accurate basis by the use of instruments which respond to light in a manner comparable with that of a normal

human eye. The appendix on spectrophotometry contains very little indication of the use of instruments which enable quantitative measurements of absorption to be made in the ultra-violet and the infra-red regions of the spectrum.

In making these criticisms we must, however, bear in mind that we are examining a small section of a large treatise, and it is possible that many of the items now omitted may find a place elsewhere in the completed work. Thus, in the chapter on Tyndall photometry, no mention is made of recent work on nephelometric methods in biochemistry; but the list of sections in course of preparation includes one on nephelometry, which is grouped with ultramicroscopy. The third chapter contains an instructive account of several types of stop-watches. Chronographs and microchronographs are not included, but reference is made in this connexion to another volume of the work.

The chapter on colorimetry deals with the simpler and more frequently applied part of the subject, namely, the determination of the comparative luminosity of the total light transmitted by a coloured body, as distinct from the calculation of the colour of the light. Here the chemist will find a considerable amount of information with regard to instruments and methods which permit him to use colour estimations in various branches of analytical work.

(2) The object of Dr. Löwe's book is to provide, in a readily accessible form and at a reasonable price, a comprehensive presentation of the advances that have been made since 1914 in optical instruments and their application in chemistry and medicine. The book admirably fulfils its purpose. The subjects dealt with are spectroscopy, refractometry, and interferometry. Developments in these regions have been particularly rapid during the period under review, and the author has had plenty of material with which to work. The selection he has made is good and the treatment is excellent.

Each section of the work contains an account of recent improvements in instruments and their employment in the routine examination of solids, liquids, and gases, and in special investigations, together with tables of constants for use in the interpretation of the results of observations, and a useful bibliography. These should prove of value to the worker in any branch of analytical chemistry. The author emphasises the advantages to be derived from a more extended use by chemists of the facilities which optical methods provide for making quantitative measurements. Such methods are undoubtedly neat and rapid, and this admirable survey should tend to popularise their use. In doing so, it will serve a very useful purpose.

NO. 2930, VOL. 116]

Our Bookshelf.

Biologie der Flechten: Entwicklung und Begriff der Symbiose. Von Prof. Dr. Friedrich Tobler. Pp. viii + 266 + 1 Tafel. (Berlin: Gebrüder Borntraeger, 1925.) 13.50 gold marks.

THE original intention of the author was to write a complete account of the lichens, but in this he was forestalled by the publication of Miss Lorrain Smith's "Lichens," with the result that the present volume is confined to a survey of their biology. The historical and modern aspects of the subject are treated as a connected whole and discussed in the light of the most recent work. A full bibliography is given at the end of the book, with brief notes as to the contents of most of the papers.

The author regards the lichens as essentially a biologic rather than a systematic group, the keynotes to the whole volume being metabolism, symbiosis, and the relation of external conditions to the balance of the two symbionts. These views are brought out in discussions on such problems as the relative biologic and systematic significance of soredia and isidia—vegetative methods of multiplication, which are affected by external conditions but occur only in certain lichens, suggesting that their formation may be associated with particular structural types of cortex. The section on physiology includes a survey of the lichen acids, which are interesting as indications of the peculiar metabolism of lichens, and also useful for the identification of lichens, owing to their characteristic colour reactions with certain reagents.

The lichens are regarded as a synthetic group and one particularly favourable for the study of symbiosis. Illustrations are given of all stages from a loose association of fungus and alga to the complex types of symbiosis, where the relationship of the two symbionts is so intimate as to produce a peculiar and characteristic type of morphology and metabolism. This relationship is again closely bound up with external conditions—particularly light and moisture—extreme changes in which are liable to destroy the balance of the two symbionts.

The British Hydracarina. By Chas. D. Soar and W. Williamson. Vol. 1 (Ray Society Vol., No. 110). Pp. x + 216 + 20 plates. (London: British Museum (Natural History), 1925.) n.p.

ONCE more we are indebted to the Ray Society for an arachnid monograph. Instituted in 1844, Blackwall's classic work on spiders was one of the products of its youth. In the 'eighties it gave us Michael's Oribatidæ, to be followed at the beginning of the twentieth century by the same author's Tyroglyphidæ, and now we have the first instalment of the Hydracarina.

The present volume begins with a short historical section, for some reason only brought up to 1842, though later workers have some notice when classification is discussed. An interesting chapter on general characters and life-history follows, and makes it abundantly clear that there is here a large field for further research. The complications introduced by parasitism on the early instars of insects which presently leave the water are responsible for most of the gaps which still

exist in our knowledge of the habits of these curious creatures. The Koenike-Viets classification is adopted without comment, and three families are recognised—Halacaridæ, Limnocharidæ and Hygrobatidæ. Precedence is given to the Limnocharidæ, and about eighty species are dealt with in 126 pages of text, followed by twenty useful—if not sumptuous—plates.

Messrs. Soar and Williamson have begun their task well, and the monograph will be necessary to all interested in this rather isolated group. We confess to finding occasional obscurities of language. For example, "our observations on the hatching of *P. longipalpis* extended over seventeen days" (p. 24) appears from the context to mean that seventeen days was the incubation period; and what is the precise value of observations "stated to have been made by Piersig"? These, however, are small blemishes. We are grateful to the authors and to the Ray Society, which appears to be establishing a "corner" in Acarina. May we hope in due time for a reduction of the chaos which exists in the Gamasidæ and the Trombididæ? C. W.

An Introduction to Palæontology. By Dr. A. Morley Davies. Second impression. Pp. xiii + 414. (London: Thomas Murby and Co.; New York: D. Van Nostrand Co., 1925.)

WE welcome a second impression of the useful little introduction to the study of fossils by Dr. Morley Davies. It is, indeed, a most practical handbook both for the student of geology and the amateur collector, and is admirably designed to give an insight into the methods of palæontological science. It is not a systematic treatise on the various groups, but shows clearly how each is to be studied, and it provides a series of synoptical tables of classification which will suffice for those who are chiefly concerned with fossils as indicators of the age of rocks. There are also in the appendix synopses of the divisions of geological time and the stratigraphical distribution of fossils.

The second impression of the book differs little from the first, except that certain errors have been corrected. It still retains the birds curiously as an order of reptiles intercalated between the crocodiles and pterodactyls. There is also an oversight in describing insects in amber as preserved by the "antiseptic character" of this substance: they are never preserved—they have merely left cavities where they were originally embedded. The descriptions, though always concise and clear, are sometimes overburdened with technical terms which are liable to repel rather than attract the beginner and amateur. One, however, who has plodded through the book with actual specimens of the fossils referred to, will be amply equipped to use special treatises and proceed with independent research. A. S. W.

Department of Scientific and Industrial Research: Radio Research Board. Special Report No. 3: Variations of Apparent Bearings of Radio Transmitting Stations. Part 2: Observations on Fixed Stations, March 1922–April 1924. By Dr. R. L. Smith-Rose. Pp. viii + 107. (London: H.M. Stationery Office, 1925.) 4s. 6d. net.

THIS report discusses the progress of the investigation into the variations of the apparent bearings of radio transmitting stations from March 1922 to June 1923,

when the observations on the longer wave-lengths ranging from 2000 to 9000 metres were discontinued. Observations, however, made at Lerwick, Shetland Islands, from July 1923 to April 1924 are included.

Experiments on the shorter wave-lengths are to be published in Part 3.

The results with the longer wave-lengths prove that when the waves travelled overland, distances ranging from 30 to 200 miles, abnormally large variations were recorded during night time. For distances less than 30 miles, the majority of the direction finder readings had an inaccuracy of about 2°. When the path between the transmitting and observing station is entirely oversea, the errors in the observed bearing were found to lie within the 2° limit for distances up to 100 miles. For most navigational purposes this accuracy suffices. It was found that, within the limits of the experiments, no appreciable effect on the results could be attributed either to the wave-length or to the use of damped or undamped waves.

The Elements of Internal-Combustion Engineering. By Telford Petrie. Pp. xi + 236. (London: Longmans, Green and Co., 1925.) 10s. 6d. net.

AMONG the available text-books on the theory of the internal combustion engine, there are few which present a good account of the subject within a moderate compass and can be recommended to a student in his undergraduate course. This book would appear to satisfy this requirement and is a worthy contribution to the subject. The first three chapters give a brief historical sketch and a descriptive account of the cycles employed in the various types of gas and oil engines now in use, including the Still engine and the Humphrey gas pump. The next five chapters contain a good account of the thermodynamics of the subject, including a chapter on variable specific heats so far as they affect the transformations in an actual engine, the whole of which is well arranged and clearly written.

In the remaining chapters, such matters as the formation of combustible mixtures and temperature effects are dealt with. In the former case the account contains much useful information relating to combustion which should prove of considerable interest to designers as well as to students; in the latter, however, the treatment is necessarily rather superficial, as the various subjects which are included in it could scarcely be dealt with satisfactorily in the space allotted to them. A chapter on the possibilities of development and a collection of good examples conclude the book. E. H. L.

Primer of Arithmetic for Middle Forms. By E. M. Marzials and N. K. Barber. Pp. xii + 262. (London: Oxford University Press, 1925.) 3s. 6d. net.

THIS book is intended to follow a preliminary course up to compound rules, practice, and unitary method. It has many excellent features which make it worthy of consideration by all teachers, but a serious defect is the neglect to train pupils in estimating for themselves the degree of accuracy which may be expected of their results; they are invariably given the number of significant figures required in the answer. It is regrettable that the absurd questions on finding the cost to the nearest penny of papering rooms have not been allowed to die a natural death.

Letters to the Editor.

Violent Spore-discharge in *Tilletia Tritici*.

Tilletia Tritici and *T. laevis* are fungi which cause the well-known stinking smut disease or bunt of wheat. An affected wheat grain becomes transformed into a sack filled with several million, closely packed, minute, brown chlamydospores which, in the mass, have the odour of decaying fish. These spores become powdery and, under natural conditions, are passively dispersed by wind and rain. In the artificial process of threshing, the smut-balls are broken open and much of the chlamydospore-powder becomes adherent to the outer surface of the sound wheat grains. When smutty grains are planted in the soil, the fungus attacks the wheat seedlings and once more gives rise to the smut disease. Farmers in Canada and other countries treat the seed-wheat with formalin or some other poisonous substance. This kills the chlamydospores and greatly reduces the incidence of the disease.

When a chlamydospore germinates on a wet substratum (Fig. 1, A), it gives rise to a short germ-tube or basidium (promycelium) which at its apex produces a crown of from four to sixteen slender rod-shaped structures, called by Brefeld and others primary conidia. These conidia have been regarded by botanists in general as morphologically equivalent to the basidiospores of mushrooms and of rust fungi.¹

The primary conidia, often while still on the basidium as illustrated by Brefeld,² conjugate in pairs, each pair forming an H-shaped structure. The work of Rawitscher³ has shown that, during conjugation, a nucleus present in one of the two conidia passes via the bridging hypha into the other conidium, so that this becomes binucleate. The primary conidia readily become detached from the basidium-body which has borne them, but they are never discharged by that organ in a violent manner.

Each H-shaped pair of primary conidia, while still attached to the basidium-body, or after becoming detached, may put out a short sterigma at the end of which there is developed a sickle-shaped spore, called by Brefeld and others a secondary conidium (Fig. 1, A). Or, if malt-agar or other suitable nutrient medium be supplied, each H-shaped pair of primary conidia may put out a germ-tube which branches and rebranches for a long time and produces singly, at intervals along its hyphae, many scores or hundreds of the sickle-shaped secondary conidia (Fig. 1, B). Each sickle-shaped conidium is produced aerielly on a short conical sterigma to the end of which it is attached in an asymmetrical manner. As in the basidiospores of mushrooms and rust fungi, the axis of the basal part of the conidium is inclined to the axis of the sterigma at an angle of about 45°. Hitherto, no one seems to have suspected that the sickle-shaped secondary conidia are the basidiospores of the stinking smut fungus.

One of us (A.H.R.B.) was struck by the great resemblance of the sickle-shaped secondary conidia and their sterigmata to the basidiospores and sterig-

mata of the Hymenomycetes (mushrooms and toadstools),⁴ Uredineae (rust fungi),⁵ and the three species of the recently described basidiomycetous yeast-genus *Sporobolomyces*;⁶ and it was therefore thought probable that these smut conidia, like the basidiospores just mentioned, are shot away from their sterigmata with the accompaniment of drop-excretion at the spore-hilum. The other author (T.C.V.) of the present communication undertook to test this supposition, with the result that, after overcoming the technical difficulties associated with (1) the germination of the chlamydospores in sterile 4 per cent. malt-agar and with (2) the development of the secondary conidia under conditions in which they could be watched for hours under the microscope, he made preparations which have enabled both of us to witness

FIG. 1.—Diagrams illustrating spore-production in *Tilletia Tritici*. A: a chlamydospore *c*, with its basidium *b* crowned by six primary conidia *p* which have conjugated in pairs; two of the pairs have produced short sterigmata *st* terminated by sickle-shaped secondary conidia *s*, *sub*, a damp substratum. B: a pair of conjugated primary conidia *p* on malt-agar; their germ-tube has developed into a branched mycelium *m*, which at intervals sends up into the air short sterigmata *st*, which bear sickle-shaped secondary conidia *s*. C: stages in the discharge of a single secondary conidium; *a*, a full-grown spore on its sterigma; *b*, the same with a drop of fluid just appearing at the spore-hilum; *c*, the same, about 20 seconds later; *d*, the same, one second after *c*, the spore and the drop have been violently shot from the sterigma. D: a discharged secondary conidium *s*, which has fallen on malt-agar and has germinated; *g*, its germ-tube. Magnification: A and B, 300; C and D, 400.

the violent discharge of the secondary conidia, with the accompaniment of drop-excretion. Since 1883, the year in which Brefeld began to publish his classical researches on the smut fungi, many mycologists, phytopathologists, and general botanists have studied these organisms; but, hitherto, the fact that a smut fungus should display violence in the discharge of its spores has not been observed and does not even seem to have been suspected by any one.

A sickle-shaped spore, under laboratory conditions, takes about an hour and fifteen minutes to develop from a tiny rudiment to full size and to mature. At the end of this time, if all goes well, a tiny drop of fluid begins to appear on the spore-hilum at the base of the spore just above the sterigma (Fig. 1, C). The drop grows visibly, protruding laterally, and, in about 20

seconds, attains a diameter equal to about one and one-half times the thickness of the spore. Then, suddenly, the spore and the drop are shot away from the sterigma to a distance of about one-half a millimetre. The sterigma left behind is apparently unchanged. Under suitable conditions, a thin spore-deposit of discharged spores gradually accumulates. On 4 per cent. malt-agar a spore begins to germinate within an hour of discharge from its sterigma (Fig. 1, D).

Sometimes abnormalities in spore-discharge may be observed. (1) A spore may grow to full size in the usual time, but there may be no drop-excretion at the hilum and no discharge. One spore remained seated on its sterigma unaltered for three days. (2) A spore may grow to full size and then, within an hour, may germinate at its apex. Such a spore never excretes a drop of fluid and is never violently discharged. (3) A spore may grow to full size and then, within an hour, a drop may be excreted at the spore-hilum; but the drop and spore are not discharged. Instead, the drop may run up the spore and then grow to an abnormally large size about the middle of the spore. The drop may dry up slowly and then the spore, while still seated on its sterigma, may germinate by sending out a germ-tube at its apex. The failure of the drop to be excreted and excessive drop-excretion, accompanied by failure of the spore to be discharged, as just described, have been observed by one of us as not infrequent abnormalities of the spore-discharge mechanism both in the Hymenomycetes and the Uredineæ.⁷ Also in *Puccinia graminis* the same author has observed that a basidiospore, which has failed to be shot away, often germinates *in situ* at its apex.⁸ Thus the abnormalities connected with the phenomenon of spore-discharge in the secondary conidia of our stinking smut fungus find their exact parallels in the abnormalities one may witness in a mushroom or in the fungus which causes the black stem rust disease of wheat.

Our discovery that the sickle-shaped spores or secondary conidia of Brefeld and others are violently shot away from their sterigmata, with accompanying drop-excretion at the spore-hilum, is of considerable theoretical importance; for it not only confirms with new and weighty evidence the correctness of the view generally held by botanists that the Tilletiaceæ belong to the great group of the Basidiomycetes, but it also allows us to draw the following new conclusions: (1) the so-called secondary conidia of *Tilletia Tritici* and of other species of *Tilletia* are in reality the true basidiospores; and (2) the sporidia or primary conidia of Brefeld and others are morphologically equivalent to sterigmata. Finally, it seems to us probable that further research will show that our new conception of the basidium in the genus *Tilletia* may be successfully applied to the basidia of the other genera of the Tilletiaceæ.

Wireless Time Signals: Changes in the French Issues.

FOLLOWING a series of resolutions adopted at the meeting of the International Time Commission at Cambridge in July last, certain changes will be made in the issue of time signals from radio stations in France, commencing on January 1, 1926.

⁷ A. H. R. Buller, "Researches on Fungi," vol. 2, 1922, pp. 18, 308-310; vol. 3, 1924, pp. 500-509.
⁸ *Ibid.* vol. 3, Fig. 203, p. 503.

The present series of signals from the Eiffel Tower [FL], Lyons [Douai, YN] and Bordeaux [Lafayette, LY] will be withdrawn and will be replaced by the following series:

No.	G M T.	Signal	Station	W.L.	
1	8 0	International and Rhythmic Signals	FL	2,600	Spark
2	8.0	International and Rhythmic Signals	LY	19,000	CW
3	9 30	International	FL	2,600	Spark
4	20 0	International and Rhythmic Signals	LY	19,000	CW
5 6, 7	22 45	Old Semi-automatic Signal Short-wave emissions—see below.	FL	2,600	Spark

This series will be put into operation in the first instance for a period of four months, after which it is contemplated that No. 3 may be withdrawn and No. 5 replaced by an issue of the International and Rhythmic Signal from FL, simultaneously with that from LY at 20^h. By that time it is expected that the issue on spark from FL will be replaced by an issue on modulated CW.

In the meantime the issues Nos. 3 and 5 will take the same form as hitherto, and for ordinary users the only service which is withdrawn is the issue of the Old Semi-automatic Series from FL at 10^h 45^m.

The form taken by the issue No. 1 is the following:

- [a] Preliminary signal.
- [b] Times of issue of rhythmic signal of the *previous day* as determined by the *Bureau International de l'Heure*, Paris.¹
- [c] Commencing at 7^h 57^m 55^s, the International Signal as hitherto, except that the three dashes which have constituted the Time Signal are to be replaced by six dots, commencing at the seconds 55.0, 56.0, 57.0, 58.0, 59.0, 60.0 and lasting each about 0.2 sec.
- [d] Commencing at 8^h 1^m 0^s, a new rhythmic issue of 306 signals, falling as follows:

1 ^m 0 ^s ,	1st dash followed by 60 dots.
2 ^m 0 ^s , 62nd	" " "
3 ^m 0 ^s , 123rd	" " "
4 ^m 0 ^s , 184th	" " "
5 ^m 0 ^s , 245th	" " "
6 ^m 0 ^s , 306th	" " "

The commencements of all these signals are to be evenly spaced; the commencements of the dashes are intended to fall precisely at the commencements of the seconds of mean time and they will be each about one-half second in duration; the dots will be about one-fifth of a second in duration.

Besides these issues upon the wave-lengths hitherto employed by FL and LY respectively, issues Nos. 6 and 7 will be made at 8^h and at 20^h simultaneously with the other issues, by the station FL on *short wave-lengths*, namely, 32 metres and 75 metres, on the same pattern as the issues Nos. 1, 2 and 4 above, during the probationary period of four months. After that, it is contemplated that one or other of these wave-lengths may be suppressed and the other retained permanently in addition to the series [1]-[5] above.

A period of probation of four months has been adopted in order to ascertain how far the new issues meet both general and scientific requirements.

Any comments which are the result of experience on the working of the new issues, or upon the abolition of the old issues, should be addressed either to *M. le Directeur, Bureau International de l'Heure*,

¹ An intimation received since this circular was prepared places [d] subsequent to [d], commencing at 8^h 6^m 5^s or 20^h 6^m 5^s.

Observatoire National, Paris, XIV^e, or to the undersigned.

They should arrive not later than the beginning of March.

President, International Time Commission.
Royal Observatory, Edinburgh,
December 10.

Experiment and Philosophy.

THIS letter is a dogmatic rejoinder to nobody in particular.

There is a wise Scots saying which warns us against showing half-done things to "bairns and fules." It ought to hang as a text by the bedside of every scientific researcher, with a note appended that "bairns" is to be glossed "non-scientific thinkers and the educated public." The Great Educated Public thirsts, very properly, for knowledge; but it loves best, if it can, to get the wine of learning all raw from the presses, dispensed by the vintners themselves, and to suck it up through the sweet straw of analogy. Of late years there has been a remarkable indulgence of this crude taste for "the last word in science"; and one immediate result has been that a good many metaphysically-minded folk have hastily engorged certain possibilities, perceived and put forth by men of science to be further tested by men of science, but forming draughts too heady and unmaturing for the novice. Dazzling themselves with the tentative speculations of science, such pseudo-philosophers comfortably conclude—see them at it in any of the current reviews—that, after all, the scientific method can now be proved (with the aid of its own results!) to be merely argument in a circle.

So: all is well; the lamb of mysticism can now lie down with the lion of science, for the poor lion is exposed as nothing but a cud-chewing ruminant. Surely it is time that the lion gave a gentle roar or two, if only as a salutary reminder to the lamb who skips up bleating for more room than the lion is ready to concede?

The root of the trouble seems to lie in this: that non-scientific people are in such impetuous haste to "know" (as they are pleased to call the process of "being informed") that they will not understand the need to wait patiently for years—in large questions, for centuries—before suspicions now private to first-hand inquirers can be turned into public assertions. "Here's the latest," they seem to say; "let's have it; fling away what went before it and what went to make it." Yes; and fling away *this* latest, too, in a little while, so soon as real science shall have caught up with it and have made it a trifle dull and *démodé* because surer and better-balanced; and fling away, at the ghost of a permissive hint, whatever may any more obscure the glorious verities of untutored guessing. "How much better and finer it is (besides being much less trouble) to be able at last to ignore, as of old, the figments of science! (Of course, we don't mind using soap, we don't mind telephoning to our doctor to come quickly in his car to diagnose and cure our ailments, or to the surgeon to save our lives and minds—these scientific figments we tolerate, for we like them!)"

All this would not matter very much—the unlearned will perhaps know better in a few generations—if it were certain that it will not prejudice experimental science. But we buy a book purporting to teach the experimental man of science the inwardness of his business; we expect, perhaps, a helpful exposition of Whitehead's sane, lucid, and logical "Pan-physics," or else the elements of logical inference; but we get a

confounding blend of two or three universes of discourse, an ambitious and premature synthesis of the only partially-analysed, which leads the working human reader into a barren and impotent finality.

The motto of this journal, Wordsworth's sentence, surely abides, nor can it be wrested from its meaning by crying (with the materialists of last century) that Nature includes all mind. No experimenter holds, in his inmost soul, the converse; namely, that mind includes all Nature, has indeed created it; nor will he admit, for generations still to come, that our real knowledge yet suffices to probe the vast theorems that our hurrying philosophers broadly accept as already settled. Of those lugubrious thinkers, those reactionaries whose claim once again is *Totam Asiam peragraré*, and who seek to cast three hundred years of patiently-won lore into the melting-pot, to gain the Indies out of the crucible: of these none are experimenters. They are like the jaded urban hero in the story, whose regeneration depends on his coming "close to the green and growing earth"; they have attenuated honest sense-facts by unremitting abstractions to the *n*th degree; they have lost the last touch with reality.

The working man of science at least has his feet well planted in the solid ground of observation; and if the soaring philosophers accuse him, on the contrary, of having his head too tightly embedded in that same ground, let him at all events show them that his protruding extremities nevertheless have not lost the power of vigorously kicking.

THOMAS HOBBES, Junior.

A *pp'* Group in the Arc Spectrum of Zinc.

ONE of us (R. A. S.) in a study of *pp'* groups in atomic spectra, which will be published in full later, has observed that in many two-valence-system spectra the frequency of the first *pp'* group is nearly a mean between the frequency of the first line of the principal series of singlets in the spectrum and the first line of the principal series of doublets of the once more ionised atom.

The rule holds for the *pp'* group in cadmium given by Ruark (*J.O.S.A.*, vol. 11, 1925, pp. 199) where we have

Cd I, 1S	-2P	$\nu = 43691$
Cd I, 2p ₁	-2p ₁ '	$\nu = 44088$
Cd II, 1s	-2p ₁	$\nu = 46618$

We were accordingly led to apply this rule to zinc where an exactly analogous group to that in cadmium was easily located.

The complete cadmium group as given by Ruark is:

λ .	Int.	ν	Classification.
2329.27	10R	42918.6	$2p_2 - 2p_1'$
2306.61	5R	43340.3	$2p_1 - 2p_0'$
2267.46	5R	44088.6	$2p_1 - 2p_1'$
2239.86	5R	44631.7	$2p_0 - 2p_1'$
$\Delta p_1 p_2 = 1170.1$, $\Delta p_0 p_1 = 543.1$			
$2p_1' = -2206.6 \text{ cm.}^{-1}$			

The group is anomalous in that only four lines appear instead of six lines as in a normal *pp'* multiplet, but the classification is fixed by the known Zeeman pattern of the line $2p_1 - 2p_0'$.

In zinc we find a similar group of four lines which we have classified as follows. The wave-lengths of Eder are used.

λ .	Int.	ν	Classification.
2104.34	2	47505.7	$2p_2 - 2p_1'$
2096.88	2	47674.7	$2p_1 - 2p_0'$
2087.27	2	47894.0	$2p_1 - 2p_1'$
2079.10	2	48082.2	$2p_0 - 2p_1'$
$\Delta p_1 p_2 = 388.3$, $\Delta p_0 p_1 = 188.2$			
$2p_1' = -4629 \text{ cm.}^{-1}$			

This group obeys the rule stated in the first paragraph as follows:

Zn I, $1S - 2P$	$\nu = 46745.8$
Zn I, $2p_1 - 2p_1'$	$\nu = 47894.0$
Zn II, $1s - 2p_1$	$\nu = 49354.7$

It also has within reasonable limits the separations of the known $2p$ levels of zinc which are:

$$\Delta p_1 p_2 = 388.9, \Delta p_0 p_1 = 189.8.$$

The Zeeman pattern of none of these lines is available so far as we can find.

We have been permitted to examine these lines on a spectrogram taken with a Hilger E 1 quartz spectrograph by Dr. R. V. Zumstein, National Research Fellow, at the University of Michigan. All four lines are sharp and like in appearance, although $\lambda 2087$ appears to have a close diffuse companion barely resolved from it on the short wave-length side. There is a fifth line which might conceivably belong to the group, although its diffuse character would seem to exclude it. This line is

$$\lambda 2070.11 \quad \text{Int. I} \quad \nu 48291.2$$

If this line were classified as $2p_1 - 2p_2'$ and the short wave-length companion of $\lambda 2087$ classified as $2p_2 - 2p_2'$, we should then have a normal pp' triplet group. In view of the fact that $\lambda 2070$ is diffuse and quite different in appearance from the first four lines, we hesitate to make this assignment. It may be said in favour of it that the diffuse companion to $\lambda 2087$ mentioned above might be interpreted to mean that p_2' has a diffuse nature. We know, however, of no similar example of this sort.

On a New Device for the Study of the Compton Effect.

ACCORDING to a recent tentative suggestion of W. R. Smythe, a study of the intensities of the Compton modified scattered X-ray spectrum lines might serve to prove whether the electrons effective in the scattering which produces the modified radiation are completely "free" or whether they are "bound" to atoms of the scattering substance. If "modified" scattering is produced by free electrons only, then the intensity of the modified line should be jointly proportional to the intensity of the incident radiation (number density of radiant corpuscles) and to the number of free electrons present. But this latter is itself at least roughly proportional to the intensity of the incident radiation, since it is safe to assume that most of these free electrons are rendered so by the photoelectric action of the incident X-radiation. Hence the intensity of the modified scattered line should vary roughly as the square of the incident intensity, or at least as some greater power than unity of the incident intensity.

Up to the present date, so far as I am aware, it has been necessary to study the Compton effect by very greatly prolonged X-ray exposures, or by ionisation chamber methods requiring extremely powerful X-ray tubes for the incident intensity, and very sensitive electrometer methods for detecting the presence of the lines. This is largely due to the fact that the original radiation must be scattered twice in succession, once to obtain the effect and once at an analysing crystal. The photographic exposures are frequently

prolonged to 100 or 200 hours' duration and occupy a good portion of the life of an X-ray tube.

In order to investigate Smythe's suggestion, and for other purposes, I have constructed an X-ray tube of special design in which both scattering substance and analysing crystal are contained in a small metal box mounted on the end of the anti-cathode. The distance from the source of primary X-rays to the scattering material is so greatly reduced that the radiation available for the scattering is of the order of two thousand times more intense than that heretofore available. *It has been found possible to produce photographic spectrograms of the Compton effect with this apparatus in thirty seconds that would by previous methods have required a hundred hours' exposure.* Very moderate currents such as 5 ma. suffice for exciting the primary X-radiation. The possibilities of such an apparatus for high dispersion studies and many other purposes will be immediately evident to any one familiar with this field of work.

Preliminary studies with the new "target spectrometer" seem to show very little evidence for any intensification of the Compton modified lines greater than a strict proportionality to the incident intensity would require. It is too early, however, to decide this question with precision. If Smythe's tentative prediction is not eventually supported by experiment, then the theory that bound electrons are responsible for the observed "softening" of X-radiation scattered by light elements is strengthened.

Work is now in progress with the new apparatus which I hope will decide the above-mentioned question. A study of the fine structure of modified and unmodified lines by means of the new instrument is also under way. One of the novel features of the present target spectrometer is that it permits the study of radiation that has been scattered at an angle of almost exactly 180° . This angle offers several advantages in the study of the fine structure of the modified line.

Genes and Linkage Groups in Genetics.

I WOULD like to ask Prof. MacBride to clear up one point in his review in NATURE for November 28, p. 776, for otherwise those who are not geneticists may be led astray.

Prof. MacBride writes of "the crude conception of the linear arrangement of the genes in the chromosome, and the idea of crossing-over." He is here, however, confusing two distinct points: (1) the linear arrangement of genes within linkage-groups, and the phenomena of partial linkage; and (2) the identification of the linkage-groups with the chromosomes. Even if the latter were disproved, the evidence for the former would remain in its entirety, and it is with this alone that I wish here to deal.

Mendelian differences do occur; some genetic bases for them exist ('genes'); genetic research, starting from Bateson's fundamental work on coupling and repulsion ('linkage') has shown that they exist in groups, and that within each group they are in orderly arrangement; and finally, Jennings has shown mathematically that a linear arrangement is the only one so far proposed which will fit the genetical results.

These seem to most biologists to be important facts; and if Prof. MacBride will admit them, I should feel that there was a common basis for discussion. He does go on to discuss 'linkage,' but it is not clear to

me what exactly he intends. If there be any other explanation of the genetical linkage-results than what, following Morgan, I have given above, it is important that it should be fully and clearly set before us

JULIAN S. HUXLEY.

King's College,
Strand, W.C.2.

THE confusion is in Prof. Huxley's mind and not in mine.

Of course, I recognise that there are such things as 'linkage groups' and that these must have some basis, but what that basis was I thought that I had made clear in my review. It is, I believe, an impairment of what for want of a better name may be called the 'developmental energy' of the organism which leads to an inhibition or slowing down of one or more of the independent processes of growth which make up its development.

The so-called 'genes,' 'unit factors,' or 'mutations' that are linked are so many symptoms or results of this weakening. According to its intensity, more or fewer of them may make their appearance, hence the variable character of the linking. The alleged 'orderly arrangement' of genes within each group is in my opinion a figment of the imagination to which, so far as I am aware, Dr. Bateson has never committed himself.

Jenning's 'proof' that the linear arrangement of the genes is the only one mathematically possible is, like so many examples of 'proofs' given by this school, a fine example of reasoning in a circle, for it assumes the breaking of the chromosome and the 'crossing over' of its pieces, which, as I have shown in the review, is a physical absurdity. I am confident that when the same physiological analysis is applied to the development of *Drosophila* which has been employed in the case of *Vertebrata*, its many mutations will be seen to be the multiform effects of a few simple causes, and I should like to remind Prof. Huxley that Johannsen, perhaps our foremost geneticist, has expressed a desire that the term 'unit-factor' should be proscribed, for the change to which we give this name is merely, he says, a "disturbance of the chromosomes." With this opinion I cordially agree.

E. W. MACBRIDE.

Moulting of Insects.

THE usual explanation of moulting, namely, that the chitinous integument, being elastic only to a limited extent, cannot keep pace with the increase in size of a growing insect and is therefore periodically shed, does not seem to have a very strong foundation. While experimenting upon the effect of starvation on insects, I have incidentally observed the following facts which strongly tell against such an explanation:

As is now well known, the usual length of the larval stage in *Tenebrio molitor* (the common meal-worm) is 7-8 months, during which they moult 14-15 times. When the worms were intermittently starved, the larval period was extended to so many as 18 months, during which they moulted 30-31 times. The interesting point to be noted is that the size and weight before pupation of the 18 months' old larvæ (starved) and of the normally fed 7-8 months' old worms were the same. Since the ultimate size and weight remain the same, then, if moulting is simply to allow growth, there is absolutely no necessity for extra moults. Moreover, in one experiment, in which the worms were completely starved for 5 months and were actually losing weight and shrinking in size, the larvæ moulted 4 times, though, of course, this

number was smaller than that in the normally fed individuals.

A similar state of things was observed in *Pieris brassicae*. In this species the larval stage extends over about 3 weeks in Great Britain (August). Starved caterpillars, which pupated about one month later than control individuals, moulted five times instead of four times, as is usual for this species and as was done by the normally fed individuals. The size and weight of both the starved and the control caterpillars just before pupation was almost the same.

Evidently, moulting cannot be solely and possibly is not mainly correlated with growth, because while growth does not exhibit itself unless there is a moult, the process of moulting can occur without being followed by growth. F. Balfour Browne, while rearing dragonflies, also observed that while some moults were followed by an increase in size, in the case of others the individual did not show any such increase (*Proc. Zool. Soc.*, 1909). That the number of moults is in proportion to the length of the larval life is better explained by considering that moulting is primarily connected with metabolism. Totally starved meal-worms moult less frequently than normally fed individuals, because their metabolism is at a low ebb.

Rate of Growth of Fungus Rings.

IT is well known that on air-photographs of the chalk downland, fungus rings are often very clearly shown. Sometimes they form the most prominent objects on the photograph and their size is considerable. It has been noticed that they are best developed upon land which has not been under plough for a very long time: in fact they seem never to occur well developed on land which has been ploughed at some time during the last century or two and afterwards reverted to grass.

Before investigating this matter further on the air-photographs here, I should be grateful for information as to the rate of growth of these rings. Is it possible to tell the age of a ring from its diameter? I would gladly lend prints showing fungus rings to any one who is interested in this branch of study and might be able to supply reliable information on the subject.

Einstein Shift and Doppler Shift.

MAY I ask whether the Einstein shift of spectral lines is supposed to be due to some change of frequency associated with an atomic occurrence while generating waves, or to direct influence of the gravitational potential on ether vibrations after they are generated.

For example, I suppose the observed shift in light from the companion of Sirius occurs in light primarily emitted, and not merely scattered, from that star. The light from a differentially moving dark satellite would exhibit to us a differential Doppler effect, but the satellite would presumably not affect the light borrowed from its primary with an Einstein shift, however concentratedly massive it might be.

I am not sure that this is correct: hence my question.

OLIVER LODGE.

December 8.

Evolution.¹

By Sir OLIVER LODGE, F.R.S.

THE word "evolution" is often employed as an antithesis or opposition idea to creation; and it is quite possible that when Herbert Spencer was trying to extend ideas derived from Darwin as to the natural processes by which species had originated, and to apply them to the production of everything, that some idea of that kind was in his mind. He probably felt that he was exploding the popular idea of a sudden creation, a sudden production of things by a creative fiat, and substituting a long, slow, and gradual process, by which the simple evolved into the complex, and the potentialities latent in the atoms of matter became unfolded, developed, evolved; thus substituting or replacing a personal process, guided by something like will and intention, by an atomic and, so to speak, mechanical operation among the things themselves.

How mind and consciousness could come into such a scheme was scarcely known, though there were and had been guesses about that too; and the doctrines called "parallelism" and "epiphenomenalism" were sustained by different philosophic writers. Indeed, how life, even of the lower organisms, originated, was never answered; and though many attempts were made, all over the world and for centuries, at spontaneous generation (some of them in late years by Charlton Bastian at King's College, London), they never succeeded in producing life except by faulty experimentation. It was gradually established, and accepted by Huxley, that life only proceeded from antecedent life, so far as our experience went: that if all vital germs were excluded, no life, even of the lowest kind, appeared.

It was research on these lines which summoned the great Pasteur from chemistry to biology. It laid the foundation for his theory of disease, and it was the noble work of Lister to apply it with beneficent results to surgery. Thus and by all these channels was emphasised the doctrine of biogenesis: that life alone could produce life. Life produced itself; still, however, in its various forms, by a process of evolution, and by no act of special creation. The vital steps were gradual and could all be followed, once given the germ of life. The origin of life itself was left as an insoluble mystery, or rather as a mystery to be solved by science at some future date. It was thought, at any rate by some, that once life made its appearance in the scheme, the evolution of mind was only a further step in the process. Mind was apparently a stage ahead to which life might aspire, for life in the course of ages might blossom into mind.

The attempt thus to explain evolution as a gradual self-acting process was a legitimate one, and contained, as we now see, many of the elements of truth. It led to a materialistic philosophy, which for a time held the field, and attracted the attention and the enthusiasm of a multitude of workers. It was, however, not the whole truth: it was a working hypothesis. It went a certain distance with success, and only gradually were its weaknesses perceived. It was not so much wrong as incomplete. It sought to account for things it could not account for. But as an intermediate step it was

helpful and stimulating, and invigorated the science of biology with a working hypothesis which has proved of great service. It served as a clue or guiding light among a multiplicity of phenomena which without it had seemed detached and disconnected; and it stimulated observation and experiment to a remarkable degree. It carried workers a long way, and it carried enthusiasts too far. It led to the exclusion of mind or purpose from the universe, and replaced it by mechanism. If a materialistic philosophy had worked, it would have been justified by results. But it was incomplete; and gradually its weaknesses and omissions became apparent; so that by this time, as a complete account of the universe, it is recognised as insufficient and faulty. The mistake—if it can be called a mistake—lay in the thoughts or contentions of those who put it forward as in opposition to the idea of creation, instead of regarding it as a method of creation.

The old idea of creation as a sudden achievement without intermediate steps, without any process that could be followed by the human mind, and without any extensive lapse of time, was seen to be erroneous. Yet, amid much crudity, most of us now perceive that it contains some elements of truth; just as the working hypothesis of mechanical evolution did. The time was not yet ripe for identifying and unifying the two. They seemed to be in the field as opposition theories, one against the other. They seemed to be mutually exclusive; so that if one were accepted, the other must be rejected.

Whether this opposition of the two views was seriously in the mind of the philosophers of that period may perhaps be questioned; in all probability it sometimes was. Among the rank and file it certainly was: many half-educated people leapt to the conclusion that the universe could be explained on mechanical principles and in terms of matter, and that in matter could be found the full potentiality of life and mind and everything that we have so far discovered or experienced in the universe. Whether or not that was the intention of the leaders may well be doubted. Huxley himself made it abundantly clear that in his view a materialistic philosophy had its limits, and that consciousness could not thus be accounted for. Nevertheless the two views, in the popular mind, were in opposition; and it led to alarm among the Churches at the doctrines of Darwinism and at the teachings of evolution generally. This feeling of antagonism between the two views, and the feeling of alarm and dislike of one of them, has survived in certain States of America, and has led to an attempt to suppress the disliked view by legal enactment.

However irrational this procedure may be, there is some excuse for it; and it is possible to regard their conscientious action with sympathy, even though the sympathy is mingled with amusement. Not in that way is truth really served. Freedom is the life-blood of science; and freedom is only consistent with the power of making mistakes and going wrong, as well as with the power of ascertaining truth and going right.

Crudities were not confined to one side of the controversy. Old doctrines of creation were crude; new doctrines of evolution were equally crude: and either

¹ From the Huxley Lecture delivered at Charing Cross Hospital on Thursday, December 3.

side could have their teeth set on edge by the other. Young and enthusiastic teachers, perceiving only one side of the problem, could rush into extremes; could not only uphold their own view, but also could pour scorn upon the other. Since the sectarian differences between religious bodies had led to the suppression of what may be called Biblical teaching in State schools, as the only alternative to strife and sectarian controversy,—since the freedom of the orthodox was limited, and they were prevented from teaching the young their own special and detailed creeds,—it became obnoxious to allow perfect freedom to the opposition side, which took no interest in sectarian controversy, but would gladly sweep away the whole of the doctrines associated in the popular mind with the mysteries of religion. Sectarian differences had limited freedom on one side; it seemed time to limit freedom on the other too; and that, I take it, is the explanation of what otherwise seems an irrational and foolish procedure.

There are, I know, a multitude of people in Great Britain who still feel the fundamental opposition between the two views, and some who in their heart sympathise with the action of those Southern States who have put the law in operation against one of them. There is always some justification for any human action which is well intentioned and sincere, however mistaken it may be. We are all of us constantly making mistakes: the proverb says that "it is human to err." It is part of our training to be able to make mistakes with perfectly good intentions, one of the mistakes being to think that we have an infallible guide when we have not. Infallibility has not been granted to man. We have to make our way among pitfalls and obstacles, to make progress slowly and with difficulty, and gradually to learn what is true by finding what is false; never learning the whole truth—for that we could not apprehend—but making our way towards the truth, in a blundering but persevering manner.

The very documents to which some of the ultra-orthodox pin their faith are full of misstatements and errors committed by humanity in the past; and however full they are of inspiration—as in many parts I am sure they are; much more, as I think, than some educated people are always inclined to admit—yet they are human documents, full likewise of the mistakes, misinterpretations, slips and errors appropriate to the human vehicles through which they have come. It is our business to try to sift the true from the false, the genuine from the mistaken, the misinterpretations of scribes, the faulty reports of occurrences, and thus to dig down to the underlying essence, which gives these documents their supreme value.

The book of inspiration, by which I mean the thoughts of the great thinkers and seers and saints and prophets of all time, is one avenue of truth: the book of Nature, explored by a multitude of energetic workers, that is to say, the book of science, is another. In so far as both are true, they cannot be in opposition. In so far as either is mistaken, opposition is inevitable; and although the virulence of the opposition is now greatly mitigated, and is not fierce and uncompromising, as it was even in the lifetime of some of us, some amount of opposition exists still. Indeed, in the minds of half-educated people its virulence is still manifest, and some fierceness of opposition still subsists to this

day. It is so easy to take one side only of a controversy, to regard that as completely right, and the other as hopelessly and completely wrong. We find this attitude even in party politics. We find it more or less in the forensic activities of counsel in the law courts. It is understood, there, as a method of laying the case before the judge, to whom is left the impartiality of scrutinising the evidence for what it is worth, and coming to a judicial and balanced decision.

We ourselves, however, in our own minds and with our own responsibility, are both counsel and judge. There are moods in which we emphasise one side; there are moods in which we emphasise the other: but ultimately we try to hold a balance between them, and we doubtless hope that our ultimate convictions will be based on the evidence, and will lead to a true and impartial verdict.

My thesis is that there is no essential opposition between creation and evolution. One is the method of the other. They are not two processes, they are one—a gradual one which can be partially and reverently followed by the human mind. We have the right to study the methods so far as we can, the right to probe into the manner by which the manifold things around us are interrelated, and how they have come into their present form. We try to set forth the physical processes in detail, and for that special purpose to limit ourselves to the mechanical, the physical, the chemical, the calculable, and the directly observed, without the least trace of impiety, and without being reasonably accused of denying a great tract of country which is not on our beat, which we are not exploring, and which, though through lack of time and energy we perforce neglect, we do not (if we are wise) ever think of denying.

[Then followed an account of the process of cosmic evolution so far as modern science is able to formulate it, based upon the work of Eddington and Jeans. The question was then raised as to whether a linear process of evolution—a procedure in time with a beginning and an end—was likely to be the last word, or whether there was any way of overcoming the dissipation of energy and prospective stagnation.]

Now consider what happens when light of all kinds, ultra-violet light, X-rays, and all others, encounters a particle of dust, or, in other words, some atoms of matter, which have been driven to the confines of space by the pressure of light. What happens has been investigated in our laboratories, and is known as photo-electricity. An electron jumps out of the atom: the atom is ionised.

This ionisation of matter by light is becoming, or is likely to become, familiar in medicine. The photographic and chemical actions of light are constantly being studied, its action in polymerising sap in the leaves of trees and vegetation generally, the action of light on the skin also, and its familiar though remarkable effect on the nerve-supplied retina of the eye. How are these chemico-physical actions to be accounted for? Surely by the photo-electric property; that is, by the power of waves of the right frequency of vibration to eject an electron from an atom. An immense amount is now known about this process. Electrons are

revolving in fixed orbits inside the atom, as conceived by Prof. Bohr, and under the stimulus of radiation they jump from orbit to orbit as birds jump from perch to perch. An incoming wave can make them hop to a higher twig, or else fly away altogether.

This last process is called ionisation; for the atom, having lost an electric charge of one sign, is now charged with the opposite sign: it is an ion; it is no longer neutral and inert, it is active and chemically fierce; it is no longer satisfied, it seeks to combine with another. Chemical affinity is in full blast, and the molecular changes in protoplasm, in silver salts, and in the leaves of trees, occur. In the retina the nerves are bombarded by the ejected electrons, each striking with an energy appropriate to the frequency of the received vibrations, and thus give the different colour sensations through the extraordinary interpretative power of the mind through its organ the brain.

The destructive influence of this action on micro-organisms such as an anthrax bacilli, when they are exposed to ultra-violet light, is well known; and the health-giving power of these same ultra-violet rays—at present so sadly and wastefully and thoughtlessly obscured by the atmosphere of towns—is constantly receiving more and more expert attention.

Surely here we have a region of physics of great use in preventive medicine: a lavish supply of ultra-violet light is sent us by the sun; it only remains for us to enable this light to reach our bodies and our homes. We know how to generate such radiation in the laboratory also, and can use these rays for curative rather than for preventive purposes. A study of radiation—radiation of all kinds—has proved of late years intensely illuminating. Thereby that mysterious but fundamental entity, the quantum, has been detected; thereby the temperature, the constitution, the age, the speed, the history, of the various cosmic masses has been and is being elucidated; thereby the formation of wood, and the growth of vegetation on which animal life depends, has been explained; and now the sanitary and invigorating and beneficent work of sunlight on the human organism is being more and more appreciated, and more and more studied and applied by those who have the requisite training, who will watch for the dangers of excess, and regulate the appreciation of any kind of ray with patience and wisdom. I hope that a recognition of the electric and ionising power of such rays, which I urge as a reasonable explanation of their chemical and physiological activities, may be a hint in the right direction to those engaged in this work.

Reverting now to what I was beginning to deal with, namely, the hypothetical effect of stray or apparently waste radiation when it reaches the confines of space and encounters the supposed age-long accumulation of cosmic dust, which pictorially and for the present purpose we represent as more localised than it is at all likely to be; it may be said that the light, when it has travelled to those enormous distances, will be too feeble to do anything; but apparently it is not so. The jump of the electron is effected, not by the energy of the light, but by its frequency, its rapidity of vibration; and that is just the characteristic which it will retain unaltered, no matter how far it goes, or how weak it gets. Light of the critical frequency—which depends on the nature of the atom and the position of

the electron in it—will be able to ionise it, however impoverished by wide-spreading the light is.

It is true that the number of electrons liberated depends on the intensity of the light, though the energy of each does not so depend. If the light is very weak, the number of ions formed will be few, but the area available is enormous. Nothing like such an area of matter exists in the visible cosmos. If only one or two ions a second were formed per square kilometre, the loss of matter from millions or even billions of suns could be compensated.

Now consider what happens when an atom is ionised. It has lost a negative charge: it has therefore become a positive ion. The negative-charge has gone away, and will attach itself to some other atom, which thereby becomes a negative ion. Sooner or later the two may meet. They will not discharge into each other; that is not what happens; they will combine to form a molecule, a chemical compound. The process of chemistry has begun; under the influence of light.

We are evidently returning to the stage at which we begin the consideration of the course of evolution. Radiation gives up its own being, the energy takes the form of electrical separation. It then takes the form of chemical combination: aggregates of matter are formed. This aggregation may go on until the particles begin to feel the effect of the gravitative attraction of the far-distant cosmos. No longer will the particles be sustained and separated and driven away by light. They are now big enough to have effective weight; and slowly they will begin to make their way back; bringing with them in potential form the lost and radiated energy; and so begin once more the clash of atoms, the formation of nebulae, the birth of stars, and ultimately of planets.

It may even be that fresh matter in the form of electrons and protons can be *generated* by radiation, apart from its photo-electric effect on already existing matter. To me it seems not unlikely. But that is going outside our laboratory knowledge: of that process of "beknotting" in the ether we have as yet no inkling. A knowledge of that may come, but not yet. Meanwhile we have something which, if not sufficient, seems at any rate a step towards reconstruction, rehabilitation, regeneration.

Some may feel this doctrine depressing, and ask: Is there then no progress, no increase of value, no real improvement, nothing but a universal level of uniformity, so that what is always has been and always will be, not only without change and decay, but also without rise and advance? That is not the deduction that we are entitled to make. For remember that we have been dealing with the physical universe only; we have not touched on the universe of mind, soul, spirit, or any of the emotions and faculties of man. We have been studying the course of physical evolution, and have imagined it as evolving in a cycle. I believe that is the essence of the physical universe, to follow a cycle, round and round:—The plant assimilating inorganic materials, elaborating them into food for animals, the animals returning them in the inorganic form, ready for the plant; energy taking the potential form, then the kinetic, then the potential again, and so on alternately for ever; water evaporated, rising as vapour, then falling as rain, getting back into the sea, and being

evaporated again. Everywhere we find a cyclical process in the material universe.

What about the mental universe? Surely there we find growth, development, increase of value, rise in status; the lower organisms becoming intelligent creatures, then developing into man. And what of man? If his death is the end of him, the value of his existence may be doubtful. But if, as I know, that is not the end of him, then there may be infinite progress in store. The cyclical machinery of the physical universe is employed to develop value in the mental and spiritual universe; just as the revolution of a fly-wheel may be the means of turning out a woven fabric

of beauty and design. The fabric will age and turn to dust: so may a picture or a statue. But what about a poem or a piece of music? They have in them the seeds of immortality, and if great enough, will last so long as humanity endures. All things last for ever, if what we have been saying is true; but while the physical things last by a kind of evolution of cyclical change, the evolution of spiritual things has no necessary regress. They advance continually through higher and higher stages towards perfection. This, I take it, is the real meaning of evolution. This is why the physical universe exists. This is the real aim and purpose of the ultimate and infinite term "God."

Surveys of the Great Pyramids.¹

By Sir W. M. FLINDERS PETRIE, F.R.S.

THERE seems a periodicity in the attention to the size of the Great Pyramid: the French survey 1799, Howard Vyse 1838, my survey 1881, and now Mr. Cole's survey in 1925, are at nearly equal intervals. The difficulty in measurement results from the Arab destruction of nearly the whole of the fine sloping blocks of casing, about 3 feet thick, thus leaving the inner core of masonry in steps, and further, the banking of the ruins up to 20 or 30 feet against the faces, which obstructs the base. The last remains of the lowest course of casing are only a short length in the middle of each side, and the purpose of this recent survey was to utilise more of these points of the original casing than had been seen before, such being more accessible since the removal of large quantities of the fragments, for making the road and building an hotel. In 1881 it was a risky affair to sink pits in loose rubbish 20 feet deep; I only escaped burial by a few seconds; seventeen shafts were sunk, but the casing edge was only found once on each side. In 1925 it was possible to uncover the casing over lengths of between 45 and 170 feet on different sides, and the use of such further material was very desirable in order to define the faces more precisely.

The 1925 survey was in two parts: (1) the prolongation of the alignment of the remaining portions of casing out to the corners by theodolite sighting, and (2) the survey of these produced corners by triangulation. The general order of accuracy that should be sought is indicated by the levels of the pavement, of which the mean error is only 0.21 inch; certainly it would be easier to achieve equality of length than of level. The method of setting a theodolite over an estimated edge of sloping casing, and then of telescopic estimation of such an edge at more than 100 feet away, is a risky process on the sand-blasted, pitted and chipped surfaces. The differences between 1881 and 1925 surveys depend on a third of an inch in such estimations. After that, the results depend on the 1925 triangulation for fixing the corner intersections by a chain of eight points joined by a traverse around the pyramid; this had a difference of 9.6" = 2.7 inches if on the whole distance, which was distributed equally in the reduction. The 1881 survey included the whole pyramid in a single triangle, the discrepancies of which averaged

0.04 inch; these station marks can always be re-used, as they were drilled in the rock, and the co-ordinates were all published.

The results of the two surveys are, in inches of length of the side and angular orientation of face:

	1881.	1925
N. side	9069.4 - 3' 20"	9065.1 - 2' 23"
E. side	9067.7 - 3' 57"	9073.0 - 5' 30"
S. side	9069.5 - 3' 41"	9070.5 - 1' 57"
W. side	9068.6 - 3' 54"	9069.2 - 2' 30"
Mean	9068.8 - 3' 43"	9069.4 - 3' 6"
Mean differences	0.7 12	2.3 12

There is a check on the estimated prolongation of the sides in 1925, as there is the 1881 estimate of the planes touching the core masonry. These were:

	1881.	Difference to Casing 1881.	Casing 1925.
N.	9002.3 - 4' 35"	+1' 15"	+2' 7"
E.	8999.4 - 5' 26"	+1' 29"	- 4
S.	9001.7 - 5' 23"	+1' 42"	+3' 26"
W.	9002.5 - 5' 39"	+1' 45"	+3' 9"
Mean	9001.5 - 5' 16"	+1' 33"	+2' 10"
Mean differences	1.0 20	1.0	1 8

As the planes of the core could be estimated within an inch of variation (=23") this is a useful check. It shows that the casing was adjusted 1' or 2' differently after the core was built. The divergence of the 1881 casing lines from the core have only 10" irregularity; the 1925 results show 1' 8" of irregularity; as this latter is equal to 3 inches on the length of the side, the core is competent evidence in favour of the 1881 survey. It may also be observed that a building with mean error in level of 0.2 inch is more likely to have a lineal error of 0.7 inch found in 1881 than of 2.3 inch found in 1925.

On all grounds it seems highly desirable to settle more precisely the exactitude of the most accurate human work of such large size. Station marks are needed at the side of each end of the lines of casing observed, to be connected with the more accurate triangulation of the 1881 net, which has less than 0.1 inch probable error in stations. Offsets should be taken between the new stations to the estimated edge of the casing all along. These would show how exactly the straightness was maintained, on which depends all evidence for prolongation of the short lengths of remaining casing.

¹ "Determination of the Exact Size and Orientation of the Great Pyramid of Giza." By J. H. Cole. (Survey of Egypt, Paper No. 39, Government Press, Cairo.) 1925. 8vo. 9 pp. 1 pl. 10 P.T. (2s 1d).

The bases of some of the other pyramids are also known from my surveys. That of King Sneferu at Meydum immediately preceded the Great Pyramid, and was planned on a similar system of measures. Both have the proportion resulting from the height being the radius of a circle equal to the circuit of the base, the angles found being

By π theory	51° 51' 14" 3
Khufu's pyramid	51 50 40 $\pm 1' 5''$
Sneferu's pyramid	51 52 $\pm 2' ?$

The dimensions found are:

Khufu's, height 7, circuit 44, $\times 40$ cubits.
Sneferu's, " 7, " 44, $\times 25$ cubits.

The modulus of design being thus 40 or 25 cubits shows the deliberate intention to embody the proportion of 7:22. The cubit required would be 20.61 or 20.66 respectively, and the best examples of early masonry elsewhere show a cubit between 20.62 and 20.65 inches. The mass of theories, which extend from good reason into a morass of impossibilities, would be too much to touch on here.

The accuracy of construction of the measured pyramids is, in inches:

Dynasty.	King.	Place.	Base.	m.d.	Azim.	m.d.
III	Sneferu	Meydum	5682 0	6.3	-24' 25"	5' 30"
IV	Khufu	Gizah	9068 8	7	-3' 43"	12
IV	Khafra	"	8474.9	1.5	-5' 26"	33
IV	Menkaura	"	4153.6	3.0	+14' 3"	1 50
XII	Senuser II.	Lahun	4168.5	1.9	-2' 8"	2 30
?	?	S. Dahshur	7439 0	3.7	-9' 12"	4 3
			2064.6	1.1	-14' 8"	10 12

From these measures it seems that Menkaura and Senusert II. laid out 200 cubits as a base, and the South Dahshur pyramids are of 360 and 100 cubits on each side.

In the XIIth dynasty the passion for accuracy led to regarding that as the finest sacrifice in honour of the dead; the granite sarcophagi, which were never intended to be open to examination, or even seen, have mean errors from a straight line, and from true planes, of 1 in 15,000, or on one edge 1 in 23,000. No race ever seems to have appreciated so keenly the charm of perfection of work as did the magnificent men of the pyramid age.

Current Topics and Events.

IN a recent series of papers in the *Chemical News* (Oct. 30, Nov. 6, 13, 20 and 27) Messrs. Druce and Loring put forward claims that they have identified the elements of atomic number 75, 85, 87 and 93 by an X-ray examination of certain manganese salts. The element 75 is that recently isolated by Noddack and Tacke (rhenium), the others are in the radioactive region. An examination of the evidence on which these claims are based suggests that it is far from sufficient definitely to establish them. The element 75 is identified by two lines, 1.430 and 1.233, which are taken to be the α_1 and β_1 lines of its L spectrum; 85 by two lines, 1.086 and 0.895; 87 by a single line 1.040, and 93 by two lines, 0.895 and 0.693, the 0.895 line being the same as that used for the identification of the element 85. Of these six lines four, 1.430, 1.233, 1.040 and 0.895, are within error limit identical with the $K\alpha$ line of zinc and the three strongest lines (α_1 , β_1 , γ_1) of the mercury L spectrum. The authors quote a control experiment in which a six hours' exposure with a copper anticathode gave only the copper spectrum. This is rather surprising, as mercury is used to evacuate the tube and brass for the window of the tube and the slits of the spectrometer. Also, in a recent experiment made elsewhere and suggested by past experience, a two hours' exposure with a copper anticathode and apparatus similar to that used by the authors gave, in addition to the copper lines and the silver and bromine absorption bands, lines which were identified with the zinc $K\alpha$, the mercury $L\alpha_1$, $L\beta_1$, and $L\gamma$ (?), and other lines at 0.950, 0.72 and 0.67. These are of doubtful origin but are possibly due to irregularities in the crystal oscillation or imperfections in the crystal. The authors in their papers give at least five lines which they observed and are unable to explain, although from the other six lines they identify four elements.

MR. HAROLD J. COOK, in a communication to *Science* for November 25, maintains that "good

dependable evidence of human artifacts in the Pleistocene of America" has at last been found. The evidence in question comes from a point near the Colorado River, near the south-eastern end of the Staked Plains and near the little town of Colorado, Texas, on Lone Wolf Creek. The first work leading up to the discovery was done in the summer of 1924, when fossil animal bones were discovered by Mr. Nelson Vaughan. The site was visited by Mr. Cook, who checked the geology of the area in May 1925. In taking up a large block of material containing the articulated ribs and vertebrae of a fossil bison, of which the whole skeleton was discovered in association and splendidly preserved, the first artefact, a point, was found under the cervical vertebrae. A second point was found under the femur, and a third was found "in position with the body of this skeleton." These artefacts are large arrow heads or lance points, and are of unexpectedly fine workmanship, being more refined than modern types found in the area, and of distinct culture and design. It is suggested that the animal had been wounded and died on this spot, as the condition in which the remains were found appears to preclude the possibility of its having been water-borne or otherwise deposited. A number of other fossilised remains have been found, but in the season just past no further evidence of man has been brought to light. These fossils occur in valley gravels solidly cemented by calcareous deposits which rest between the present stream erosion and the old triassic walls of the former valley. Everything points to these deposits being entirely undisturbed. Similar bones and types were found in all places where fossils could be located, and included, besides the extinct bison—*Elephas*, *Equus*, and *Camelus* or *Camelops*, as well as others at present unidentified.

THE Linnean Society of New South Wales has just issued a history of its fifty years of activity since its foundation in 1874, for "The cultivation and study of the science of Natural History in all its branches,"

with illustrations of its various homes, and of its successive presidents. It has published forty-nine volumes of *Proceedings* during its career, and is a standing witness to its benefactor, the late Sir William Macleay (1820-1891), who sustained its early efforts and finally provided it with a permanent building and adequate endowment. It has never exceeded 200 members, so that the constant support of its first president has been of essential help to its maintenance. More than twenty thousand pounds were devised by its benefactor for the general use of the Society, the appointment of a bacteriologist and the Macleay fellows. It suffered a terrible misfortune in 1882, when the building in which it was housed was completely destroyed by fire, but by outside help its library was renewed, though all its possessions and official records for the first eight years of its existence were lost. The volume ends with an account of the eighteen Macleay fellows who have benefited by the ample foundation. Few societies can boast of the constant and generous support which this Society has enjoyed and made so effective.

PART 4 of volume 26 of the *Transactions of the Optical Society* is devoted to a description by Dr. W. H. Steavenson of the instruments and apparatus in the possession of Sir William Herschel at the time of his death in 1822, and now preserved by two of his grand-daughters in the old Observatory House at Slough. The collection includes one of the mirrors of the famous 40-foot telescope; one of the mirrors of the 20-foot instrument, a number of mirrors for smaller instruments, flat mirrors for Newtonian telescopes, a number of eyepieces and a complete 7-foot telescope. The apparatus has all been marked by Dr. Steavenson and the grand-daughters of Sir William, and a list is given of all the items with a short description of each. In the case of the mirrors, after cleaning with ether and lemon juice they have been examined as to their optical properties, and they show to what perfection the figuring of them had been brought by Herschel 130 years ago. The whole of the eyepieces are single lenses, the most powerful a double convex of 0.02 inch diameter and 0.01 inch thick. They substantiate Herschel's claim that he obtained powers between 1000 and 6000 on his 7-foot telescopes. Twelve photographs of instruments and observatory complete an interesting and valuable document.

WITH the commencement of our issues for the New Year we shall conduct and publish a column, to be continued weekly, under the title "Contemporary Birthdays." In this the dates of birth of various men of science resident in Great Britain, our Dominions, and in foreign countries will be recorded, and the essential details of the careers of some of them will be set forth, in so far as is possible under the limitations of space which NATURE must observe. The first of the series will appear on January 2.

A CURIOUS problem of the Arctic is noted in the *Geographical Journal* for December. In August 1924 Dr. Livingstone, of the Canadian Government ship *Arctic*, found on Pim Island in Smith Sound, about half a mile inland from the north-west end, part of a

small leather case bearing the Royal Crown and the cypher V.R.I. in gold. The Director of the National Resources Intelligence Service of Canada suggests that this is part of a spectacle case dropped by an officer of the Nares expedition of 1875. The vessels of this expedition appear to have been the only British naval vessels to land parties on Pim Island during the reign of Queen Victoria. A drawback to this explanation is that Queen Victoria did not acquire the title of Imperatrix until 1876, the year of the expedition's return. Furthermore, it seems doubtful if any member of the Nares expedition had an opportunity of going so far from Payer Harbour, some few miles along the coast of Pim Island. The editor of the *Geographical Journal* would welcome information that could throw light on this problem, especially on two matters: evidence of the use of the cypher V.R.I. before 1876, and knowledge of any visit to the north-western extremity of Pim Island before 1924. An illustration shows the leather case. It has not been possible to trace any such gift to any member of the Nares expedition.

THE annual report of the Director of Research to the Council of the British Photographic Research Association shows that members of the research staff are continuing their investigations into the principles that underlie the practice of photography, and that during this year nine papers have been published in various scientific journals. In addition, various summaries of literature and more popular articles have been written, and various confidential investigations carried out for the members of the Association. The staff took a very active interest in the sixth International Congress of Photography held in Paris, and submitted to the Congress the only concrete proposals on the standardisation of plate-testing methods. It is to be hoped that the discussion of this subject at Paris will lead to more uniformity in the expressions of sensitivity and the other properties of photographic plates. The selenium density meter designed by the staff, and referred to in last year's report, has extended the possibility of work on experimental emulsions, and has been appreciated by many other laboratories.

REPORTS of committees appointed to award the Godard and Brocas prizes in the gift of the Société d'Anthropologie of Paris are published in the recent issue of the Society's bulletin (t. 5, sér. 7, fasc. 4-5-6). The Godard prize for 1924 is awarded to Dr. Maurice Neveux for a thesis entitled "Religion des noirs: Fétiches de la Côte d'Ivoire," which embodies observations made in 1909-1910 and 1914-1915, when the author was in charge of the medical services of that area. Two awards of the Brocas prize are made. The prize for 1922 is awarded to Dr. Fritz Sarasin, of Basle, for his work on the anthropology of the New Caledonians, and to Dr. E. Pittard, of the University of Geneva, for his book on the peoples of the Balkans. The prize for 1924 was divided between Dr. Antoine Delattre for a thesis on the comparative anatomy of the axis in mammals, M. Chame, of Bordeaux, for his work on the digastric muscle, and M. Cipriano Lidio, of Florence, on the human patella.

THE brief account by Prof. R. R. Gates of his trip up the Amazon during the summer vacation of 1925, which is published in the *Quarterly Summary of the Royal Botanic Society*, Regent's Park, for October, is a timely reminder that improvements in communication are throwing open this interesting botanical region under much more favourable conditions than previously. The Botanic Garden of Rio de Janeiro has recently circulated particulars of a new biological station, attached to the forest reserve of Itatiaya, which is available for visit by biologists. It is situated in a region where tropical and alpine floras co-exist within a small area, with a range above sea-level from 800 to 3000 metres. A small library is attached to the laboratory at the station, for which the Director of the Botanic Garden solicits further publications from naturalists. The address of the new station is, Estação Biologica de Monte Serrat, Barão Homem de Mello, Estado do Rio, Brazil.

THE *Marine Observer* for December, issued by the Meteorological Office, Air Ministry, completes the second volume, the publication having been issued in monthly parts for two years (London: H. M. Stationery Office; 2s. net each part). The Marine Superintendent of the Meteorological Office is quite sanguine that it fills the place intended, and while it has already stimulated considerable interest from the Mercantile Marine, he appeals to those afloat to contribute articles, sketches, and photographs to add to the value, attractiveness, and utility of the journal. The publication takes the place of the *Monthly Pilot Charts* previously issued, and by preserving the copies intact, much information of value to the navigator is at hand, and, with the index to the separate volumes, there is easy access to the information. No. 24, for December, contains an article by Captain L. A. Brooke Smith, the Marine Superintendent, on "Developments in Wireless and Weather: An Aid to Navigation," and it is clearly shown how valuable the weather information will be to airships over the sea. Much value is attached to the weather registers kept for the Office by the captains and officers in the mercantile marine.

THE *Sitzungsberichte der Physikalischen-medizinischen Societat* at Erlangen is always worth reading. A recent issue (Band 54 und 55, 1922, 1923) contains a number of interesting papers by various authorities, among whom we are pleased to note Prof. Eilhard Wiedemann. Prof. Wiedemann, whose output of articles on the history of science is rivalled only by that of Prof. von Lippmann, here contributes a short study on the history of music among the Arabs. He gives translations of the appropriate sections of the encyclopædic *Mafātīḥ ul-'Ulūm* (Keys of the Sciences) and of Al-Akfānī's *Irshād al-Qāṣid* (The Right Guidance of the Seeker), and illustrates them with very interesting notes and explanations. Other articles of importance are (i.) On a method of estimating the melting-point of gelatin solutions, by Rudolf Reiger and Fritz Gernert, and (ii.) On the construction of the world according to Ibn al-Haitham, by Karl Kohl. A lighter note is struck by Alexander

Gutbier in a popular lecture on "Die chemischen Elemente und der Weltenraum." On the medical side, Reinhold Wissmann gives a long account of his work upon war injuries to the eyeball. This occupies some 150 pages and deals with the subject in a masterly and exhaustive fashion.

WE sincerely share the regret, expressed by Dr. F. H. Gravely in the Report of the Madras Government Museum for 1924-25, "that limitations of staff make it impossible to continue, without neglecting other work of still greater urgency, the ethnological investigations so admirably begun years ago by Mr. Thurston." It is urgent enough that ancient customs rapidly disappearing under modern influences should be recorded without delay. On the other hand, one is glad to note that the University of Madras, by arrangement with the Fisheries Department, is establishing a Marine Biological Station on Krusadai Island in the Gulf of Manaar. Dr. Gravely is therefore preparing an introduction to the littoral fauna of the island.

THE Academy of Natural Sciences of Philadelphia, having managed for more than a century to perform admirable service under an act of incorporation and by-laws dating from 1817, but altered from time to time, at last found it necessary in 1924 to amend the charter and totally to revise the by-laws. The results are set forth in the Year-Book recently issued. Administration by council and curators has been abolished, a board of trustees created to manage the administrative and financial affairs of the academy, and a new council established to act in matters relating to the pursuits of the scientific staff. A new position of director of the museum has been created, and to it Mr. Witmer Stone has been appointed. The various sections of the Academy—geological, ornithological, etc.—have ceased to exist, but their place is taken by the Philadelphia Mineralogical Club, the Delaware Valley Ornithological Club, the American Entomological Society, and the newly formed Leidy Microscopical Club. Thus an easier opening is made for younger students.

ON Tuesday, December 15, the Priestley Club celebrated its jubilee by a dinner in the University of Leeds, to which a number of distinguished guests, representing various phases of activity, in pure and applied sciences, were invited. Sir J. C. Irvine, in proposing the toast of the Priestley Club, contrasted the conditions of experimental work in the days of Joseph Priestley with those which have been made possible by the development of institutions of the type of the newer universities in Great Britain. The advantages afforded by a general scientific society such as the Priestley Club in bringing together for the purpose of discussing scientific topics the various research workers in specialised provinces, were emphasised by Prof. A. Smithells, who pointed out the debt the present members of the Club owe to its founders, amongst whom were the late Sir T. E. Thorpe, Sir Arthur W. Rucker and Prof. L. C. Miall. Other guests included the Vice-Chancellor of the University of Leeds and the Rev. W. L. Schroeder, who

in succession to Priestley is the pastor of the Unitarian Chapel at Mill Hill, Leeds.

MESSRS. Casella and Co., of Parliament Street, London, have recently issued a price list of barometers. The list is well illustrated and a good description is given with each instrument, together with the price and any extra charge for the National Physical Laboratory certificate. Barometers of all descriptions are catalogued, standard instruments of the highest scientific principle as well as more ordinary mercurial barometers for observing stations and for use on board ship, for fishermen or lifeboat stations, and also a pit or miner's barometer. Aneroid barometers of various designs are shown, both large and small, for ordinary use, for mining and surveying, or for special use in aeroplanes. Barographs are listed, and these instruments, which are of great interest to the ordinary public, are of a reasonable price, the guarantee of the firm being of the highest order.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A deputy curator of the Public Libraries, Museum, and Art Gallery of the County Borough of Sunderland—Chairman of the Libraries, Museum, and Art Gallery,

Committee, Town Hall, Sunderland (January 4). A junior assistant (a botanist with good knowledge of chemistry, preferably biochemistry) at the laboratories of the British Cotton Industry Research Association—The Director, Shirley Institute, Didsbury, Manchester (January 13). An assistant at the Mount Stromlo Observatory, Australia—The High Commissioner for the Commonwealth of Australia, Australia House, Strand, W.C.2 (January 15—*extension of date*). The De Beers professorship of mechanical engineering in the University of the Witwatersrand, Johannesburg—The Secretary, Office of the High Commissioner of South Africa, Trafalgar Square, W.C.2 (February 1). A professor of social anthropology (who will be also the director of the school) and a senior lecturer in social anthropology at the School of African Life and Languages in the University of Cape Town—The Secretary, Office of the High Commissioner of South Africa, Trafalgar Square, W.C.2 (February 15). A pharmacist under the Government of Iraq—Crown Agents for the Colonies, 4 Millbank, S.W.1, quoting M/14126.

ERRATUM.—In NATURE of December 12, p. 861, five lines from end of first column, for 15⁴ ergs read 10⁻⁴ ergs.

Our Astronomical Column.

COMETS.—The *Times* of December 16 contains the announcement of the discovery of a new comet in the constellation Reticulum by Mr J. Ensor of the Pretoria General Hospital. It is stated that the comet is not visible to the naked eye, but that it has been observed at the Union Observatory, Johannesburg, and that its tail is 15' long.

The position of the comet on December 14 was R.A. 3^h 38^m, daily motion minus 12^m. S. Decl. 61°, daily motion 24' S.

NAKED EYE SUNSPOTS.—The solar activity recently commented upon in these columns has continued. During the first half of December, two naked eye spot disturbances have been observed. The first of these was seen without a telescope only by persons of keen sight, but the second has been a distinct marking on the sun's disc when screened by fog or artificially with a dark glass. The former group was on the central meridian on December 10, when it was composed of two large composite spots. Although a new and apparently independent centre of activity, this group was not far distant from that of the naked eye group of November 8–20, which has not outlived the rotation.

The second group grew from some spots seen close to the sun's west limb on November 24 and 25, which, when brought again into view on the eastern limb on December 9, had become a long stream stretching 15° in longitude. The axis of the stream was inclined about 17° to the solar equator, the latitude of the leading spot being 21° N. and that of the follower 25° N. At the present phase of the sunspot cycle, spots in this latitude are usual, but groups so large as this present one are more commonly found between latitudes 10° and 15°. These are, of course, the zones most active near the maximum phase of the cycle. A very large group of spots appeared, however, in latitude 32° S. in February 1894, and one exactly on

the sun's equator in May 1921 (see NATURE, vol. 107, p. 399).

Particulars of the recent spots are given in the table below. No considerable magnetic disturbances have been recorded as yet this month at Greenwich.

Date on Disc, 1925.	Central Meridian Passage (G M T).	Latitude.	Maximum Area.
Dec. 4–16	Dec. 10 3	20° S.	1/900
Dec. 9–(22)	Dec 16 0	23° N.	1/500

(Areas are corrected for foreshortening and express the proportion of the sun's hemisphere.)

TOTAL SOLAR ECLIPSE OF JUNE 29, 1927.—It is not too early to commence plans for the eclipse of June 29, 1927, total in Wales, England, and Norway. A large scale map of the track in Great Britain (10 miles to the inch) has been constructed by Mr. B. F. Bawtree (late of the Nautical Almanac Office), and is published in the B.A.A. Handbook for 1926. The central line runs from Crickieth (Carnarvonshire) to Hartlepool, passing through Colwyn Bay, Southport, Settle, and Richmond (Yorkshire). The north limit of totality runs just north of Beaumaris, Bangor, Lancaster, Durham, and just south of Sunderland. The south limit runs a little south of Denbigh, Liverpool, Accrington, Saltburn-on-Sea, and through Burnley.

It must be counted a fortunate circumstance that three of the observatories in the Nautical Almanac list (those of Bidston (Birkenhead), Stonyhurst College, and Durham) lie within the totality track. Stonyhurst specialises both in solar study and spectroscopy, and preparations for the eclipse are already in progress. The altitude of the sun is 13° on the east coast, and the duration of totality increases from 21.6 sec. on the west coast to 24.5 sec. at Hartlepool.

The conditions in Norway are far more favourable both as regards height of sun and length of totality, and those who propose to undertake important researches should certainly go there.

Research Items.

POTTERY FROM ANCON, PERU.—Dr. W. D. Strong has published a further instalment of his valuable studies of the collections of pottery from Peru which were made by Dr. Max Uhle, and are now in the Museum of the University of California. In No. 4 of Vol. 21 of the *Publications in American Archaeology and Ethnology* of the University, he deals with the collections from Ancon, which do not, it is true, exhibit the same variety as the collections from some of the other sites previously described, but are nevertheless of considerable interest as exhibiting what is, in the main, a continuous local development, although outside influence is to be discerned. The earliest pottery found—early Ancon—came from shell mounds and is characteristically a one-colour ware, often unslipped, and with incised rectilinear and curvilinear designs. Dr. Uhle believed it similar to proto-Nazca, but probably it is rather an early widespread Peruvian type from which proto-Nazca developed. In the following period, middle Ancon I, the earliest from the necropolis, two types are found, one resembling early Ancon, the other consisting of polychrome foreign styles showing the influence of proto-Nazca, proto-Chimu, and Tiahuanacu. Middle Ancon II again shows two types, one local, the other a degraded Tiahuanacu of wide distribution. In late Ancon I a "black, red, and white" ware, and late Ancon II, a black and white pottery, foreign influence apparently had little effect. Only in the upper layers is Inca pottery found. Dr. Uhle places the earliest period at approximately 100 B.C. It would seem that Ancon had already been abandoned at the time of the Spanish conquest.

GROWTH IN STATURE OF INFANTS—A recent issue of the *Bulletin of the Société d'Anthropologie de Paris* (T. 5, Sér. 7, fasc. 4-5-6) contains two communications dealing with the modality of growth in stature in infants and the causes of its abnormalities by M. Variot and his assistant, M. Alfred Ruesco, of the Hospital of Notre Dame Perpétuel du Secours. M. Ruesco's results are based upon observations upon 602 infants. He finds that in the first twelve months there is usually a regular upward curve up to six months, but that after that age, in 82 per cent. of the cases, there are breaks in the regularity of the curve which are represented on the graph by horizontal lines—*paliers*—of which the first is the most serious. The duration of these breaks may vary from one week to six or eight weeks. A further analysis of the figures gives the following results:—Interruptions in regularity of curve of growth—infants above normal in weight, 29 per cent.; breast-fed infants, 75 per cent.; breast and artificial feeding combined, 76 per cent.; artificial feeding from birth, 84 per cent.; premature, 89 per cent.; infants below normal in weight, 100 per cent. These percentages bear no relation to absolute height, which may be quite normal, but represent only irregularities in rate of increase. It would appear, therefore, from an inspection of these figures, that there is a close connexion between nutrition and regularity in increase in stature. While food is regular, abundant, and well adapted to the needs of the organism, and nutrition is at the same time uninterrupted by morbidity, as, for example, by the anorexia of dentition, growth in stature is regular and continuous. M. Variot carries the matter further and shows, first, that the nutrition of the osseous system, which governs increase in stature, sometimes proceeds apart from nutrition of the organism generally, which regulates weight; and secondly, that on plotting various crises of the first

year on the graphs, it appears that the *paliers* coincide with eruptions of the teeth.

AERIAL SURVEY OF A DELTA.—The difficulty of adequately surveying the channels and featureless swamps of the Mississippi delta and the need for the revision of the charts of that region suggested the possibilities of aerial survey. Previous experiments on the coast of New Jersey proved the value of these methods. A brief illustrated account of the survey, with notes of the cost, is contained in Special Publication No. 105 of the United States Coast and Geodetic Survey, by Mr. G. C. Mattison. The field work was done in 1921-22 with a seaplane, since the marshy condition prohibited the use of aeroplanes. The seaplane could not attain a higher altitude than 8000 ft., which was found to be a disadvantage. Since the use of aerial photographs was largely experimental, control by triangulation was arranged. The delta was divided into sections with natural features as boundaries, and over each compass flights were made. Flights were also made along the principal channels. The photographs had about 50 per cent. overlaps, and when the work was complete very few gaps between the strips were revealed. Results were fairly satisfactory, but left room for some improvements. At the same time, it is doubtful if ground of this nature could have been so well surveyed, and certainly not so quickly and cheaply, by any other method.

AMMONITES OF PORTUGUESE EAST AFRICA—A collection of Upper Albian Ammonoidea, belonging to the Transvaal Museum form the subject of a paper by Dr L. F. Spath (*Ann. Transvaal Mus.*, 11, Pt. 3). The specimens, which are all from Catuane in Portuguese East Africa, include 33 ammonites and 69 heteromorphs. The fauna is of great interest, for it includes not only important and new forms of *Inflaticeratidae* but also the majority of specimens belong to groups of "Criceras" hitherto known mainly from Australia. The author briefly revises his former opinions based on a study of the Aptian ammonites from Zululand, Madagascar and Angola, recognising now that they came from beds of different and not the same dates. In strictly contemporaneous beds similar assemblages, if not identical species, are found. Ammonites are not only remarkably independent of facies, but are also of surprisingly world-wide distribution. In an appendix three ammonites from the Cenomanian of Maputoland are described.

ICE IN THE ATLANTIC.—The *Meteorological Magazine* for November contains an article by Lieut.-Comdr. Edward H. Smith, U.S. Coast Guard, on ice in the North Atlantic. It was off the tail of the Grand Banks that the giant passenger ship *Titanic* met with the appalling disaster on the night of April 14, 1912, through colliding with a low-lying iceberg. The Ice Patrol Service was established in consequence. The management of the service was accepted by the U.S., several nations sharing the expenses of the project, Great Britain contributing approximately 30 per cent. of the outlay. The Patrol has been operating for the past thirteen years and the U.S. Hydrographic Office co-operates with the Coast Guard in giving publicity to the ice information. The writer claims that there has not been a single life lost or a serious marine accident on the United States-Europe routes since the inception of the Ice Patrol. There are two ships detailed for ice patrol duty. The Patrol finds two general forms of ice, sea ice and land ice. The sea or field ice lasts from

February until May. Land ice consists of parts broken off from the ice sheets which cover certain land areas in the far north, and this constitutes a far greater menace to navigation than does sea ice. The iceberg season covers the period March 15–July 15. Records kept by the Patrol, 1913–1925, indicate a tendency towards uniformity in the drift of icebergs. The amount of ice drifting out of the north into the open Atlantic is subject to great annual variations. Based on past experience in association with correlation of other data, arrangements are now being made to begin a service of North Atlantic ice forecasts beginning with the season of 1926.

ROTATION OF BODIES DURING EARTHQUAKES.—During the St. Lawrence earthquake of February 28, 1925, many bodies were rotated on their bases, and these were examined by Mr. E. A. Hodgson (*Journ. R. Astr. Soc. of Canada*, vol. 19, 1925, pp. 169–178) in the hope that they might throw light on the position of the epicentre. This area is known to lie in an unsettled region between the St. Lawrence and Saguenay rivers and between their junction and Quebec. Though the main object of the inquiry was not attained, it was found that the rotation effects were confined, as a rule, to the region near the epicentre in which the vertical component of the motion was most marked. They depended greatly on the depth of the soil—the deeper the soil the greater the rotation for any given distance from the epicentre—on the slope of the ground and on the presence of tree roots near the monuments. As a rule, the rotations north of the St. Lawrence river were in the clockwise direction, and those on the south side in the counter-clockwise direction; but, while there were practically no exceptions to the rule on the north side, there were a considerable number on the south shore. The author concludes that this old earthquake problem (first considered by Mallet in 1846) is still unsolved.

THE EXCITATION OF HYDROGEN SPECTRA BY COLLISIONS WITH ELECTRONS.—Messrs. P. M. S. Blackett and J. Franck describe experiments in the *Zeitschrift für Physik* of October 20, showing that when very pure hydrogen is bombarded under suitable conditions by cathode rays, a spectrum is emitted which indicates that hydrogen molecules are split up in individual collisions into a normal and an excited atom, the latter afterwards emitting light. Precautions were taken to avoid the accumulation of free atoms in the tube, which included the coppering of the interior walls, cooling the tube with liquid air, and passing a rapid current of low-pressure hydrogen through it, the spectra are due neither to the excitation of neutral atoms by collision with electrons nor to excited molecules. The Doppler effect of the H_{α} line in these experiments was compared with that obtained when many free atoms were present and the spectrum was due to their excitation; it was found to be much greater in the first case, the lines being broadened so that the fine structure observed in the second case became blurred. This is explained as being due to the relative velocity of the two atoms of the dividing molecule. The authors consider it possible that the continuous hydrogen spectrum, reaching from the far ultra-violet to long wavelengths, may be explained as due to the surplus energy available when the molecules are broken up by collision with electrons into two neutral atoms. The continuous spectrum referred to is not that connected with the series limit.

THE CONVECTION OF LIGHT BY MOVING MATTER.—In a recent communication (*Phil. Mag.*, Ser. 6, vol. 49, 1925, p. 579) and in an earlier one (*C.R.*, t. 175, 1922, p. 574) M. Charles L. R. E. Menges has pointed out an

error in the usual deduction on Newtonian principles of the velocity of light in a moving medium, from which the conclusion has been generally and, according to M. Menges, wrongly drawn, that the older electromagnetic theory is contradicted by the results of the experiments of Fizeau and Zeeman on the velocity of light in moving media. If the refractive index of the moving medium be defined as the ratio that the velocity with which the light reaches the moving medium bears to the velocity of propagation of the light within the medium, then according to M. Menges it follows that the proper formulæ for the differences of phase in the experiments of Fizeau and Zeeman are those of Fresnel and H. A. Lorentz respectively, and that the usual incorrect results are due to the use of an incorrect expression for the refractive index, namely, that of the medium, when it is at rest, instead of that which belongs to the same medium when it is moving and when due allowance is made for the change of frequency of the incident light on account of the Doppler effect. Whilst it must be admitted that M. Menges appears to be right in his main contention that a proper choice of refractive index for the moving medium is essential, yet his own deduction is not entirely free from ambiguity, in so far as equation (11) in his earlier and more fundamental paper leads at once to the expression $\mu' = \mu A(n' - n)$, where n and μ respectively denote the frequency and refractive index of the medium at rest, whilst n' and μ' denote the same quantities when the medium is moving. For A , which is a constant of integration, M. Menges puts $(\mu - 1)/n + d\mu/dn'$, as he says, in accordance with the assumption made by H. A. Lorentz that $d\mu/dn'$ does not vary from n to n' . It is not easy to see any sufficient reason for this identification of A , but if its validity be granted, the formulæ of Fresnel and H. A. Lorentz follow at once. Both of these formulæ have been deduced from the special theory of relativity by M. von Laue (*Ann. der Phys.*, F. 4, B. 62 (1920), p. 448); consequently, if the contention of M. Menges be correct, the experiments of Fizeau and Zeeman can no longer be regarded as deciding between the theory of relativity and the older electromagnetic theory.

NICKEL CATALYSTS.—The results of an X-ray investigation of nickel catalysts of different activity have been published by Clark, Asbury and Wick in the *Journal of the American Chemical Society* for November. The catalysts were prepared by reduction with carbon, ethyl alcohol, ethyl acetate, hydrogen and sodium hypophosphite, and they were examined in a spectrograph in powder form in an atmosphere of nitrogen. With the exception of the product obtained by the last method, which was colloidal, the space lattice and type were the same in all cases. No information was obtained concerning the surface of the catalysts. The results do not contradict the generally accepted theory that, above all, the condition of the surface determines the activity.

TOXIC PRINCIPLE OF INSECT POWDER.—In the *Scientific Papers of the Institute of Physical and Chemical Research*, Tokyo, for August 1925, R. Yamamoto gives the results of investigations on the insecticidal properties of insect powder. The insect powder was obtained from the dried flowers of *Chrysanthemum cinerariifolium*, and by extraction with suitable solvents and vacuum distillation a light brown syrup was obtained which was highly toxic to insects. This liquid, called pyrethron, when saponified yielded a liquid and two solid alcohols in addition to two acids, all of which were inactive towards insects. The formulæ for these substances and for pyrethron have been deduced.

The Instituto Oswaldo Cruz.

By Prof. T. D. A. COCKERELL.

FOR many years past I had been receiving the *Memorias do Instituto Oswaldo Cruz*, published at Rio de Janeiro, and sent with the utmost liberality to students and libraries in many countries. I had wondered at the variety and excellence of the papers, and the beautiful illustrations. I had seen some of the scientific results received as of fundamental importance, and incorporated in text-books. Accepting all this with due gratitude and appreciation, it was natural to feel puzzled to know how it all came about. Brazil is a great country, of enormous but largely undeveloped resources. Talk to any one who has been there, or who lived there, and the conversation is certain to drift toward a criticism of Brazilian politics and politicians. To be sure the same sort of

at Lima was also closed during the few hours when it was possible for me to visit it. The Instituto Oswaldo Cruz is so much a working institution that I imagine it is rarely closed during daylight hours, but it is at Manguinhos, a suburb of Rio, and my wife and I were very grateful for the courtesy of the director in sending a car to take us out. Prof. Carlos Chagas, the director, took us over the building, and explained its history and the nature of the work. Oswaldo Cruz was not a man of wealth, but a practising physician in Brazil. Having studied in Paris, and come in contact with the keenest investigators of his time, he returned to Brazil full of scientific zeal. He was able, through his dominating and persuasive personality, to enlist the co-operation of his countrymen,

FIG. 1.—The Instituto Oswaldo Cruz.

thing happens in the United States, but we know something of the virtues of the northern continent and can weigh one thing against another. The foreigner approaching Brazil is sure to feel that "every prospect pleases," but more than likely to add that "only man is vile." I myself at one time could only suppose, in a vague manner, that the Instituto Oswaldo Cruz must have been founded and endowed by some multimillionaire, whose munificence had created an organisation essentially alien to the general spirit of the country. This supposition was entirely wrong.

Approaching Rio de Janeiro in the s.s. *Vestris*, and knowing that I should have only a day and a half in the city, it seemed prudent to send a wireless message to the Instituto, to make sure that I should not fail to see it. It is not always easy to get into South American scientific institutions; I found the magnificent museum at Rio closed, with no means of access; I was told that the Botanic Garden was closed; and the La Plata museum in Argentina was closed when I first visited that city. The museum

with remarkable results. He was credited with having banished yellow fever from Brazil, or at least from the populous districts, utilising the results of modern work on the relation between mosquitoes and the fever. Through the work of the Instituto, smallpox has also essentially disappeared, the co-operation of the Government having been secured to make vaccination compulsory. It is evident to any one who gives attention to the subject that the whole problem of Brazilian progress and development is tied up with that of preventing disease. Cruz early perceived that this was the case, and went to work to demonstrate it and obtain public support for his efforts. The response was generous, and the fine building in Moorish style was erected at Manguinhos. Dr. Cruz was the first director, and when he died a favourite disciple, Dr. Chagas, was placed in charge. In a great public building in Rio are large and beautiful mural paintings illustrating the history of the country. Prominent among these is one of Dr. Cruz, represented as ministering to a group of people suffering from various diseases.

The expenses of the Instituto are not derived from any Brazilian Rockefeller or Carnegie; the funds come about half from the Government and the other half from the sale of vaccines and serums which are made there. Thus the whole thing, from first to last, is to be regarded as a flower of Brazilian civilisation, one of the chief instrumentalities for Brazilian progress. As such, it should be known to the world and to the people of Brazil. As I, the foreigner, went over the building, enthusiastic at what I saw, a long-time resident of Rio also went the rounds, and confessed to us that until that day he never imagined what lay so close at hand. The latest number of the *Memorias* (vol. 17, part 2) was just being distributed, containing articles on ciliate Protozoa parasitic in guinea-pigs, a revision of the scorpions of Brazil, an account of worms parasitic in birds, and a statistical study of the incidence of disease due to parasitic worms among the children of Paraná. These papers are in Portuguese, but are accompanied by translations into English or French.

The work for which Dr. Chagas is especially well known is that on the disease called opilacao, caused by a trypanosome which is communicated by a large hemipterous bug, the *Triatoma megista*. The trypanosome was described by Dr. Chagas as *Trypanosoma cruzi* in 1909. The bugs frequent native houses, flying and attacking at night, as was graphically described to me by Dr. C. Spegazzini when I met him at La Plata. Dr. Chagas showed us the parasites in the fibres of the human heart and in the blood of a dog inoculated with injected human blood. Other species of *Triatoma* also carry the parasites. *Triatoma geniculata* gets its trypanosomes from the armadillo, *Dasypus novemcinctus*. The opilacao disease is not coincident with the distribution of *Triatoma*. Dr. E. Escomel of Arequipa, Peru, told me that *Triatoma infestans* was found between Arequipa and Mollendo, but harboured no trypanosomes. He had observed that it was attacked and killed by the spider *Lathrodictes mactans*, common in that region, as also in North America. *Triatoma sanguisuga* of the United States once enjoyed newspaper notoriety as the

"kissing bug," but it appears to carry no trypanosomes. There can be little doubt that it would be capable of transmitting *Trypanosoma cruzi*, were it once infected.

The Instituto has a museum, and a library of 40,000 volumes, in uniform red binding. This is the largest medical library in South America. Behind the main building are smaller ones for physicochemistry and mycology. The department of pathology was started in 1918 under the direction of Dr. Bowman C. Crowell, now of South Carolina. Dr. Crowell had specialised in tropical diseases in the Philippines, and was able to establish the work at Rio on a thoroughly scientific basis. Reports are now made on all autopsies in the Rio hospitals. Thus the progress and incidence of disease is watched with unceasing vigilance. There is of course a good collection of mosquitoes, including those concerned with malaria and yellow fever, the exact distribution of which is mapped. Mosquitoes are such fragile insects that in many collections, especially when much used, they soon become badly broken. At the Instituto this is avoided by placing them in small tubes, pinned on the cork. Thus they can be examined with a lens, without risk of damage. I regretted not to meet Dr. Adolph Lutz, so well known for his studies of blood-sucking Diptera. He was absent giving a course in parasitology in Venezuela, at the request of the Government of that country.

The museum contains a large collection of Batrachia and of poisonous snakes. Dr. Chagas said that Lachesis is the most dangerous form. Around the room are exhibits to illustrate all the important tropical diseases, some of which are little known to people of other regions. Fleas are important in this connexion: the collection of fleas is now being studied by Mr. Cezar Pinto, who has also described species of leeches. There is a small lecture theatre, and courses in bacteriology, proto-zoology, helminthology and entomology are given for graduate students of medicine. Even fresh-water Mollusca (*Planorbis*) have received critical attention, on account of the parasites they harbour.

Recent Researches on the Physiology of the Stomach.

THE large amount of work which has been carried out on the secretory processes and movements of the stomach might suggest that further investigations could add but little to our knowledge; such is, however, far from being the case. Recent advances made in this subject are due in the main to two quite different lines of approach; the improvement in surgical technique has produced more clear-cut results from animal experiments, and the application of these results to man has been facilitated by the discovery of methods of investigating the physiology of the stomach in human beings, whereby essential information, without which the true significance of animal experiments may be obscure, has been obtained.

As an illustration of the former method of advance, recent work by R. K. S. Lim, A. C. Ivy, and J. E. McCarthy may be cited (*Quart. Journ. Exper. Physiol.*, 1925, vol. 15, pp. 13 and 55). The authors, working with dogs, have developed a technique by means of which the entire stomach can be separated from the rest of the alimentary tract; the continuity of the latter is restored by an œsophageo-duodenal anastomosis, while the cut pyloric end of the stomach is made into a permanent fistula, the cardiac end being closed. The animals live well on a diet of ground meat, bread, milk and desiccated pancreas, with unlimited water, but raw meat is passed almost unchanged.

Experiments were also performed on animals provided with different types of stomach pouches and fistulae, following the original technique of Heidenhain and Pavlov and its various modifications.

Consideration may first be given to the arousal of gastric secretion by stimuli acting on the stomach itself; these are of two types, mechanical and chemical. The authors show unequivocally that mechanical stimulation by distension of the organ or a pouch thereof with a balloon causes a secretion of gastric juice, which occurs not only after severance of the vagus nerves, the main secretory and motor nerves of the stomach, but may be seen also in an isolated fundus pouch when the main stomach is distended, or in the stomach when a pyloric pouch is stimulated. There is a latent period of five to fifteen minutes after the beginning of the distension before secretion appears.

These observations are of great interest, not only because they confirm the opinions of some of the older physiologists, whose views have found little favour in modern teaching, but also because they suggest that certain observations on man, in which a mechanical stimulation has been suspected, are probably to be taken as really due to this cause. Many previous observations have shown that a flow of gastric juice can be obtained by the application of certain sub-

stances to the mucosa of the stomach, the authors have confirmed these results, showing that raw meat juice, β -alanine, and histamine stimulate, whereas undigested foods are without effect. The actual mechanism of stimulation is, however, not yet finally settled. The presence of extrinsic nervous connexions is unnecessary, but since a denervated pouch responds to the stimulation of the main stomach, one must assume that the effective stimulus is a chemical agent, carried by the circulating blood.

The authors have been unable to obtain unequivocal evidence of a hormone, such as postulated by Edkins, in the blood, and therefore incline to a view which advocates a common mechanism, as the basis of both mechanical and chemical stimulation. The stimuli produce an increased blood flow through the gastric glands resulting in an increased flow of gastric juice; in the case of mechanical distension, the motility of the stomach is involved in this effect. It is, however, possible that increased blood flow consequent on increased movements due to distension may be concerned only in the effects of mechanical stimulation, whilst the hormone mechanism may explain the results of chemical stimulation, more especially as Ivy reports, in a recent review of the subject, that a gastric pouch transplanted to a mammary gland secretes when gastrin (an extract of gastric mucous membrane) and histamine are applied to the surface of the main stomach, in which case an increased blood flow seems scarcely adequate as an explanation (*v. Journ. Amer. Med. Assoc.*, 1925, vol. 85, p. 877). It is to be noted, moreover, that in the case of the secretion of saliva, an increased blood flow through the salivary glands does not produce an increased secretion.

The gastric juice produced by local stimulation of the stomach is only part of that secreted in response to a meal. Before the food enters the stomach secretion occurs, produced reflexly by impulses set up by the sight and smell of the meal, together with those arising from its presence in the mouth itself. The arcs concerned in the latter reflex are situate in the brainstem, since the "psychic" secretion, as it is called, occurs in a decerebrate dog when given food. But Lim, Ivy, and McCarthy have added yet a further period to the secretion of gastric juice by showing that it is aroused by the application of digestion products such as peptone, amino-acids, and amines to the mucosa of the small intestine. If a meal were given to their dog with a pouch of the entire stomach, a

secretion of gastric juice occurred about one to three hours later, depending in part on the time for digestion in the small intestine, in part on the time of appearance of the bile, which also acts as a stimulant. Hence gastric secretion can be divided into three phases, a cephalic (or "psychic"), a gastric, and an intestinal. It is only on an accurate knowledge of these processes that a rational therapy of gastro-intestinal tract disease can be based.

A certain amount of doubt has arisen as to the actual nature of the movements in the stomach, chiefly owing to the fact that different types have been described in man and animals; sometimes even different observers have found different appearances in the same species. E. D. McCrea, B. A. McSwiney, J. W. Morison, and J. S. B. Stopford (*Quart. Journ. Exper. Physiol.*, 1924, vol. 14, p. 397) have investigated the movements of the stomach in the rabbit, cat, dog, and man, both by means of the X-ray and also, in the animals, by direct inspection of the organ exposed under saline. Their observations clarify and correlate those of previous investigators. The fundus and part of the body of the organ remain almost quiescent during digestion, slowly contracting on the mass of food and forcing it into the more distal parts. In the latter two types of movements occur; in both there is a peristalsis of the remaining part of the body, but in one this is arrested at the pyloric antrum, whilst in the other the wave passes over it and reaches the pylorus; in the former case the peristaltic wave over the body is followed by contraction of the pyloric antrum and canal as a whole, in the same manner as the heart contracts in systole. The first type of movement is predominant in the stomach of the dog, rabbit, and man, the second in that of the cat; but occasionally the opposite type may occur, except that the second has not been observed in the dog's stomach. A transitional form is sometimes seen, namely, ripples running over a tonically-contracted pyloric antrum. The rhythms of the two parts of the stomach may be different. Movements can also be seen in the quiescent part of the fundus in man if the air-cap is displaced and its place taken by the barium sulphate meal. The authors conclude that the variations observed are due to differences in the type and consistence of the food, in the degree of tension in the muscular wall, and in the actual arrangement of the muscular fibres therein in the different species. The research system atises the somewhat confusing observations which have been previously made on this subject.

American Work on Tides.¹

THE United States Coast and Geodetic Survey has done useful service in issuing the special publications referred to below. The manual prepared by Mr Schureman was designed primarily for the tidal computers of the Survey, but the aim was to produce a convenient work of reference on the subject of the harmonic analysis and prediction of tides. It gives a résumé of the work of Kelvin, Darwin, and Harris. Part I. is devoted to the development of the tide-generating force, to the methods of analysis used by the Survey, and to a description of the U.S.A. tide-predicting machine. The method of analysis is worthy of comment. It makes use of several thousand stencils for the special summations required for the isolation of the constituents. The manual indicates, apparently for the first time, some of the more recent improvements in the method, and these are such as

to diminish considerably the labour of calculation. In older methods only those constituents of which the speeds are exactly in the ratios 1 to 2, 3, 4, 6 and 8, were treated together until the final processes of the analysis were reached, but in this method constituents the speeds of which are approximately in these ratios are treated together in the earlier stages of the summations, and "secondary stencils" are then used to isolate the respective constituents.

Parts II. and III. are most useful to computers and research workers in other countries. Part II. contains tables of standard functions used in analysis and prediction, Harris's tables having been extended and others added. The astronomical arguments are now given from 1850 to 1999. Part III. consists of a noteworthy list of harmonic constants for nearly a thousand places scattered throughout the world. Hitherto research workers have had difficulty in obtaining lists of such constants, and no such comprehensive list has ever been published, though no doubt several manuscript lists have existed. The Survey has received constants from many sources,

¹ A Manual of the Harmonic Analysis and Prediction of Tides, by P. Schureman; Tides and Currents in New York Harbour, by H. A. Marmor; Tides and Currents in San Francisco Bay, by L. P. Disney and W. N. Overshiner; A Portable Automatic Tide Gauge, by G. T. Rude. Special Publications Nos 98, 111, 115, 113. (Washington: Government Printing Office.) Prices 100, 30, 20, and 10 cents respectively.

and it must have been difficult at times to make sure that the constants were accurately given. The amplitudes for Gibraltar are ten times too great, but in general the constants appear to be trustworthy.

An immense amount of labour must have been expended in preparing these tables, and all concerned in the production of the manual deserve congratulation upon the efficient manner in which the work has been carried out.

Another activity of the Survey is shown by the two publications dealing with the tides and currents in New York Harbour and in San Francisco Bay. Altogether apart from their importance in navigation, tides and tidal currents enter as important factors into a number of problems connected with harbours and ports. These special publications are not devoted to the discussion of any involved mathematical theory of tides and currents, but are intended to present and discuss the results of observations in such a manner that they will be of interest and practical value to the mariner, the engineer, and the scientific worker. Mr. Marmer's introduction, however, is an admirable statement in simple language of the general characteristics of tides, and this is reprinted in the second publication.

The heights of various planes, such as mean sea level, mean tide level, mean high-water level, storm high-water level, and so on, from year to year are tabulated, explained, and discussed. Engineers must find this information exceedingly useful. Maps give the

directions of current flow at intervals of time related to high-water time or to the time of high-water slack.

The importance of tidal currents is becoming increasingly recognised, and the Survey has taken the lead in preparing a separate annual volume of predictions of tidal currents. Hitherto, the current predictions for San Francisco Entrance refer only to the times of slack water for each day of the year, with suitable indications as to whether the current is about to turn from east to west, or vice versa. Beginning with the year 1926, however, the predictions will be considerably elaborated. For each day will be tabulated the time of slack water before flood, the time and velocity of each maximum flood, and corresponding times and velocities connected with the ebb. It will be noticed that fifty per cent. more information is given for the currents than for the elevations.

To meet the need for a portable tide gauge suitable for the use of hydrographic parties requiring tidal observations during a period of soundings, an instrument has been designed which appears to have reached almost the lowest practical limit of size. When encased, the instrument is almost a cube of 11 inches side, and it is supported on $3\frac{1}{2}$ -inch stock iron pipe which serves as a float-well at the same time. According to Commander Rude the apparatus will function for a week without attention. The gauge appears to be well suited to the purposes for which it is designed.

A. T. DOODSON.

Research in Textiles.

THE Fabrics Co-ordinating Research Committee was appointed in 1921, its members being representatives of the fighting services, the National Physical Laboratory, and the research associations for the textile industries. The duties of the Committee are the maintenance of co-ordination between research work on fabrics carried out by Government departments and others, and the direction of new investigations which appear necessary in the national interest and of civilian as well as of naval or military importance. The report recently issued¹ on the activities of the Committee during the past four years gives a lucid summary of progress in the scientific investigation of several problems of considerable national importance and of very diverse character.

The academic research worker will be interested to learn how frequently, in the solution of such problems, the application of laboratory results is limited by considerations apparently foreign to the subject, a striking illustration being afforded by the search for an antiseptic which will give protection to a fabric from the attacks of micro-organisms and, at the same time, have no deleterious effect upon it. This seemingly simple problem becomes very complex in practice, most antiseptic substances being excluded on account of some objectionable quality or an equally objectionable action on the properties of the fabric or the substances employed in dyeing or finishing this.

The Committee has initiated work on the deterioration of fabrics by the action of light, a problem of great urgency in connexion with aircraft, clothing and tentage, and a summary is given of recent work on the determination of the destructive band of the sun's spectrum (3900 Å.U. to 3100 Å.U.), the protective action of dyes having an absorption band covering this region, and the mechanism of deterioration. Much further work on the latter subject is required, for the causes are still obscure; but an interesting theory of the action of ozone in the

connexion is outlined. This takes account of the oxygen adsorbed by the fibres and the possibility of this being ozonised by the direct action of sunlight, and is based upon a calculation by Lindeman that the ozonisation of the adsorbed air may be effected by light of wave-length 3200 Å.U.

Future progress depends largely upon the provision of more suitable sources of light for experimental purposes than sunlight or the mercury vapour lamp, and a more delicate means of measuring deterioration than the strength test. It is satisfactory to learn that research is being conducted on both these subjects.

An interesting appendix on the deterioration of fabrics by micro-organisms sketches the organisation of a large-scale attempt to collect systematically the organisms capable of causing the decay of fabrics. Specimens of the latter are being exposed, under the supervision of mycologists, at a number of stations in the British Empire, and arrangements are being made for the examination of the specimens after exposure. Again, the possibility of a more suitable test of deterioration than those now available requires further exploration.

A large section of the report is devoted to a comparison of fabric strength tests carried out on machines of different makes and capacities. From a technical point of view this is probably the most important section, for the results are of direct practical significance. They should, naturally, be read with great interest by all concerned with the mechanical testing of fabrics and the scientific investigation of the principles underlying the methods employed.

As a précis of the results of scientific research the report is highly commendable. A misleading statement has been noticed on p. 30, where it is stated, in a discussion of rate of loading, that, when textiles are broken, a larger percentage of the interlaced fibres are "disentangled" and slip past one another without breakage. So far as the writer is aware, there is no evidence supporting this generalisation, which, for example, certainly does not apply to a fine yarn broken on the ballistic tester.

• University and Educational Intelligence.

BIRMINGHAM.—At a degree congregation held on December 18, the degree of D.Sc. was conferred on Douglas Heber Ingall for five published papers mainly on the relation between mechanical properties of metals and alloys and heat treatment and cold-work.

THE annual distribution of prizes was held at the Sir John Cass Technical Institute on Tuesday evening, December 15, when the prizes and certificates were distributed by Sir Thomas Kirke Rose, past president of the Institution of Mining and Metallurgy. The Chairman of the Governing Body, the Rev. J. F. Marr, in giving a summary of the work of the Institute for the past session, stated that real progress has been made in consolidating, strengthening and correlating the work of the science departments, in which more accommodation is much needed for advanced and research work. Twenty-seven students have been engaged in research work during the session and 11 investigations have been published, bringing the total number of papers issued from the Institute to 165. Following the distribution of awards, Sir Thomas Kirke Rose delivered an address on "Metallurgy and Mining," in the course of which he emphasised the effect the Institute has had in helping the industries of the neighbourhood and not least in its metallurgical work in aiding the Royal Mint. He dealt at some length with the still unsolved problems of minting which have so far baffled metallurgists, in order to bring out the fact that there are still worlds to conquer even in such an old-established industry as minting.

SALARIES of university professors in the United States increased rapidly after the War, so much so as to cause some temporary embarrassment to the administrators of the Carnegie Pension Fund. In the *Forum* for October, however, Dr. Frank Bohn asserts that college and university faculties are being deserted by their first-class members at a rate which calls for a drastic reform of the salary schedules. In a case which he cites as typical, a professor of psychology left the university where he was receiving 5000 dollars a year, and accepted an advertising position in New York in which he was able to earn five times as much. Dr. Bohn suggests that all major gifts to the universities, say those amounting to ten million dollars or more (which totalled during the past ten years no less than 1,435,500,000 dollars) should during the next ten years be devoted to the increase of salaries of university teachers. He holds that the starvation of the teaching profession is destroying the very foundations of higher education, and civilisation is in jeopardy of being submerged in "the noisy flood of ignorance and vulgar materialism." The universities are becoming less and less capable of fulfilling the hope of a generation ago that they would be the prophets, the priests, and the philosophers of democracy. Nor is "starvation" of their professors the only reason. "They suffer primarily from elephantiasis, and the first step might well be a restriction of the number of students by imposing entrance tests which would be at least as severe as the general demands made of the Rhodes scholars. The group of professional schools should include only law, medicine, education, public administration, and the beaux arts. The number of students being thus reduced to, say, 1500, and the professors' salaries being raised to 20,000 dollars as a minimum, the universities' best teachers would no longer seek to escape on the first convenient opportunity, and the intellectual élite of the land would be drawn to them.

Societies and Academies.

LONDON.

Physical Society, November 13.—R. G. Edwards and B. Worswick. On the viscosity of ammonia gas. The viscosity of ammonia gas has been determined at three different temperatures by transpiring the gas through a capillary tube which had previously been calibrated with air. Sutherland's constant is found to be roughly 370, and the mean collisional area of the ammonia molecule 0.633×10^{-16} sq. cm.—T. G. Hodgkinson: Valve maintained tuning forks without condensers. The conductance of the valve grid decides the direction in which the electrode coils must be wound. It is also advantageous, particularly in the case of low frequency forks, to interpose transformers between the valve electrodes and the fork magnets.—C. Chree: The times of sudden commencements (S.C.'s) of magnetic storms: observation and theory. Dr. Bauer's early claim that S.C.'s are propagated from east to west or west to east, with velocities of from 100 to 200 kilometres per second, has been criticised adversely. Since then, Prof. S. Chapman and Fr. Rodés, of the Ebro Observatory, have propounded theories differing from one another and from Dr. Bauer's. Recently Dr. Bauer and Mr. W. J. Peters have concluded that the motion in longitude is much more rapid than according to Dr. Bauer's original estimate, and that it is really a case of propagation from the magnetic equator towards either magnetic pole. The Section of Terrestrial Magnetism and Electricity of the International Union of Geodesy and Geophysics has recently approved a scheme aiming at the construction and use of special instruments to find out whether S.C.'s have a finite rate of propagation. Suggestions are made as to the new apparatus and the stations most suitable for the investigation.

Royal Microscopical Society, November 18—Sydney Dickenson. A simple method of isolating and handling individual spores and bacteria. The spores or bacteria are moved from place to place under continual observation in a local thickening of a water film. This water film is formed between a film of agar and a fine glass rod, which is moved in three dimensions by an apparatus designed for the purpose.

Royal Meteorological Society, November 18—Sir Gilbert Walker and E. W. Bliss: On correlation coefficients: their calculation and use. An account is given of a new method of working out correlation coefficients. Calculations are shown (i.) of the likelihood that with a given coefficient r , the forecast and the actual departures will have the same sign, and (ii.) of the frequency with which, r being given, it will be possible to make a forecast with a 4:1 chance in its favour.—Catharine O. Stevens. Note on the variations in transparency of the atmosphere observed by means of a projected telescopic image of the sun. There is relation between the colours associated with a projected telescopic image of the sun in a darkened room and issues of weather. Meteorological conditions normal to clear weather with rising barometer yield a predominance of red, orange, and blue, to the exclusion of other colours. With steady barometer and cloudless sky, any pronounced departure from this colour-scheme is informative. Thus, if green is included, rain threatens; if purple or violet, electrical conditions are indicated; and in case all colour is whitened, a fall of barometric pressure is heralded.—N. L. Silvester. Notes on the behaviour of certain plants in relation to the weather. The analysis of 1300 observations upon pimpernel, daisy, chickweed, clover, dandelion, marigold, and gentian

to test the local forecast value of plants reputed in weather-lore gives a negative answer. Temperature of the soil surrounding the roots is a control factor in the movements of daisy and chickweed. Above the critical temperature in these two plants, and in the pimpernel, relative humidity becomes the dominant factor—a value of 80 per cent. approx. being the critical maximum in every case. Clover leaves respond to wind velocity. The closing movement commences when the velocity at 42 ft above the surface exceeds 20 m p h. Plants responding to relative humidity can thus be used for prediction of rain only in so far as its incidence is preceded by the pre-requisite humidity increase.

Society of Public Analysts, December 2.—J. S. Owens: Measuring the smoke pollution of city air. The methods of measuring smoke pollution are based on: (a) Measurement of deposit from the air; and (b) measurement of suspended matter before it is deposited. The methods of the Advisory Committee on Air Pollution fall under the headings of: (1) Measurement of deposit by means of standard gauges, (2) measurement of suspended impurities by means of automatic filters, or records; and (3) measurement with the Owens' jet dust counter. The material trapped on dust records from 50 c.c. of air on an average winter's day in London weighs about 1/20,000 mgm, and consists of about 600,000 particles.—Oscar L. Brady and Gladys V. Elsmie. 2:4-Dinitrophenylhydrazine as a reagent for aldehydes and ketones. Aldehydes and ketones can be identified by the crystalline forms, colours and melting points of the dinitrophenylhydrazones which they yield with 2:4-dinitrophenylhydrazine. A solution of the hydrochloride is a suitable reagent for aldehydes and ketones soluble in water; it gives a filterable precipitate with 0.003 gm. of acetone or acetaldehyde.—Gunner Jørgenson: The determination of phosphoric acid as magnesium ammonium phosphate. The most trustworthy method of obtaining magnesium ammonium phosphate of the correct composition is to precipitate it from a nearly boiling solution (accuracy about 1:1000). This is the only sufficiently exact method for determining phosphoric acid in mineral phosphates and fertilisers. Precipitation of ammonium phosphomolybdate in the cold is less accurate (accuracy about 1:100). Precipitation of magnesium ammonium phosphate from a cold solution gives a precipitate much affected in composition by the conditions of precipitation.—C. H. Thomson: On the effect of blowing on the composition of certain fatty oils. The rise or fall in the composition, viscosity, and other constants of cottonseed, whale, sperm and shark oils are simultaneous at each stage of the process, but the rates of change are not the same. The changes produced by varying the conditions of "blowing" are not comparable, except that the viscosity and refractive index rise simultaneously. None of the oils after "blowing" yields ether-insoluble bromides.

CAMBRIDGE.

Philosophical Society, November 23.—R. C. Punnett. On a case of matriclinous inheritance in *Antirrhinum*.—J. B. S. Haldane: The change with age of a linkage between Mendelian factors in fowls.—M. S. Pease. A note on the inheritance of yellow fat in rabbits.—K. Emeléus: Notes on the electrical counter.

DUBLIN.

Royal Dublin Society, November 24 —K. C. Bailey. The radiations from radon promote interaction of

ammonia with either carbon monoxide or carbon dioxide. In both cases ammonium cyanate and urea were formed. No ammonium cyanide was thus obtained from ammonia and carbon monoxide.—Paul A. Murphy and R. McKay: Methods for investigating the virus diseases of the potato, and some results obtained by their use. Most experiments on these diseases require two years to carry out, and necessitate keeping the plants free from insects during the first year. A method is now described whereby tubers may be infected with the mosaic diseases during the winter and the final results secured in June, the plants being grown in the open field. The method is more trustworthy than any previously used. It also separates the mosaics from leaf-roll. Methods more exact than those hitherto used are described for determining the rate of spread of the virus in a plant.—E. J. Sheehy: An examination of the errors introduced by the various approximate methods used for estimating the total quantities of milk and butter fat produced during a lactation.

MANCHESTER.

Literary and Philosophical Society, November 24.—Kenneth M. Smith: A study of the feeding methods of certain sucking insects in relation to the spread of "virus diseases" of the potato by such insects. "Mosaic" disease in potato is disseminated by insects, more particularly by those of the sucking type, such as aphides or leaf-hoppers. The whole process of infection of a healthy potato plant with mosaic disease would appear to be somewhat analogous to the infection of man with malaria by the mosquito. The insects have been studied with the sucking organ *in situ* in the tissue of the plant host. By this method it is possible to determine the exact part of the tissue tapped. Other points elucidated include the effect of the salivary secretions of the insect upon the health of the plant, the path followed by the beak through the tissue, *i.e.* an inter- or intra-cellular path, and the method of penetration of the cells, whether by pressure alone or by the solvent effect of the saliva upon the cell walls. Those insects which tap the phloem of the vascular bundles seem to act as carriers. Undue disorganisation of the surrounding tissue by the salivary secretions of the insect may tend to isolate the virus and thus prevent infection. This appears to be the case with certain insects the saliva of which is unusually toxic to the plant.

PARIS.

Academy of Sciences, November 16.—E. Fichot: The submarine relief of the Bay of Biscay. The supposed plateau in the Bay of Biscay does not exist. The outline is unchanged since the survey made in 1828.—Jean Baptiste Senderens: The preparation of the ether oxides of the fatty series. Details of the preparation of ethers from heptyl, cetyl, secondary amyl, and allyl alcohols, using sulphuric acid as catalyst.—Ernest Laura: An extended class of surfaces.—Georges Bouligand: Some points in the theory of harmonic functions.—A. Guillet: The chronostrobometer.—Alex. Véronnet: Equilibrium through the influence of radiation alone is impossible in the sun and in the stars. Internal equilibrium is isothermal and homogeneous.—Paul Helbronner: The geodesic junction of Corsica and continental France.—Mlle. A. Serres: A new magnetic state of the cobalt ion Co.—A. Portevin and P. Chevenard: The influence of cold hardening and of tempering on the elastic properties of various metals and alloys.—A. Petit: Contribution to the study of the aluminium silicon

alloys.—Díaz de Barros: The nuclear numbers. The nuclear number is defined as a whole number equal to half the difference between the atomic weight of an element and its atomic number. Some properties of the numbers thus defined are given.—Raymond Delaby: The isomerisation of the vinyl-alkyl-carbinols $\text{CH}_2:\text{CH}.\text{CH}(\text{OH}).\text{R}$ into β -alkyl-allyl alcohols $\text{CH}_2(\text{OH}).\text{CH}:\text{CH}.\text{R}$. The chain of reactions is as follows: addition of bromine, action of sodium formate, decomposition by heat of the diformin and saponification of the formic ester of the primary alcohol required. The operations are simple and yields fair (20 per cent.).—René Bourret: The Annamitic cham and the Bas-Laos plateaux to the west of Hué.—Eugène Raguin: The discovery of a fauna of Foraminifera, very probably Cretaceous, in the highly metamorphosed limestones of the Vallon du Pâquier near Grand-Motte (Savoy).—R. Cerighelli: The influence of the conditions of the medium on the germination of seeds in the absence of calcium. Whether the culture medium is sterile or not, the cotyledons immersed or not, or whether the water is present as liquid or vapour, it is proved that seeds cannot germinate properly in the absence of calcium.—V. Lubimenko: Chromatic adaptation in the marine algæ. Marine algæ are very poor in chlorophyll, the amounts found varying from 37 per cent. (green algæ) to 18 per cent. (red algæ) of the amount usual in higher plants. The red algæ adapt themselves to the light in two different ways: each species increases or diminishes the total quantity of pigment according to the depth. The proportion of phycoerythrine varies with the different species increasing with the depth below sea-level.—Eberhardt and J. Chevalier: A new treatment of the diseases of the potato. The plants are sprayed with an emulsion of a thiohydrocarbon derived from resin by a simple process. The results of experimental cultures with eight kinds of potato are given. The treatment destroys parasites, arrests the development of fungi, and gives an increased weight of crop.—E. Séguy: The characters common to the Ostridæ and the Calliphorinæ.—Maurice Piettre: The preparation of the albumen of muscle or myoalbumen by the acetone method, its principal properties. Full details are given of the method adopted for the separation and purification of myoalbumen. Its properties are similar to those of serum albumen, lactalbumen, and ovalbumen, but is differentiated by coagulating at 45° – 47° C., not as a fine sandy precipitate but in small flocks, and by its specific rotatory power, about half that of serum albumen.—Max Aron: The evolution of the genital glands of young tritons transplanted into adults of the same species. The idea of internal conditions limiting the development of the sexual cells.—Constantin Gorini: *Gastrococcus*.

SYDNEY.

Linnean Society of New South Wales, September 30.—R. J. Tillyard: A new fossil insect wing from Triassic beds near Deewhy, N.S.W. Description of a wing which, from a study of its venation, is placed in a new family in the order Protohemiptera.—J. R. Malloch: Notes on Australian Diptera. No. vii.—I. M. Mackerras and M. J. Mackerras: The Hæmatozoa of Australian marine Teleostei. The blood of 200 marine Teleostei taken in the vicinity of Sydney, N.S.W., was examined. Two new species of *Trypanosoma* and three of *Hæmoglobarina* are described, thus bringing the Australian hæmatozoal fauna into line with that of other parts of the world. In addition, a new species of *Trypanoplasma* is described, this being apparently the first record of the occurrence of a member of this

genus in the blood of a marine fish.—G. H. Cunningham: *Gasteromycetes* of Australasia. (iii.) The genera *Bovista* and *Bovistella*. Two species are allowed to remain in *Bovista*, six of those recorded in Cooke's Handbook being excluded from the genus. In *Bovistella* three species are retained and seven species are excluded on the ground that they possess the typical *Lycoperdon capitatum*.—R. Greig-Smith: The influence of certain colloids upon fermentation. Pt. II. Yeasts and bacteria have their fermentative activities accelerated by the presence of certain minerals and other colloids such as talc, kieseguh, silica, fuller's earth, charcoal and agar. The isolated enzymes are not influenced by the same colloids.

Royal Society of New South Wales, October 7.—R. H. Cambage: *Acacia* seedlings (Pt. xi). The first half-dozen or so of the youngest leaves first assume a recumbent position, and may actually lie down on the ground before closing their leaflets at night. Tests were made to ascertain the strength exerted by these tender leaves when regaining their upright position in the morning, and it was found that with a weight of 0.227 gm. placed at 6 cm. from the base of a leaf 8 cm. long, the terminal point of the leaf in one case was carried upwards 6.5 cm.—H. R. Seddon, W. L. Hindmarsh, and H. R. Carne: Further observations on *Stachys arvensis*, "stagger weed," as a cause of staggers or shivers in sheep. As frequently happens with poisonous plants, it is not equally noxious at all stages, and its harmfulness depends to some extent upon the type of sheep which are fed upon it. Thus it has happened that certain feeding experiments have been entirely negative, whilst in others all animals have developed staggers. Green, succulent plants produce staggers, whereas yellowish, harsh plants are comparatively or entirely harmless. The staggers-producing principle seems to be most abundant in, if not confined to, the seed, and is contained in the ether-soluble fraction of the seed. When removed to other feed, sheep rapidly lose the staggers condition, certainly within a week. Young animals are much more susceptible than adult sheep.—F. R. Morrison: The fixed oil of the seeds of the Kurrajong (*Brachychiton populneum*, Syn. *Sterculia diversifolia*, G. Don). The oils obtained by extraction with ethyl ether and light petroleum ether respectively, were of a golden-yellow colour, and consisted of the triglycerides of palmitic, oleic, and linolic acids, together with smaller quantities of free palmitic, oleic, and linolic acids. The oil is thus of the semi-drying class.—M. B. Welch: Notes on the principal indigenous timbers of the natural order Saxifragæ. There are about twenty genera in Australia, of which twelve are endemic and many are monotypic. Eight genera produce trees which reach a large size, and notably *Ceratopetalum*, *Weinmannia*, *Geissois* and *Ackama* are of commercial importance. The woods are diffuse-porous, the vessels bearing either scalariform or simple end perforations. The wood fibres show transition stages to fibre tracheids and even tracheids. The rays are normally heterogeneous and multiseriate.—R. K. Newman, V. M. Trikojus, and G. Harker: The use of phosphorus pentachloride in the preparation of glycerides. The preparation of a simple fatty substance, tributyrin—a compound of glycerol and butyric acid—is described. Two methods employed gave high yields. In one of these phosphorus pentachloride acts upon a mixture of glycerol and sodium butylate; in the other the tributyrin is prepared direct from glycerol and butyric acid, while special means are provided for the continuous removal of the water formed during the reaction. The pure tri-

butysin prepared by either process has a much higher boiling point than that usually accepted, namely, 315.5° instead of 287°C . No matter what method was used, the same triglyceride was always formed, and there was no evidence of isomerism.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 11, No. 11, November).—Edward W. Berry. The age and affinities of the tertiary flora of western Canada. The flora seems to be mainly late Eocene and consists of hardwood assemblages of broad leaf types and coniferous trees resembling existing species in the Chinese uplands. The major element, of newer types, probably entered North America from Asia by land connexions in the Bering Sea region during the Upper Cretaceous or earlier Eocene.—S. Loria. The metastable $2p_2$ -state of mercury atoms. A mixture of mercury vapour, thallium vapour, and nitrogen illuminated by light of wave-length $2537\text{ \AA}$.U. gives activated mercury atoms in the $2p_2$ -state. On collision with nitrogen molecules, the main part of the activation energy may be retained in the $2p_2$ -state of the mercury atom. The time for which the atom retains this energy depends on the surrounding gas, and can be measured, in this case, by the increase in intensity of the fluorescence spectrum of thallium.—H. D. Smyth. Some experiments on collisions of the second kind. Iodine vapour at a high temperature contains electrons with energies greater than that corresponding to the electron affinity of iodine (3.5 volts), due apparently to "collisions" in which an electron approaches a system of neutral iodine atom and electron; i.e. collisions of the second kind. Some evidence was also obtained with ozone that the critical increment of energy for decomposition is dissipated in a similar way.—Vladimir Karapetov. General criterion for the circular locus of the current vector in A.C. circuits and machinery.—Edward V. Huntington. Postulates for reversible order on a closed line (separation of point-pairs).—Raymond Dodge. The hypothesis of inhibition by drainage. The hypothesis assumes that there is a definite amount of available neural energy in the nervous system which can be concentrated into specific neural paths and consequently drained from others. Using the knee-jerk and wink reflex in the human subject, it was found that the reflex action is unmodified by voluntary reaction to the stimulus. The hypothesis is therefore discarded pending new evidence.—George E. Hale. A test of the electromagnetic theory of the hydrogen vortices surrounding sunspots. There is no relationship between polarity and direction of whirl in 51 sunspots taken at random from three 11½-year cycles. It would appear that hydrogen vortices are hydrodynamical phenomena rather than electromagnetic (Stormer). Direction of whirl is determined, not by the sunspot vortices beneath them, but by the east and west deflexion, due to solar rotation, of currents flowing northward and southward towards centres of attraction above sunspots.—John W. Gowen. Recent evolution in milk secretion of Guernsey cattle. From the records of the Guernsey Advanced Registry animals, it appears that there has been considerable increase in average age-corrected milk yields, little change in butter-fat percentage, and continuous decrease in age of cows tested. The results are due to improved knowledge of feeding and care as well as to inheritance.—Calvin B. Bridges. (1) Elimination of chromosomes due to a mutant (*Minute-n*) in *Drosophila melanogaster*. (2) Haploidy in *Drosophila melanogaster*. Two individuals

carrying haploid tissue were found; the tissue in each case was female.—Henry D. Hooker. Plant growth. Carbohydrate accumulation precedes the rest period of shoots and the formation of flower-buds, suggesting that it inhibits or retards leaf formation and thus carbohydrate manufacture. These facts are in accord with the idea that plant growth is a consecutive, reversible monomolecular reaction, and a mathematical formula is developed.
